Preface

This book is intended to provide an introduction to the basic principles of electricity and electronics as they apply to refrigeration, heating, and air-conditioning systems. It combines basic principles, using very little math, with the latest applications found in the HVAC industry.

The fields of refrigeration, air conditioning, and heating are undergoing some very rapid changes. The advent of the computer chip has made it possible to control heating and cooling systems precisely and with a great deal of freedom in programming their applications. The new high-efficiency furnaces utilize the chip both for sequencing and for protection from accidental damage. Most of these programmable controllers provide instructions and technical bulletins. They are numerous, and each has its own approach to solving a given problem. This book will make it possible for you to understand these instructions and improvements.

Future technicians need to deal with the fact that change is inevitable, and that they will have to keep up with the latest developments as long as they work in the field. It is hoped that this book will make that task easier.

Introduction to Electricity

Performance Objectives

- Understand how matter and electricity are related.
- Understand how liquids, solids, and gases are similar, yet different.
- Understand how atoms, electrons, protons, and neutrons are all related to the production of electricity.
- Understand how electricity is put to work in the electric circuit.
- Understand how switches control the flow of electricity.

Introduction to Electricity

Electricity is as old as the universe. But knowledge about it is relatively new. Early humans were aware of electricity in the form of lightning. They learned of its power when they saw it starts fires and kills people and animals. But it was only about 300 years ago that people began to learn the basic laws of electricity. And only about 120 years have passed since electricity was first put to work. It has been only 100 years since the first practical electric lamp was invented, only 80 years since the vacuum tube was invented, and less than 40 years since the transistor was invented. Despite this brief time, electricity has greatly changed people's lives—our lives.

The universe consists of atoms and every atom contains at least one electron. An *electron* is the smallest particle of an atom and has a negative electric charge. When the movement of electrons is controlled, they are capable of doing work.

Static Electricity and Magnetism

There are two types of electrical effects: static electricity and magnetism.

The Greek philosopher Thales, who lived about 2500 years ago, is credited with discovering static electricity.

Magnetism is the ability of an object to attract other objects. It was discovered about 2600 B.C., or about 100 years before the discovery of static electricity. It is not certain who discovered magnetism first. Some historians say it was first observed by the Chinese. Others say that it was the Greeks. The discoverer noted that certain heavy stones have the power to attract and lift iron and some other stones. The material in these stones is called *magnetite*. It was named by the Greeks for the province of Magnesia in Asia Minor, where the stones were first found. Today, the power of this stone is called *magnetism*.

These discoveries led to extensive studies of magnetism and static electricity (see Figs. 1-1 and 1-2).

Other people studied electricity and magnetism during the sixteenth century and later in the nineteenth century. Some of these people have electrical terms named for them. You may be familiar with Ampere, Volta, Coulomb, Oersted, Ohm, and Galvani (see Fig. 1-3).

Electricity

One of the most famous experiments on electricity occurred in 1752. In that year, Benjamin Franklin used a kite and a key to successfully draw lightning from the sky. He was trying to prove that electricity is a fluid. From these and other

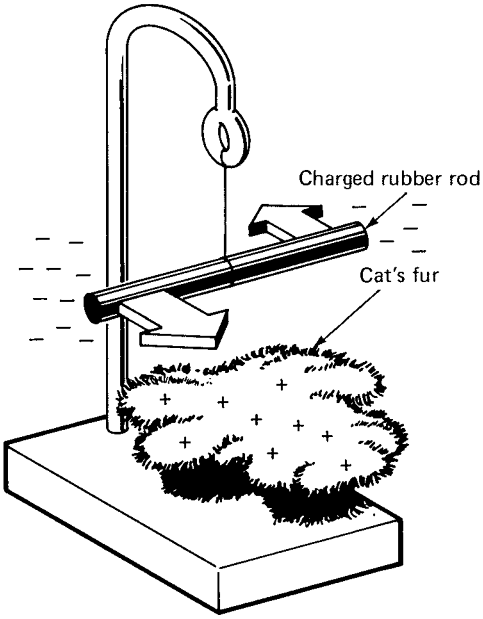

Figure 1-1 Unlike charges attract.

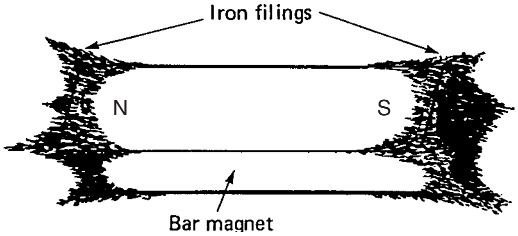

Figure 1-2 Iron filings cling to the ends of a permanent magnet. Note the north and south poles shown as N and S.

experiments, Benjamin Franklin is credited with forming the theory of positive and negative charges. It was another 80 years, though, before someone discovered that there is a relationship between magnetism and electron flow.

Electricity's Future

The effects of the knowledge and use of electricity were profound. Difficult tasks became easy. Old methods were replaced by new. Electrical machines relieved people of back-breaking labor. Machines could do the job better and cheaper than people. Fears that new inventions and methods would displace workers and create widespread unemployment did not prove true. Instead of loss of jobs,

Figure 1-3 George Ohm demonstrates his theories to some of his colleagues.

electricity led to new industries and new jobs. The new industries required more people than were replaced by machines.

Even today we hear about the possibilities of people losing their jobs because of machines and robots. Automation is the use of machines that are controlled by other machines and devices instead of people. It is another step in technical progress. It makes possible more things faster and better. Automation and robots create more jobs and a need for more skilled people. Trained people are needed to design, build, and maintain electrical equipment.

One of the greatest uses of electricity is in the production of ice and cooling for human comfort. Refrigeration and air conditioning rely exclusively on the ability of electricity to pump a fluid or gas through a system. Electricity is also used to control the temperature in heating, air-conditioning, and refrigeration systems.

Matter and Electricity

The name electricity implies the importance of the almost weightless, invisible part of an atom called an *electron*. It is electrons that cause electricity. Electricity is defined as the movement of electrons along a conductor.

An electron is only one part of an atom. An atom is only one part of a molecule. None of these can be seen by the unaided eye. Thus, most actions in electric circuits cannot be seen. An electric circuit can appear motionless although great activity is happening within it at the atomic level.

The electron can be controlled. Control of the electron is the task of an electrician, electrical engineer, or anyone else working with electricity. Electricity can perform work. It can kill. Using it requires knowledge of such things as matter and mass.

Matter surrounds us. It is said to be anything that occupies space. Thus, all physical objects are composed of matter.

Matter has mass. Mass is defined as the resistance an object offers to a change in motion. The tighter the matter is packed together, the greater is its mass. Thus, the greater is its resistance to any change in motion.

Solids, gases, and liquids

The three basic forms of matter, shown in Fig. 1-4, are solid, liquid, and gas. A solid, such as a glass container, is stable and self-supporting. By definition, a solid substance is one that offers a large resistance to forces that might change its shape. A liquid, such as water, maintains a definite volume, but assumes the shape of the container in which it is placed. A gas, such as the air we breathe, has no definite volume. It can be expanded or compressed to the shape or size of any container. The different forms of solid, liquid, and gaseous matter are called *substances*.

Pure water at room temperature is a liquid substance. All samples of pure water are identical. Pure iron is a solid, and pure carbon dioxide is a gaseous substance.

Figure 1-4 Behavior of three forms of matter: solid, liquid, and gas.

The two classes of substances are elements and compounds. An element is a pure substance that cannot be divided into any more basic substances by chemical change. The elements (there are more than 100) are the simplest forms of matter. Some examples of elements are hydrogen, oxygen, germanium, silicon, gold, and silver. A compound is a substance composed of two or more elements chemically combined. Water, for example, is a compound made up of the elements hydrogen and oxygen. Common table salt (sodium chloride) is a compound made from the elements sodium and chlorine. A molecule is the smallest quantity of any compound that can exist and still retain all the properties of the compound. For example, the elements hydrogen and oxygen, when combined, produce the compound water. A molecule of water, however, is the smallest quantity of water that has all the characteristics of water. Elements and compounds can also form mixtures. A mixture is a mixing of two or more substances in which the properties of each substance are not changed. Water is a compound but salt and water is a mixture because the salt can be separated from the water simply by filtering or by evaporation of the solvent (water in this case).

Atom

An atom is the smallest part of an element that retains all the qualities of the element. Atoms are the building blocks from which all substances are made. Figure 1-5 shows two atoms of hydrogen gas combining to form one molecule of hydrogen gas. Some substances (compounds) are formed by the chemical combination of different elemental atoms. Water is one of these (see Fig. 1-6). A molecule of water consists of two hydrogen atoms and one oxygen atom.

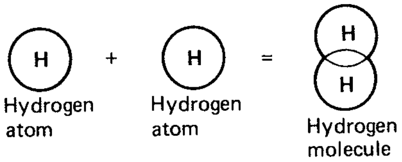

Figure 1-5 Two hydrogen atoms can be combined to form one molecule of gas.

An important part of an atom is the electron. An electric current is the result of the controlled movement of electrons in a substance.

Electrons, protons, and neutrons

The atom is the basic building block of matter, but it can be divided into many particles. The three major particles of the atom are electrons, protons, and neutrons. These three particles are important because they affect the electrical properties of the material. The protons and neutrons form the central mass or nucleus of the atom. One or more electrons circle the nucleus. The nucleus is almost 2000 times heavier than an electron. The electron is the smallest part known. It takes more than 28 billion, billion, billion electrons to weigh 1 ounce.

There is one nucleus in each atom. Elements differ because there are many combinations of orbiting electrons and groupings of protons and neutrons within the nucleus. Each element is made up of atoms having one particular combination of nucleus and orbital electrons. Each compound substance is made up of a particular arrangement of these atoms.

Another major part of the atom is the neutron. The neutron is also a part of the nucleus. However, it has no charge. Neutrons and protons have nearly the same mass. They determine, for the most part, the mass of the atom. The electron has little mass.

The simplest atom is the hydrogen atom (see Fig. 1-7a). It contains a nucleus and one electron. A helium atom (Fig. 1-7b) contains a nucleus and two electrons. In other atoms there is more than one shell of orbiting electrons. Copper has four shells. Some electrons have as many as seven electron shells. The fourth shell around the copper nucleus is made up of only one electron. It is easily

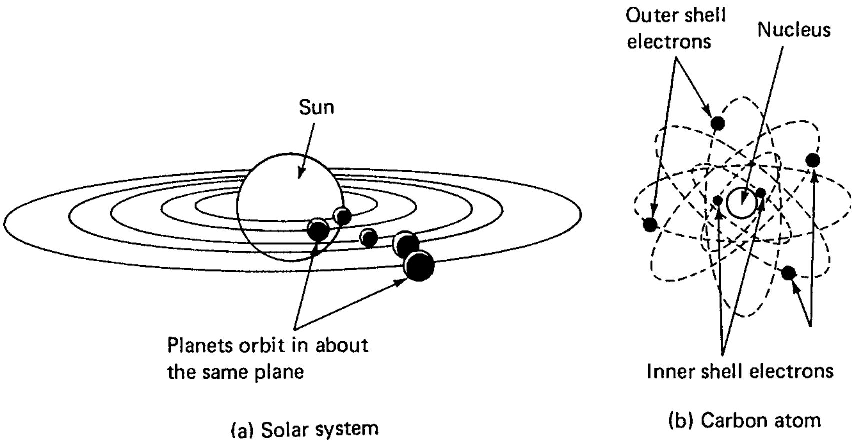

Figure 1-9 Comparison of on atom with the solar system. (a) Solar system. (b) Carbon atom.

A comparison such as the one shown in Fig. 1-9 is often made between our solar system and an atom. The nucleus of the atom is compared to the sun. Electrons revolving around the nucleus are compared to the planets revolving around the sun. A major difference between the two systems is the orbital paths of the planets and electrons. Figure 1-9 shows this difference. The planets have orbits in a fairly common plane during their trips around the sun. In contrast, the orbits of the electrons around the nucleus are constantly changing (this is present-day theory and subject to change later), and their paths eventually produce spherical shells around the nucleus. The arrangement of these spherical paths of the electrons and direction of their rotation around the nucleus determine the magnetic properties of the substance.

Properties of Electrons

The electrical properties of a substance are influenced by the number and arrangement of the electrons in the outermost shell. These electrons, located in the outer shell, are called *valence electrons*. Keep in mind that all electrons are alike. They are the same in all atoms. Electrons can be moved among like and unlike atoms. The application of an electrical force causes electrons to move from atom to atom in a controlled manner. The movement of electrons from atom to atom is called *electric current*. Because all electrons are the same, the basic atomic makeup of a substance (such as copper) is not changed by electron movement.

Orbiting Electrons

Orbiting electrons do not leave the atom. Orbiting planets do not leave the solar system. People can orbit the earth and return without being lost in space.

Two forces prevent the electrons from leaving the atom. One is the force or pull of gravity. It is the same pull that keeps things on earth. Similarly, there is a gravitational attraction between the nucleus and the electrons that causes it to be held in orbit around the atom. But this force is too weak. The main-force is the electrical attraction between the nucleus and the electron.

When a force or energy is applied sufficient to cause it to move from the orbiting path, it moves to the next atom and in moving can produce what we call electricity. This movement can cause work to be done.

Electrical Charge

Figure 1-10a illustrates the electrical charge. A ball is attached to a string and made to swing in a circle. The swinging ball tends to move away from the hand. But it is held by the string. This is like Fig. 1-10b in which the electrons swinging around an atom are pulled to the center nucleus. The speed of rotation causes them to follow an orbital path around the nucleus. The force between the electron and the nucleus is called an *electrical charge.*

The electron possesses a negative charge. The nucleus has the opposite polarity, a positive charge. In the nucleus, however, the positive charge is carried by protons. Thus, for every electron in orbit there is a proton in the nucleus. This is shown in Fig. 1-10b. There the atom has six electrons in orbit and six protons in the nucleus. The simple hydrogen atom has one electron in orbit and one proton in its nucleus.

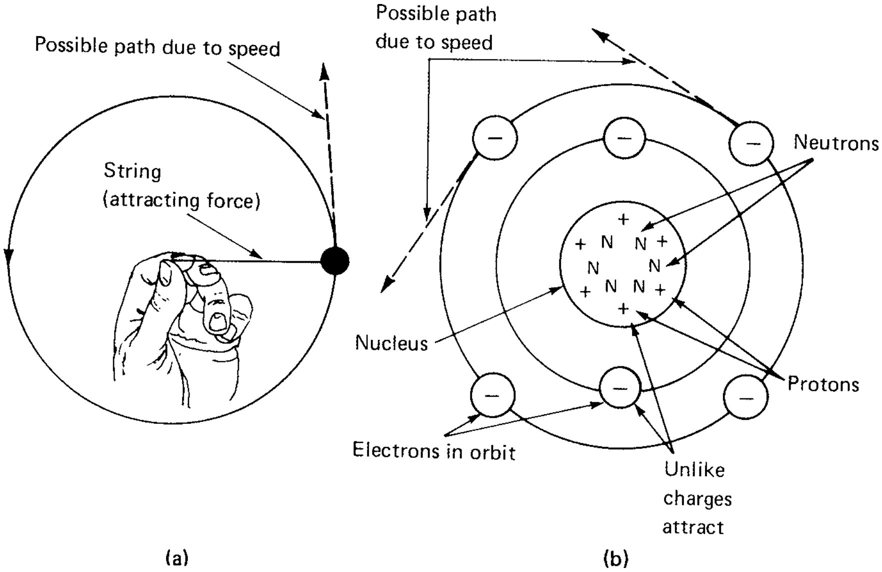

Figure 1-10 Comparison of a swinging ball attached to a string and an electron swinging around the nucleus of an atom. (a) Ball on a string. (b) Location of electrons.

Outer Shell

A basic law of electric charges is that like charges repel and unlike charges attract. The effect of charges on freely moving bodies is shown in Fig. 1-11. In the atom the positive charge of the nucleus (protons) attracts the electrons. However, the speed and energy of the electrons causes them to maintain their orbital paths. Since the forces in the atom are balanced, the electrical charges are balanced. Thus, the atom remains stable and neutral.

Electrons in the outer shell of an atom (called valence electrons) have a higher energy than electrons in the shells closer to the nucleus. External force can add energy to the valence electrons. This added energy permits their escape from the atom. Such free electrons can move from atom to atom. Being free, they are used for electric current.

Valence electrons and ions

Normally, we are concerned only with the valence electrons (outer shell) because these are the easiest to free. When one (or more) electron is removed from or added to the outer shell of an atom, the atom becomes charged. It is no longer neutral. Then the atom is called an *ion*. When an electron is lost, the atom

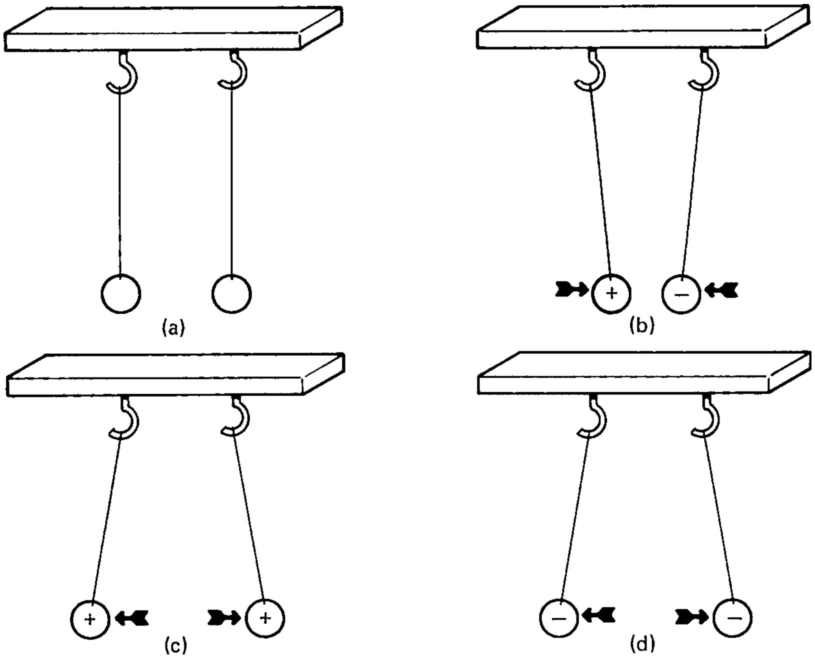

Figure 1-11 Unlike charges attract each other. Like charges repel each other. (a) No charge means there is no attraction or repulsion. (b) Positive and negative charges are attracted to each other (unlikes attract). (c) Positive charges repel each other (likes repel). (d) Negative charges repel each other, again (likes repel).

takes on a positive charge because there are more protons in the nucleus than orbiting electrons. The atom is then called a *positive ion*. Ionization of air is used in some "air-conditioning" systems.

Sometimes it is possible to add an electron to the outer shell. This results in a charged atom that is a negative ion. It is negative because there are more orbiting electrons than protons in its nucleus.

Unlike charges attract. Therefore, a positive ion will attract an electron or any negatively charged body. A negative ion, however, will repel an electron or any negatively charged body.

Unlike charges on two bodies mean there is a difference between them (see Fig. 1-12). A difference in charge exists between the four pairs of charged bodies in Fig. 1-13. This difference is 4. If a conducting path for electrons is made between any pair of bodies in Fig. 1-13, the same number of electrons would have to move from left to right in the illustration to neutralize the charges. When two bodies have the same charge and same polarity, there is no difference between them.

So far we have considered the charge in terms of electrons or numbers. Now we need to give the charge a name. A name is also needed for the difference that exists between these charges.

Any substance, molecule or atom, may have a negative or positive charge. Or it may be neutral. How much more negative or more positive can one body be charged relative to another? If a comparison is made, some unit of measurement must be used. Some standard reference should be used as a basic unit of measurement.

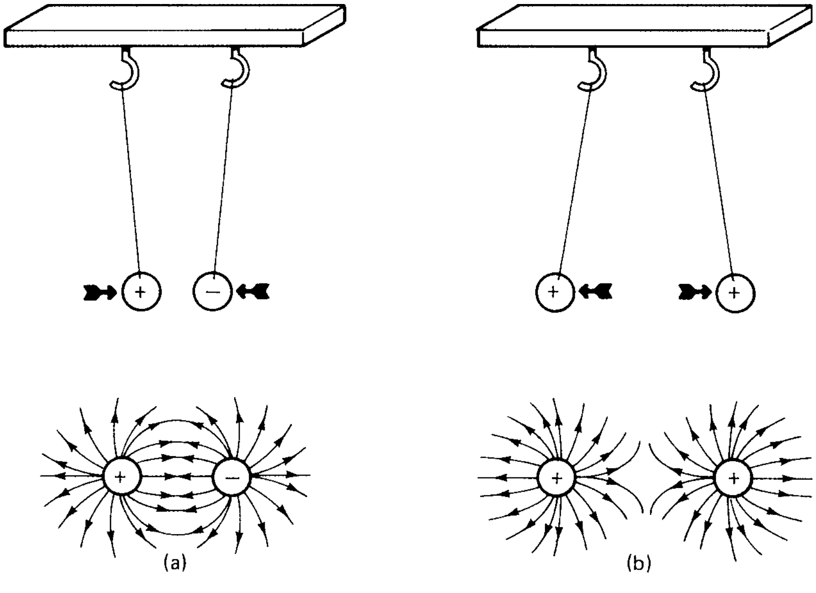

Figure 1-12 Invisible force fields extend outward from charged particles. (a) Lines of force unite and draw the unlike charges together. (b) Lines of force do not unite, so they repel.

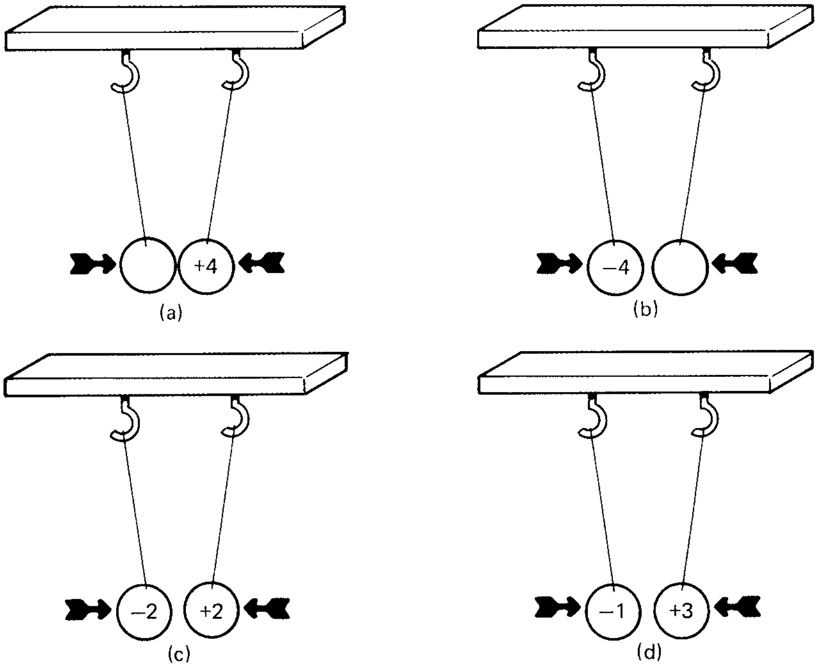

Figure 1-13 Four pairs of charged bodies with some difference of potential. Each pair of charges is attracted by the some amount of force.

The smallest negative charge is already understood to be that of the electron. And the charge of a proton is the smallest positive electric charge. Such charges are too small and not useful in terms of establishing a basic unit of measurement.

A Practical Unit of Charge

The practical unit of charge is the *coulomb*. It is the negative charge made by 6.25×10^{18} electrons. The term 10^{18} means it takes 6,250,000,000,000,000,000 electrons to produce a coulomb. Expressing it any other way than “6.25 times ten to the 18th” is awkward. (Some textbooks use 6.28 instead of 6.25. This is because 6.28 is 2π rounded off.)

The Volt

The volt is the unit for potential difference. It is used to indicate the electrical pressure or force needed to move coulombs of electric charge. The volt is also used to measure a unit of electromotive force (emf). The emf is the moving force behind an electric current. The volt is used and understood everywhere. The term *voltage* is often used to refer to potential difference.

Controlling Electrons

The controlled movement of electrons through a substance is called *current*. Current occurs only when a difference of potential is present. A good example of a difference of potential is observed by connecting battery terminals to a length of copper wire. The pressure from the battery moves the electrons.

Copper is a good path for current because of the relative ease with which electrons can be moved along its length. The one electron in the outer shell of the copper atom is free to move from atom to atom (see Fig. 1-8b). In fact, the electrons of copper drift in random fashion through the copper at room temperature (see Fig. 1-14a). If an imaginary line is set up in a copper wire, it will be found that the same number of electrons cross the line from both directions. This random movement does not produce an electric current. It takes a controlled movement of electrons to produce an electric current.

Difference of Potential (Voltage)

Electric current results when the movement of electrons is in one direction (see Fig. 1-14b). This is done by applying a difference of potential or voltage across the ends of the wire. One end of the wire attracts electrons because it is connected to the battery terminal that has a positive charge or lack of electrons. The electrons in the copper wire drift toward this positive charge. As electrons

leave the copper wire and enter the positive terminal, more electrons enter the other end of the copper wire. These electrons are taken from the negative terminal of the battery.

The difference of potential between the terminals of the battery is produced by a chemical reaction. When the chemical activity in the battery stops, the current stops.

Electron Flow (Current)

Current is the rate at which electrons move. If a point is established in the copper wire (see Fig. 1-14c), the current can be measured by the number of electrons that pass this point each second. Recall that a certain number of electrons is a coulomb. When a coulomb of electrons moves past the spot in 1 second, this amount of current is 1 ampere. *One ampere* represents 6.25×10^{18} electrons passing a given point in 1 second. The current is 3 amperes when 18.75×10^{18} electrons pass a given point in 1 second.

Conductors

A *conductor* is a material that allows electrons to move easily. Copper is a good conductor because it has an electron far away from the nucleus that can be easily forced out of orbit. When the electrons in a material cannot be moved as easily as in copper, the material is said to present a higher resistance to the motion of charges. Good conductors are said to have a low resistance; poor conductors (called *insulators*) have a high resistance. When a voltage is applied to a material of high resistance (an insulator), there will be fewer electrons in motion and less current than if the same voltage were applied to a material of low resistance.

Resistance

The ease with which electrons move in a material determines its resistance. A good conductor, such as copper, aluminum, or silver, has electrons that move freely. A low voltage will move a lot of electrons. A good insulator, such as glass, mica, or plastic, has electrons that do not move freely. Even a high voltage will move only a few electrons.

Resistance can have a wide range. It can be as low as that of a good conductor or as high as some good insulators. However, most resistances are somewhere in between good conductors and good insulators. The unit of measurement for resistance is the *ohm* (Ω). The ohm is defined as: One volt of pressure will push 1 coulomb of electrons through 1 ohm of resistance in 1 second.

Another way of saying it is that it takes 1 volt to push 1 ampere of electrons through 1 ohm of resistance.

The Electric Circuit

The workhorse of electricity is the *circuit*. It takes the electrons to where they belong or are needed. A complete circuit has a source of emf, a conducting path between the terminals of the power source, and a resistance, usually called the *load*. Note that all three elements, voltage, current, and resistance, are present in any complete circuit. And each has to be dealt with according to its presence.

The series circuit shown in Fig. 1-15 uses a battery, copper wire, and a light bulb. The battery produces the force needed to move the electrons. Chemical action in the battery makes the electrons available at the negative terminal. The copper wire is the path for the electrons to move along from the battery to the bulb. The copper wire is used because of its low resistance. Its resistance is less than 1 ohm. It is necessary to have a complete path from one terminal of the battery to the other for electrons to flow.

Electrons move only when there is a complete path between the two terminals. The second wire completes the path from the other end of the bulb to the positive terminal of the battery. This permits the electrons to return to the battery. The schematic for this circuit is shown in Fig. 1-16. This can be called a *closed* or *complete circuit*.

Figure 1-15 A simple series circuit has a battery and a bulb connected by two lengths of copper wire.

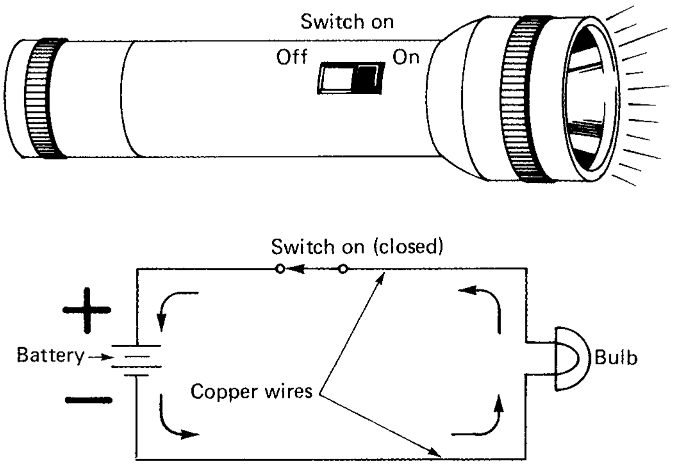

Figure 1-16 Schematic for connecting a bulb and a battery.

Connecting a Circuit

When a circuit is connected to a battery, there is a negative charge at the negative terminal of the battery. Thus, an excess of electrons is located at this point. There is a positive charge at the positive terminal of the battery. Thus, there is a deficiency of electrons at this point. Electrons flow out of the negative terminal into the copper wire. This causes a movement of the electrons in one direction. Electrons also move in one direction in the bulb. The copper wire, connected to the other end of the bulb, conducts the electrons to the positive terminal of the battery. The arrival of the electrons at the positive terminal should end the movement of electrons. However, the chemical action in the battery maintains an emf across the battery terminals, and electrons continue to flow.

The light bulb has a resistance high enough to convert the electrical energy to light and heat energy. The electric current heats the filament of the bulb. It glows brightly. Keep in mind that light bulbs do not change all of the electrical energy into light. As you know, the light bulb also becomes hot. This means that much of the electrical energy is changed to heat.

Chemical action in the battery supplies the electrical energy to the light bulb. The chemical action in the battery has a limited lifetime. Eventually, the chemical action stops because the material in the battery is used up. When this happens, the light goes out because the battery is discharged.

Switches Control Electron Flow

Electron flow can be stopped by opening the circuit at any point. One of the wires can be removed from the battery terminal or from the bulb. In most electric circuits, a switch is used at some point to permit the electron movement to be started and stopped when needed. Figure 1-17 shows a switch placed in

series with the battery and the bulb. The switch can be placed at any point in the circuit.

Schematic

The *schematic* of Fig. 1-17 shows the switch in the open position. A schematic is a shorthand way of drawing a circuit using symbols. This switch can open and close the circuit without moving wires. This simple circuit diagram shows how a flashlight is wired.

Performance Objectives

- Understand the five ways electricity is produced.
- Understand how the units of measurement for electricity were developed and used. Be able to work Ohm's law problems.
- Understand how volts, ohms, and amperes are related and function in any circuit.
- Understand how to work electrical power problems.

Sources of Electricity

The five most important sources of electricity for technicians are chemical action, heat, light, pressure, and magnetism.

Chemical action

In the electrical and electronics fields, many sources of electricity are used. In the circuit of Fig. 2-1, the battery is the source of electricity. Batteries produce electrical energy by a chemical action.

Heat

Heat can be used to free electrons from some metals and from specially prepared surfaces. When some materials are heated to a high temperature, electrons are freed from their surfaces. Any nearby metallic surface, if positively charged,

attracts these electrons and produces electron flow. The freeing of electrons by heat is called *thermal emission*.

Light

Light striking the surface of certain materials can be used to free electrons. This is called *photoemission*. With a suitable collecting surface, useful electron flow can result. Photoemission is used in photoelectric devices and television camera tubes.

Pressure

Mechanical pressure on certain crystals can be used to produce electricity. The crystal cartridge of an inexpensive record player is a good example. The needle causes a changing pressure. The crystal produces a changing voltage in step with the grooves in the record.

Magnetism

The most common method of generating electrical power is by turning a coil of wire in a magnetic field. This is the method the power station uses to generate the electric power that is used in homes, business, and industry.

Electricity is generated in two forms: direct current (dc) and alternating current (ac). A battery supplies dc electricity because the electrons flow in only one direction, from the negative terminal to the positive terminal, as shown in Fig. 2-1. A battery supplies a constant voltage of one polarity.

The ac generator is shown in Fig. 2-2. It develops a voltage across its output terminals that changes polarity and amplitude as the coil is turned. At one time, the electrons move in one direction (positive polarity). A fraction of a second

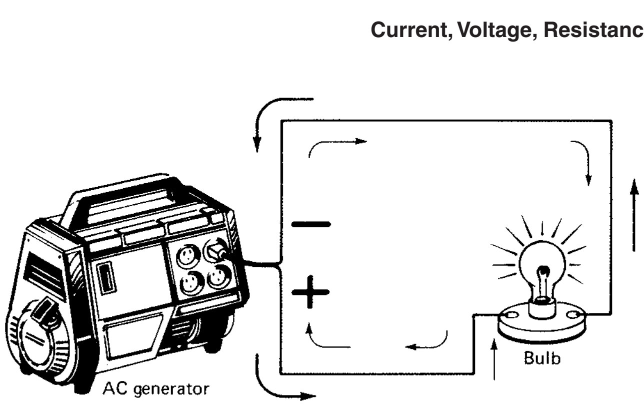

Figure 2-2 The output from an ac generator (alternator) produces a current that reverses direction at regular intervals. The current in the circuit alternates.

later, the electrons move in the other direction (negative polarity). These changes in current direction are called a *hertz*. The number of hertz completed in 1 second is called the *frequency*. In the United States, 60-hertz power is used. Some other countries use 50-hertz power. (Hertz is the newer term for cycles per second.)

When an electric circuit such as the wires and bulb shown in Fig. 2-2 is connected across the output of the generator, the direction of electron movement depends on the polarity of the voltage. When the polarity is positive, the electrons flow from the negative terminal through the load to the positive terminal. A fraction of a second later, the output voltage reverses. The electrons now flow in the direction shown by the heavy black arrows. The electrons in the circuit flow first in one direction and then in the other. Thus, the electron flow alternates. Since the current in the circuit changes direction, the voltage will also change direction. This is shown by the change in polarity (plus and minus) at the generator terminals.

There are advantages to using alternating current. One major advantage is that ac is easier to generate and distribute than dc. But many electronic circuits require both ac and dc. Such devices use power supplies to convert the ac electricity to the dc used in the circuit.

Units of Measurement

The importance of units of electrical measurements cannot be overemphasized. Electrical measurements are useful only if some standards of measurement exist. Let's review the electrical units.

Unit of charge: coulomb

The electrical charge on one electron has such a small value that it is not practical to measure it directly. A practical standard has been set up that says the unit of charge will be the total of 6.25×10^{18} electrons. This unit of charge is the *coulomb* (C). It is a basic measure of a quantity of electrical charge. Electron movement can also be measured in terms of coulombs if we include time as a second value. The electrical work performed by moving electrons depends on charge movement per unit of time. For example, a charge movement of so many coulombs per second is a rate of electron flow. This is a measurement of current or electricity at work. Remember, 1 coulomb per second is 1 ampere when it moves past a given point in 1 second.

Unit of current: ampere

A practical unit for measuring current is the *ampere*. It is used in place of the term coulomb per second. One ampere of electrical current is defined as the movement of 1 coulomb of electrons past a given point in 1 second. The ampere is measured with an ampere meter. This meter is called an *ammeter*.

Unit of potential difference: volt

The force that moves electrons is called a *difference of potential*, *emf*, or *voltage*. The unit of electrical potential is the *volt* (V). The volt is defined as the electrical force needed to produce 1 ampere of current in 1 ohm of resistance. The volt is measured with a voltage meter. This meter is called a *voltmeter*.

Unit of resistance: ohm

The opposition that a material presents to the flow of electrical charges is called *resistance*. The unit for electrical resistance is the *ohm* (Ω). By definition, the ohm represents the resistance a material offers to 1 ampere when 1 volt of electrical potential is present across the material.

The basic relation of units in an electric circuit is shown in Fig. 2-3. If there are 2 volts present across the 2-ohm resistance, there will be a current of 1 ampere. If the resistance remains the same and the voltage across the resistance is increased, the current will rise. Figure 2-4 shows the effect of increasing the voltage across the 2-ohm resistance. If the voltage stays at 2 volts, but resistance to the flow of electrons is increased to 4 ohms, there will be a decrease in current. Figure 2-5 illustrates this. Note that the ammeter indicates to 0.5 ampere.

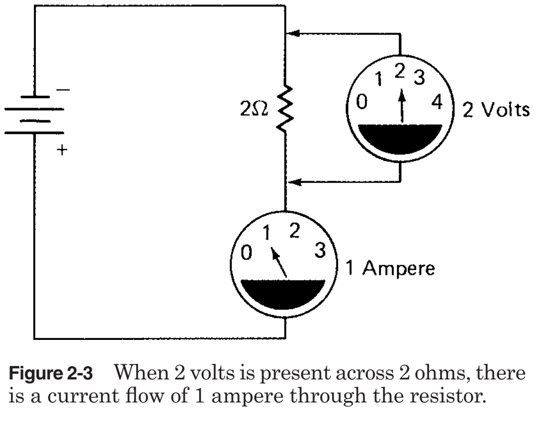

Figure 2-3 When 2 volts is present across 2 ohms, there is a current flow of 1 ampere through the resistor.

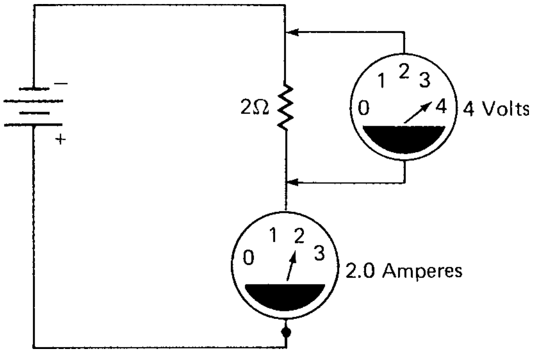

Figure 2-4 Changing the voltage to 4 volts across the 2-ohm resistor results in 2 amperes of current.

Siemens

The term conductance is also used often. It is the opposite of resistance. It is a term used to explain how well a wire or other substance conducts electricity. The unit of conductance is the *siemens* (S). The mho (ohm spelled backward) is the older term. Both are used in the literature, so it is best to be aware of both terms.

Prefixes

The ohm, volt, and ampere are units intended for practical use. For many uses, these basic units are either too large or too small. In such cases a system of prefixes is commonly used to make it easy to work with currents, voltages, and resistances.

Several of the more common prefixes are given in Tables 2-1 and 2-2. For example, a resistance of 10 million ohms can be written as 10,000,000 (10 × 1,000,000), 10 megohms, or 10×10^6 ohms. A current of 0.000003 ampere can

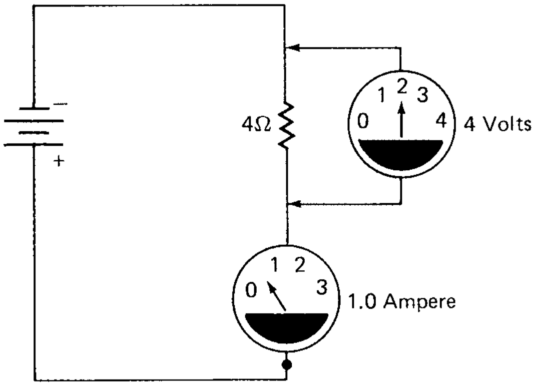

Figure 2-5 If 2 volts is present across 4 ohms, the current is 0.5 ampere.

TABLE 2-1 Common Prefixes and the Values They Represent

Prefix	Abbreviation	Multiply by	Tens power	Value
Mega	M	1,000,000	10^6	Million
Kilo	k	1,000	10^3	Thousand
Milli Thousandth	m	0.001	10^{-3}	
Micro	μ	0.000001	10^{-6}	Millionth

be represented as 3 microamperes or 3×10^{-6} ampere. A difference of potential of 5000 volts can be represented as 5 kilovolts or 5×10^3 volts.

These prefixes are not limited to the ohm, volt, or ampere. They are used frequently with other electrical units or values.

Ohm's Law

Electric current is a flow of electrons. Electrons flow when a voltage is connected to a conducting path. The amount of current depends on the amount of voltage and the value of the resistance. Georg Ohm discovered the relationship between the three factors: voltage, current, and resistance. The exact values can be determined mathematically using Ohm's law.

Current is the result of an applied electrical force. The greater the applied electromotive force or voltage, the greater will be the current or amperes in a given circuit. Thus, the voltage and current are directly related. In other words, *an increase in voltage causes an increase in current. A decrease in voltage will cause a decrease in current, if the resistance remains the same*.

The amount of resistance in the circuit also determines the amount of current that will flow. The lower the resistance (measured in ohms) in the circuit, the higher is the current (measured in amperes). Thus, current and resistance are inversely related. In other words, if one goes up the other goes down, and vice versa. Once you understand this concept, you also have a basic knowledge

TABLE 2-2 Prefixes Used with Volts, Amperes, and Ohms

Prefix	Volts (V)	Amperes (A)	Ohms (Ω)
M	1 megavolt (1 MV)		10 megohms (10 MΩ)
k	5 kilovolts (5 kV)		5000 ohms (5 kΩ)
m	10 millivolts (10 mV)	5 milliamperes (5 mA)	
μ	4 microvolts (4 μV)	3 microamperes (3 μA)	

of Ohm's law. Ohm's law states that the current is equal to the voltage divided by the resistance.

$$\text{Amperes} = \frac{\text{volts}}{\text{ohms}}$$

Usually, symbols are used for the units to form the equation:

$$I = \frac{E}{R}$$

where I = current in amperes (A)
E = voltage in volts (V)
R = resistance in ohms (Ω)

Keep in mind as you work Ohm's law problems that the basic units are the ampere, volt, and ohm. If you run into microamperes or milliamperes, they have to be converted to their decimal equivalent of the ampere. If you run into kilovolts, that unit has to be converted to volts. The same is true with resistance, which may be stated as kilohms or megohms. You have to convert them to ohms before using the formula to obtain the correct answer.

Ohm's law examples

1. What is the current in amperes when the voltage applied is 100 volts and the resistance in the circuit is 50 ohms?

$$I = \frac{E}{R} = \frac{100}{50} = 2 \text{ amperes}$$

Table 2-3 shows the results of changes in voltage and current in a circuit having a fixed resistance of 50 ohms. Our answer, 2 amperes, is circled in the second column of Table 2-3, beside the 100-volt value used in the example.

TABLE 2-3 Relationship between Voltage and Current When the Resistance Is Held at 50 Ohms (Ω) and the Voltage Is Changed

		Resistance (R) = 50 ohms

400	8	4×	4×
350	7	3.5×	3.5×
300	6	3×	3×
100	②		
75	1.5	0.75×	0.75×
50	1	0.5×	0.5×
25	0.5	0.25×	0.25×

$$I = \frac{E}{R}$$

If the voltage is doubled (increased from 100 to 200 volts), and the resistance remains fixed at 50 ohms, what happens to the circuit current?

$$I = \frac{E}{R} = \frac{200}{50} = 4 \text{ amperes}$$

When the voltage is doubled, or increased from 100 to 200 volts, and the resistance remains fixed at 50 ohms, the current is doubled. This is shown in Table 2-3 in the columns headed Voltage Change and Current Change. On the other hand, when the voltage is halved or decreased from 100 to 50 volts, what happens to the current?

$$I = \frac{E}{R} = \frac{50}{50} = 1 \text{ ampere}$$

When the applied voltage is decreased to half the original value, the current also decreases to half its original 2 amperes.

The direct relationship between voltage and current has been shown in this example. For a fixed amount of resistance, when the voltage goes up, the current goes up. When the voltage goes down, the current goes down. Thus, the current varies directly in step with the voltage.

The next step in understanding Ohm's law is to vary the resistance and keep the voltage constant.

2. What is the current when the resistance is changed to 75 ohms and the applied voltage is held at 100 volts? See Table 2-4.

$$I = \frac{E}{R} = \frac{100}{75} = 1.3333 \text{ amperes}$$

The resistance in the third column of Table 2-4 is 1.5 times the original value. The current in the fourth column is two-thirds of the original value. These values are circled in Table 2-4.

TABLE 2-4 Relationship between Resistance and Current When the Voltage Is Held at 100 Volts and the Resistance Is Changed

What is the current value for each of the resistances shown in the first column of Table 2-4? Fill in the fourth column (I) of the chart. Several answers have been filled in as examples.

Complete the third column of the chart to show the amount by which the resistance is increased or decreased. Fill in the fourth column to show the amount by which the current changes. Note that the current decreases by the same ratio that the resistance increases, and the current increases by the same ratio that the resistance decreases. In these simple problems, you have been shown that the current varies inversely with the resistance.

Ohm's law and the closed circuit

It is important to have a grasp of the relation between current, voltage, and resistance. Ohm's law is the key to understanding these relationships. Ohm's law is a tool that can be used to determine what will happen in a circuit before it is turned on. A simple circuit is shown in Fig. 2-6. What happens in the circuit if a battery with a higher voltage is used? Simple, the current increases.

Assume that you have connected the circuit, measured the current, and have found it to be low. What do you know about the circuit? Low current means that

the circuit resistance is high or the battery voltage is low. You know this because you know current is affected by voltage and resistance.

Suppose you want a certain current in a circuit (such as Fig. 2-6). What can be done to produce this amount of current? You can change to a battery that has a different voltage. Keep in mind that a different voltage will produce a different current. Or you can change the resistance because a change in resistance also produces a change in current.

3. Determine the amount of current in a circuit when the resistance is 25 ohms and the voltage is 50 volts. Use Ohm's law to solve the problem:

$$I = \frac{E}{R} = \frac{50}{25} = 2 \text{ amperes}$$

The answer is 2 amperes. It has been entered in the table of Fig. 2-7. Complete the table of values using 50 volts for each calculation. Place the values of voltage and current from Table 2-5 on the graph of Fig. 2-7.

The point for 2 amperes at 25 ohms is shown on the graph. To place a point, find the value for 25 ohms across the bottom of the graph. The value 25 is marked by an arrow. Find the value for 2 amperes on the left side of the graph. Moving up from the 25 and across from the 2 will locate the point shown on the graph. Locate a point for each of the ohm and ampere values in Table 2-5.

The points you have plotted are now connected. Mark the line 50 volts. The line can now be used to find current and resistance values for a voltage of 50 volts.

If you should need to know the current when 50 volts is applied to a resistance of 12.5 ohms, you can find it by using this line. If you divide 50 by 12.5, you get 4 amperes. That is using Ohm's law for finding the value: $I = E/R$. The

Ohm's law in other forms

It is not always necessary to find the current in a circuit. If an ammeter is handy, it will give you this information. To be able to find the resistance or voltage in a circuit when one or the other is missing, it is possible to use Ohm's law to obtain the missing value. Keep in mind that $R = E/I$ and $E = I \times R$. These are nothing more than the other forms of Ohm's law. They come in handy when working with electricity.

If you want to find resistance when voltage and current are given, you use the formula $R = E/I$. For instance, if you have a 120-volt circuit that has 4 amperes flowing in it, the resistance can be found by dividing the voltage (120) by the current (4) to give the result of 30. This 30 is 30 ohms of resistance needed to cause the circuit to draw 4 amperes. Check Table 2-6 and fill in the blanks.

The relationship between voltage and current is evident when you use the resistance of 30 ohms and a higher current is found in the circuit. Note when you use $E = I \times R$ that the voltage is directly related to the current. If the current is increased and the resistance stays fixed, the voltage has to go up or increase.

If you have 4 amperes of current and 30 ohms of resistance you use the formula: $E = I \times R$ and get $E = 4 \times 30$ or 120 volts. Place this value in Table 2-7. Now, see if you can fill in the second column of the chart in Table 2-7.

Uses for ohm's law

It is sometimes awkward to express values in basic units because many zeros or decimals are needed. For this reason, several prefixes and symbols are used. These are shown in Table 2-8. These symbols are often used in making Ohm's law calculations. They are also used for electronic terms such as frequency, inductance, and capacitance, which you will encounter in later chapters.

Most circuits have the voltage stated in volts. High-voltage cross-country transmission lines and television picture tube voltages are usually given in kilovolts or thousands of volts. Kilo (k) means 1000. Thus, 138,000 volts can be written as 138 kilovolts and abbreviated to 138 kV.

atto	a	0.000000000000000001	10^{-18}		

Some circuits, especially transistor circuits, use the terms milliamperes and microamperes. One milliampere (mA) is 0.001 ampere or one-thousandth of an ampere. The microampere unit is even smaller. One microampere (μA) is 0.000001 ampere or one-millionth of an ampere. These units have to be converted to basic units before they are used in Ohm's law formulas.

Power

Power can be understood when you take the knowledge you have and use it with Ohm's law formulas and examine them in terms of the work done. The formulas are modified slightly to produce the answers needed when figuring the work done by electricity in a circuit.

Work is done when you lift a 100-pound object for a distance of 10 feet. Power is the rate of doing work, or foot-pounds per second. If you take 20 seconds to lift the 100 pounds 10 feet, then you can find the amount of work done in foot-pounds. Power is equal to foot-pounds divided by time. In this case you have lifted 100 pounds for a distance of 10 feet. Thus, you multiply the 100 by 10 to produce 1000. This 1000 is divided by the time it took to do the job (20 seconds) to produce 50 foot-pounds of work.

If you want to convert foot-pounds to horsepower, a term you are more familiar with, you keep in mind that 1 horsepower is equivalent to 550 foot-pounds per second, or lifting 550 pounds for 1 foot in 1 second.

The 50 foot-pounds is about 0.0909 horsepower, or it can be said in fractional form as 1/11th of a horsepower.

Joule

Electrical work (joule) is done when force (E) causes the movement of an electrical charge (Q). This can be stated as joule $= E \times Q$.

The unit of electrical work is the *joule*. One joule represents the work done by a difference of potential of 1 volt (E) while moving 1 coulomb (Q) of charge (6.25×10^{18} electrons).

Power (W for watts) in an electric circuit is the rate of doing electrical work (volt-coulombs per second).

As an equation, it becomes

$$\text{Power (watts)} = \frac{\text{volts} \times \text{coulombs}}{\text{time}}$$

or

$$P = \frac{EQ}{t}$$

where P = power
E = voltage
Q = coulombs
t = time

Watt

The unit of electrical work is the *watt* (W). The letter *P* is used to represent power. One watt is equal to 1 joule per second. Thus, 1 joule and 1 watt are the same and you can convert back and forth between joules and watts easily. It takes 746 watts of electrical energy to produce 1 horsepower (hp).

$$1 \text{ horsepower} = 746 \text{ watts}$$

Putting Electricity to Work

Many jobs can be done by electricity. One useful conversion is from electricity to light. We depend on lights for the home, automobile, street lights, and flashlights. The most common conversion from electrical energy is to heat. An electric toaster or an electric iron such as in Fig. 2-8 provides useful forms of heat energy. Heat is produced in most electrical conversion devices. In some, such as the light bulb, heat is an unwanted result.

Resistors and heat

Resistors, such as those shown in Fig. 2-9, are used in electric circuits. They act as loads, voltage dividers, and current-control elements. However, in doing their job, heat is produced. For this reason, electric circuits must be ventilated to carry away the heat. Also, a resistor must be able to handle the power so that it does not overheat and burn.

Mechanical energy

Electrical energy is often converted to mechanical energy. The electric motor shown in Fig. 2-10 is a good example of a device used to convert electrical to mechanical energy. Another example is a relay, which is a switch that is operated electrically. When electrical energy is applied to the relay, a movable metal

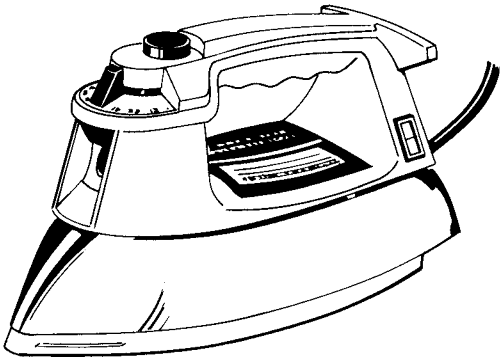

Figure 2-8 The electric iron is an example of a device that converts electrical energy into heat.

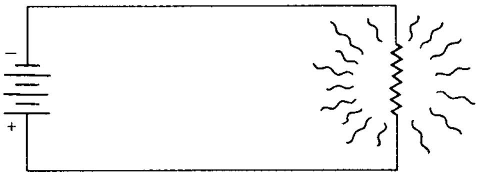

Figure 2-9 A resistor placed across a voltage source gets hot due to the current in the resistor.

arm turns on or off another electric circuit. A relay uses a low-voltage, low-current source to control high voltage or high current from a remote location. Furnaces, air conditioners, and refrigerators all use relays.

Many electrical devices are rated in terms of power and operating voltage. It is often necessary to find the current that results when the device is connected to a certain voltage source. At other times the power and the current are known, and it may be helpful to find how much voltage is needed to operate the device. Both of these problems can be solved by using one of the forms of the basic power law:

$$P = E \times I$$

$$P = I^2 \times R$$

$$P = \frac{E^2}{R} \quad \text{or} \quad P = E^2/R$$

You can also convert these formulas to

$$I = P/E \quad \text{or} \quad I = \frac{P}{E}$$

$$E = P/I \quad \text{or} \quad E = \frac{P}{I}$$

Or you can use $I^2 = P/R$ and convert it to

$$I = \sqrt{P/R} \quad \text{or} \quad I = \sqrt{\frac{P}{R}}$$

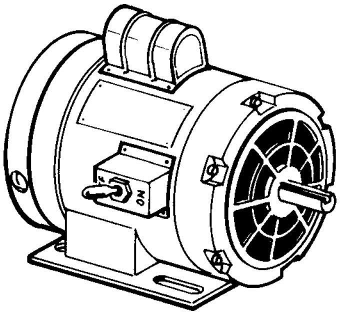

Figure 2-10 A motor is often used to convert electrical energy to mechanical motion.

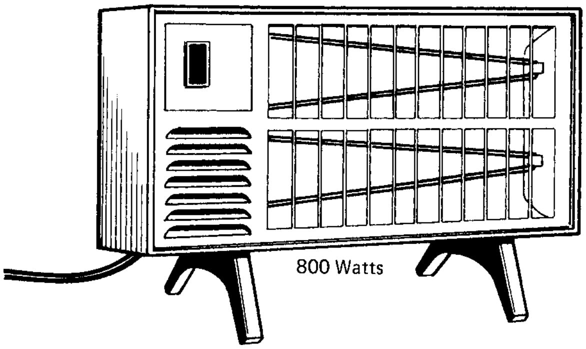

Figure 2-11 An electric heater has low resistance and high current.

A good example of how this formula can be used is found in the following problem: An 800-watt electric heater has a resistance of 2 ohms. What is the current needed to operate the heater?

First, select the formula needed. This is determined by the known values. In this case, the power and the resistance are known. You need to find the current. So, you select $I = \sqrt{P/R}$ for a formula, substitute the values in the formula, and solve.

$$I = \sqrt{P/R} \quad \text{or} \quad \sqrt{800/2} \quad \text{or} \quad \sqrt{400} = 20 \text{ amperes}$$

This is illustrated in Fig. 2-11.

Knowing that the required current is 20 amperes, you can determine the size of the wire needed to cause the heater to operate properly. You look up the current in a chart and find that No. 12 copper is the wire size for safely handling this amount of current.

A Practical Unit of Electrical Power: Kilowatt-Hour

Public utilities that furnish power for your use charge for electrical energy by using a popular unit of electric work, the kilowatt-hour (kWh). One kilowatt-hour means you used 1000 watts of electric power for 1 hour. If the cost of power is 10 cents per kilowatt-hour, and if you operate a 1000-watt iron for 1 hour, you will be billed for 10 cents. If you operate the iron for 6 hours, you will use 60 cents worth of electrical energy.

The kilowatt-hour meter is a motor-type device that accumulates and displays the kilowatt-hour usage, which is then read by a meter reader and subtracted from the last reading to see how much was used in the interval between meter readings (see Fig. 2-12).

One kilowatt is 1000 watts. One kilowatt-hour is 1000 watts for 1 hour. If the kilowatt-hour is not specified, it means the power being consumed in 1 second.

Performance Objectives

- Be able to read the resistor color code.
- Be able to recognize variable and fixed resistors.
- Understand how the capacitor is used in air-conditioning and refrigeration circuits.
- Know the difference between a standard capacitor and an electrolytic capacitor. Know the difference between an inductor and a transformer.
- Know that semiconductors such as diodes, transistors, and silicon chips are used in electronic controls for heating, air-conditioning, and refrigeration devices.

Resistance is found in every electric circuit. Voltage is the pressure that pushes the electrons through the circuit and through the resistance of the consuming device. Everything has resistance to some degree. It is possible to use certain substances in various configurations to produce a device that will limit the amount of current in a circuit. This device is called a resistor. It becomes very useful when you want a number of pieces of equipment to operate from one voltage source. It would be very difficult to use batteries of different voltages for every component in an electric circuit. Resistors of various sizes can be placed in a circuit to cause it to have the correct voltage for the various devices. Resistors are used to drop voltage.

Resistors of various sizes are available. It takes a few pages of any electronics supply house catalog to list all the types handled by the supplier. Our purpose here is to take a look at the method used to mark the value on carbon-composition resistors.

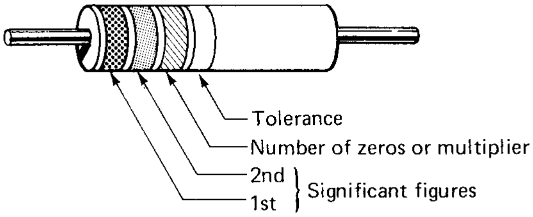

Figure 3-1 Color bands on a carbon composition resistor.

Carbon-composition resistors are small in physical size. They can dissipate $^1/_8$, $^1/_4$, $^1/_2$, 1, and 2 watts. Thus, some method must be devised to mark them. If they are placed in a circuit, it is best to be able to read the value without having to turn the resistor over. Turning it over after it has been soldered in place can cause the connection to break or the leads to break off. Color banding of the resistor seems to be the best answer to the problem of marking.

Carbon-composition resistors have been color coded for a number of years. Three color bands are used to indicate the ohmic value of the resistor. A fourth band is used to indicate the tolerance (see Fig. 3-1).

Resistance is measured in ohms. Wire-wound resistors normally have their values (in ohms) marked on them, since they are physically larger than the carbon-composition type and the lettering or printing can be made on the body of the resistor.

Color Code

The colors used on carbon-composition resistors have a definite value, which is easily read. Each color has a value assigned to it, which is agreed upon internationally, as follows:

Color	Number
Black	0
Brown	1
Red	2
Orange	3
Yellow	4
Green	5
Blue	6
Violet (purple)	7
Gray	8
White	9

When looking at the resistor, you will note that the bands are located at one end. You start reading the resistor value by checking the band nearest the end of the resistor first. Turn it so that you are holding the end with the color band to your left. Then you can read from left to right, as you usually do.

The first two color bands, A and B in Fig. 3-2, indicate the first two digits in the resistance value. The third band is used to show how many zeros are added. C shows

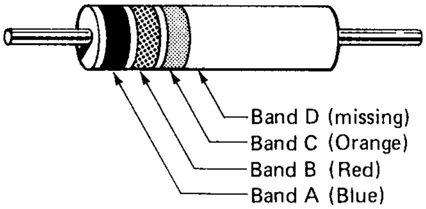

Figure 3-2 Bands A and B indicate the first two digits.

how many zeros follow the first two digits, or it is the multiplier. Sometimes the fourth band (D) is missing. If so, the resistor has a tolerance of ±20%.

Tolerance

When there is a fourth band, it will be either silver or gold. Silver means the tolerance of the resistor is ±10%, while gold indicates ±5%. The lower the tolerance number (5% instead of 10%), the more expensive the resistor is to produce and also buy. The tolerance tells how close the resistor value is to that indicated by the color bands.

Tolerance is indicated in + or – designations to tell you how accurate the resistor is. It may be in the + direction or have more resistance than the value stated by the color bands. Or it may have a – value, meaning the value of the resistor will measure less than the color bands indicate.

Examples

A few examples will make you more familiar with the code and its usefulness. Examine Fig. 3-3. Note the first three bands. The blue-red-orange bands signify 62 followed by three zeros. This produces a value of 62,000 ohms. There is no fourth band, so the tolerance is 20%.

What are the limits of the resistor when you use a meter to check its value? Take the 62,000 and multiply it by 0.20. That produces 12,400. You add the 12,400 to the 62,000 to get 74,400 ohms for the + tolerance value. You take 12,400 away from the 62,000 ohms to get the – or lowest value the resistor can have to still be within tolerance. So, 12,400 from 62,000 produces 49,600 ohms. Thus, the resistor can read between 49,600 ohms and 74,400 ohms and still be called a 62,000-ohm resistor as indicated by its color bands.

Let's take another look at the color code and what it can do for us. Check Fig. 3-4. In this figure you have three color bands to obtain the value of the resistor.

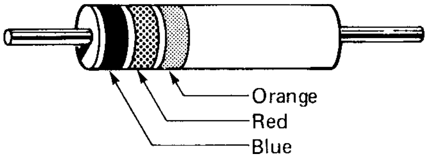

Figure 3-3 A 62,000-ohm resistor.

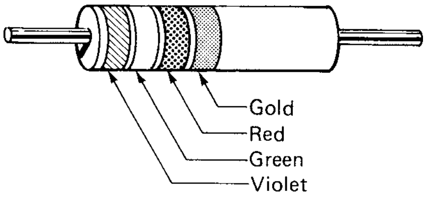

Figure 3-4 A 7500-ohm resistor.

The violet (7), green (5), and red (2) indicate that the resistor has a value of 7500 ohms. The gold band indicates it has a value of 7500 ±5%. Five percent of 7500 ohms is 375 ohms. That gives the 7500-ohm resistor a tolerance range of 7500 + 375 and 7500 – 375. The results are 7875 ohms and 7125 ohms. The resistor can read anywhere between 7125 and 7875 and still be called a 7500-ohm resistor. Sometimes you may find a resistor such as shown in Fig. 3-5. The resistance value is not 750 ohms, but 75 instead. The third band specifies the number of zeros. Since black is zero, these are no zeros after the first two digits. Thus, the black adds nothing and the 75 stands alone. The silver tolerance on the resistor indicates that it has a plus or minus value of 7.5 ohms (75 times 0.10 produces 7.5 ohms). The 7.5 ohms has to be added to and subtracted from 75 to produce the tolerance range of the resistor. So, 75 plus 7.5 equals 82.5 ohms, and 75 minus 7.5 equals 67.5 ohms. The resistor has a tolerance range of 67.5 to 82.5 ohms.

Gold and silver third bands

Carbon-composition resistors have been improved to the point where they can be made in values of less than 10 ohms. Thus, the code has to be altered to fit the situation, and using gold or silver as the third band comes in handy.

Gold as the third band means you divide the first two numbers by 10. Thus, if you have a resistor of red, red, and gold, it has a value of 22 divided by 10, or 2.2 ohms. As you can see, this makes it possible to use the color code now for indicating resistances of less than 10 ohms.

Examine Fig. 3-6. Note that the values of the resistor are indicated by a first band of blue and a second band of yellow, which produces 67. The third band is gold. So, the 67 is divided by 10 to produce a reading of 6.7 ohms for the resistor. If the fourth band is silver, it means the tolerance is ±10%. Ten percent of 6.7 ohms is 0.067 ohm. Add the 0.067 to the 6.7 and you have 6.767 ohms. Subtract 0.67 ohm from the 6.7 and you have a negative tolerance value of 6.633 ohms. The tolerance

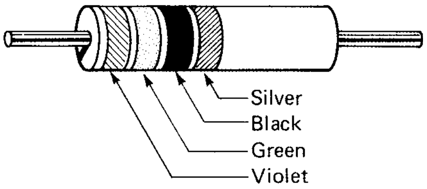

Figure 3-5 A 75-ohm resistor.

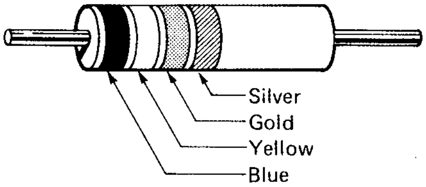

Figure 3-6 Note the third band is gold.

range is 6.633 ohms to 6.767 ohms. It takes a very good ohmmeter to measure this close a tolerance. In fact, it would be hard to see anything near the 6.7 on a conventional ohmmeter. It would probably read 7 or even as much as 10 ohms. The digital ohmmeter is used to measure this type of ohmic value.

Silver as the third band means you divide the first two numbers by 100. Thus, if you have a resistor of red, red, and silver, it has a value of 22 divided by 100, or 0.22 ohm. Take a look at Fig. 3-7. The resistor has bands of yellow, violet, and silver. The values then are 47 divided by 100 to produce the correct answer of 0.47 ohm for the resistor. Most of these resistors will have a fourth band, also. The fourth band still indicates the tolerance. So, if the resistor has a fourth band of silver, it is ±10% as usual. This means that the resistor will vary in resistance by 0.047 ohm in either direction of 0.47. Thus, resistor tolerance may be from 0.423 to 0.517 ohm. It takes a very good ohmmeter to measure this resistance range, but the advent of semiconductors has brought about more sensitive and inexpensive meters and the demand for lower resistance values and closer tolerances.

Resistors come in standard sizes. The Electronics Industries Association (EIA) sets standards for manufacturing of resistors. This helps to standarize the number of sizes of resistors made. It also makes it easy to find spare parts to use for repair jobs.

Variable Resistors

Some resistors are variable. This means that the amount of resistance can be changed. Variable resistors may be either carbon composition or wire wound. These resistors are used for special circuits. On these circuits, the amount of voltage or current that is delivered must be varied. A common example is the volume control on your radio or television set (see Fig. 3-8).

Variable resistors are easily identified because they have three connections for leads. The center lead is usually the variable contact. A variable resistor that is

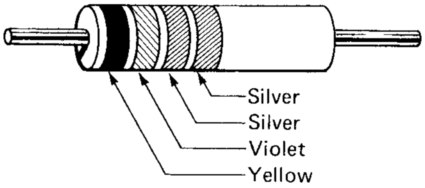

Figure 3-7 Note the third band is silver.

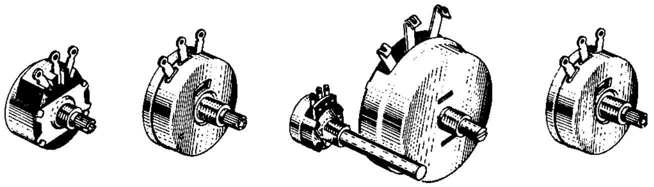

Figure 3-8 Potentiometer.

connected into a circuit at all three points is called a potentiometer (see Fig. 3-8). A potentiometer is often referred to as a pot.

Usually, a potentiometer is used to vary voltage. The device is connected across a voltage source by placing it directly across the battery or power source. The variable arm is then used to change the voltage that is available from the potentiometer. The rheostat is a variable resistor. It is used by connecting it in series not across the voltage source, as was the case with the potentiometer. Rheostats are designed to handle higher currents than potentiometers. Very few rheostats are used today because their jobs are being done by semiconductors. Usually, a rheostat is connected to a circuit at only two points. A symbol for the rheostat is shown in Fig. 3-9.

Variable resistors have a wide range of adjustments. For example, volume controls typically use carbon resistors. Resistance ratings can be adjusted from 0 to 10 million ohms. Another way to state these values is from 0 to 10 megohms (mega means million).

Many potentiometers have what is called a nonlinear resistance element. This simply means that resistance does not change at a fixed, or uniform, rate as adjustments are made. Usually, they are small, or fine, changes at the low end. At the high end, settings lead to large resistance changes. This nonuniform resistance leads to what is called a tapered control. Such devices are usually used to adjust sound volumes and are called audio taper resistors.

There are also linear taper potentiometers. They have a uniform change of resistance as the settings are adjusted. They look exactly the same as the audio taper. When replacing a potentiometer, you must be very careful not to use a linear taper one in a volume control circuit or, worse yet, an audio taper in a control circuit. This is one of the things that you, as a technician, must be aware of in making repairs. Do not try to substitute a volume control of the same resistance for a control circuit potentiometer. You will find it very difficult to make the required adjustments in the control circuit.

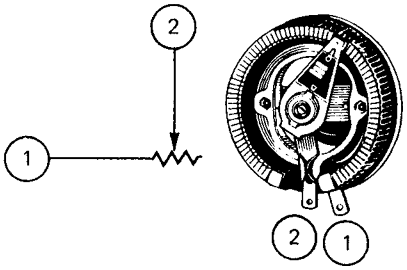

Figure 3-9 A rheostat symbol. Rheostats resemble potentiometers. A potentiometer can be made to serve as a rheostat by connecting the center terminal and one of the end terminals to form a single connection.

Wattage ratings are usually marked on the rheostat or potentiometer. It is difficult to tell the wattage rating by just observing the device. It takes practice to be able to tell the difference between various wattage ratings.

Schematic

Persons who work with electricity use a schematic to tell them where components are located and what the relationships are to one another. A schematic is a diagram something like a road map. It tells you the way from one point to another. Symbols are used to mark certain items along the way. The schematic is the road map of the electrical trade. Many types of diagrams are needed to describe the operation and construction of electrical equipment. The schematic is the most common term for the electrical diagram.

The schematic shows how the electrical or electronic components (parts) are connected. A schematic is a handy item to have when you are analyzing, explaining, or servicing heating, air-conditioning, and refrigeration equipment.

Types of Resistors

The resistor is the most widely used electrical and electronic device. Every radio, television set, and control circuit has a resistor or resistors. This component is used to provide resistance. It is designed to be used at a fixed value or as a variable-value device.

Fixed resistors

The fixed resistor is the simplest of the two types. It is made so that you cannot change the resistance. Some carbon fixed resistors are shown in Fig. 3-10. These are carbon composition and have a cover of black, brown, or green plastic. A color code is used to give the value of the resistor.

Fixed wire-wound resistors are available for use when the wattage rating is higher than 2 watts. Carbon-composition resistors come in $^1/_8$, $^1/_4$, $^1/_2$, 1, and 2 watt sizes. The physical size tells the rating. You get used to the wattage rating when working with resistors. The larger the resistor, the higher the wattage rating is.

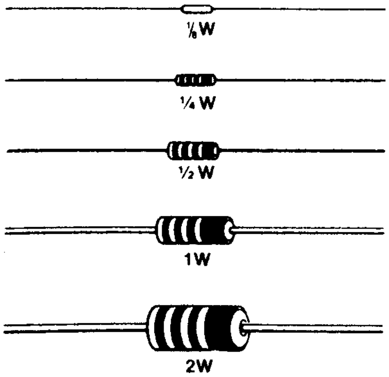

Figure 3-10 Fixed carbon-composition resistors.

The larger the resistor, the easier it is for it to dissipate heat. Since resistors put up resistance to current flow, they also drop voltage. The energy has to be dissipated as heat. Thus, the surface of the resistor must be large enough to allow the heat to be dissipated.

Figure 3-11 shows some fixed wire-wound resistors. These are made of high-resistance wire wound on an insulating core with a ceramic coating. They usually are large enough so that the resistance of the unit can be stamped on it.

The symbol for a fixed resistor is shown in Fig. 3-12. Note how the symbols vary for different users. A is the standard EIA (Electronics Industries Association) symbol. B is usually used by foreign manufacturers and occasionally by American makers of industrial equipment. C is seldom encountered, but it is sometimes used in schematics for industrial equipment and can be seen in some refrigeration and air-conditioning electrical schematics.

Tapped resistors

Tapped resistors are used in some circuits. They have taps for easy connections. They are usually wire wound, although some are carbon. Figure 3-13 shows samples of the tapped resistor. Figure 3-14 shows the schematic representation of tapped resistors.

The ceramic coating is left off the wire where the tap is to be made. This allows a sliding connection so that the tapped resistor can be made into a variable resistor or adjusted as needed.

Variable resistors

A variable resistor may be made of carbon or it may be wire wound. The idea behind the variable is to make it adjustable to meet the needs of the circuit. You are most familiar with the variable resistor as a volume control on a radio or television set. This is a variable carbon-composition type of resistor and controls a circuit to allow for increases or decreases in volume, as you desire.

A variable resistor has a movable contact that is used to adjust or select the resistance value between two terminals. In most uses, the variable resistor is a control device. It is made in many sizes and shapes. Figure 3-15 shows some of these types. The shafts of most variable resistors have knobs placed on them to make them easier to use. However, some are made to be adjusted by the insertion of a screwdriver blade in a slot on the resistor. Many adjustable resistors are used in controls for air-conditioning and refrigeration systems. Figure 3-16 shows the schematic representation for variable resistors.

Fusible resistors

In some cases, the resistor has a purpose other than providing resistance. One type is used to protect the equipment or circuit against excess current surges. This type of resistor, called a fusible resistor, is built to fail before damage is done to more expensive parts. Such units are often made to plug into a socket (see Fig. 3-17). Figure 3-18 shows the schematic symbol for a fusible resistor.

Temperature-compensating resistors

Another type of special resistor is the temperature-compensating resistor. These are designed so that the resistance value changes in a direct or inverse relation with temperature changes. Such resistors are used to provide special control of circuits that must be extremely stable in operation. The symbol is shown in Figure 3-19.

Types of Capacitors

The capacitor is used in many electric circuits in both electronics and in air-conditioning and refrigeration circuits. Two types of capacitors are used in these circuits: fixed and variable.

Fixed capacitors

The fixed capacitor is made for a certain value and is not adjustable. The fixed capacitor is divided into several groupings. It may be made with paper separating two plates of aluminum foil, or it may use plastic, mica, ceramic, or electrolytes.

Most paper capacitors have been replaced by those made of better materials, usually plastic. A typical capacitor is shown in Fig. 3-20. Capacitors are large enough to have their values printed on them. The smaller capacitors use a color code to indicate their value and working voltage. Capacitors come in hundreds of sizes and shapes. It takes a good half-hour to thumb through an electronics catalog that shows all the various types. Each type has a special or particular application. Mica types, for instance, are used for some high-frequency applications with high voltages. The ceramic type is found in circuits that use high voltages, such as television sets and radar equipment.

Electrolytic capacitors

This type of capacitor deserves special mention, but will be covered in detail in Chapter 10. The electrolytic capacitor has a very high capacitance value when compared with the types mentioned previously. These capacitors may be tubular or square in shape. They have cardboard or metal covers. Values are printed on the cardboard cover and stamped into the metal cover (see Fig. 3-21). They

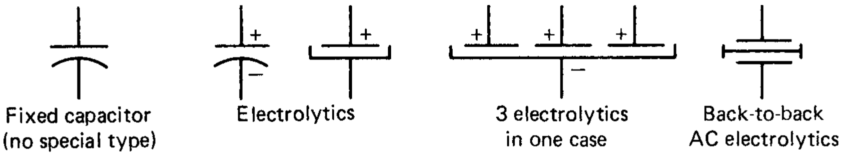

Figure 3-22 Capacitor symbols with electrical polarity marked.

are available in a variety of shapes and sizes. One characteristic of the electrolytic capacitor is its polarity. Its terminals will have − (negative) or + (positive) marked on them. This means that the circuit power must be connected correctly to avoid damage to the electrolytic capacitor. It is not to be used on ac unless it is an ac electrolytic capacitor and so identified.

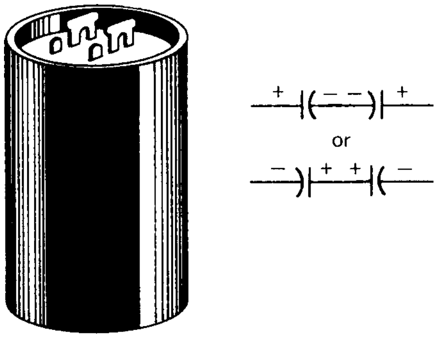
Caution*: If an electrolytic capacitor marked with a – and a + is connected to ac, it will explode, and can throw its contents over an area as large as 50 square feet. Thus it can be dangerous. Some are manufactured with a small hole in them so that their contents will spew out instead of exploding. However, safety dictates that you treat all electrolytic capacitors as firecrackers and a larger one as a piece of dynamite. This is another reason for wearing eye protection when working with electric circuits.*

Note that the symbols for capacitors in Fig. 3-22 indicate the electrolytic capacitor with polarity markings.

Electrolytic capacitors are 1 microfarad (μF) and larger in size. They can be made to operate on ac by connecting two of them back-to-back as shown in Fig. 3-23. AC electrolytic capacitors are used in electrical motors, crossover networks in speaker systems, and other places needing large capacitances in circuits that contain ac.

Variable capacitors

Variable capacitors are used for tuning purposes in radios and televisions. In most instances, you will not need them for air-conditioning and refrigeration circuits. However, in case you do see one utilized in the electronics control unit, you can identify it by using Fig. 3-24.



AC electrolytic

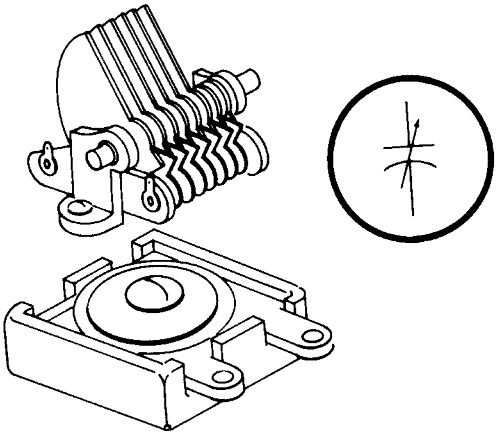

Figure 3-24 Variable capacitors with symbols.

Types of Inductors

Coils, inductors, and chokes are the names used to indicate a coil of wire. "Inductor" is preferred because inductors have inductance, a property that is utilized in many electric circuits.

Fixed inductors

The simplest coil or inductor has an air core and is made by winding a wire in a series of loops, which may or may not have a form to hold them in place. Coils are seldom color coded for value, so we look at the schematic or a parts list for the inductance value of a coil. Inductance is the electrical property of a coil, just as resistance is the electrical property of a resistor. Many coils are wound on plastic forms that support the loops of wire. The form has no effect on the operation of the coil. The symbols for air-core coils are shown in Fig. 3-25. Other types are powdered iron core and iron core. Symbols for these types are shown in Fig. 3-26.

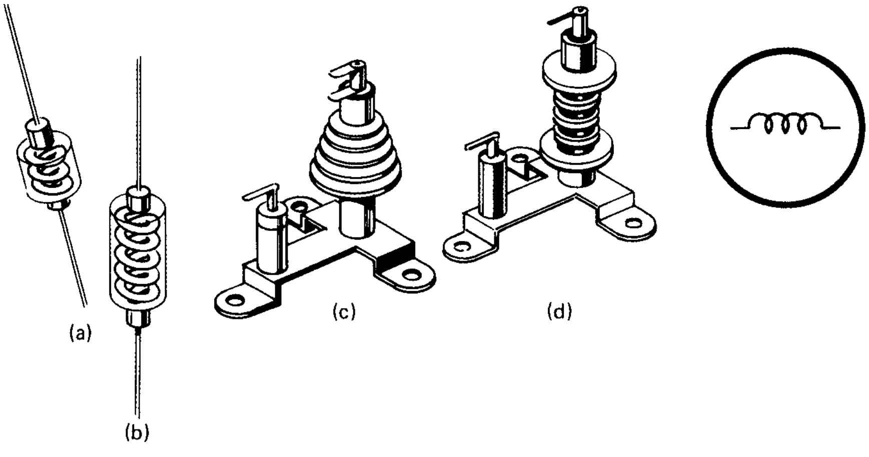

Figure 3-25 Symbols for air-core coils.

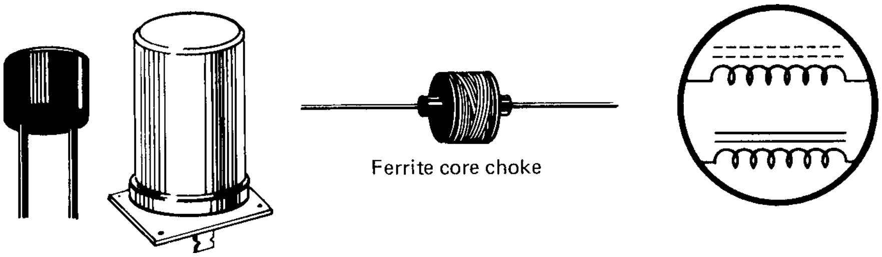

Figure 3-26 Powdered-iron-core and iron-core inductors.

Variable inductors

Some circuits need inductors that can have their values changed, some by screwdriver adjustment and others by changing the core material. Figure 3-27 shows the symbols for variable inductors. Note the differences for iron-core variable inductors. Iron-core (made of iron or steel) chokes are indicated by two straight lines over the loops. Dashed lines indicate powdered iron cores.

Transformers

The inductor has one coil. The transformer has two. The two coils of a transformer are so placed that the energy in one is transferred to the other by magnetic induction. The coil winding connected to the power source is called the primary. The winding connected to the circuit or consuming device is called the secondary. Or keep in mind that the primary is the input and the secondary is the output. Note in Fig. 3-28 that the two coils are not connected. Transformers are used in air-conditioning and refrigeration circuits for stepping down the voltage from 120 or 240 volts to 24 volts. The thermostat circuit then uses the 24 volts. The transformers you will work with have iron cores. Air-core transformers are used in electronics where radio frequencies are present.

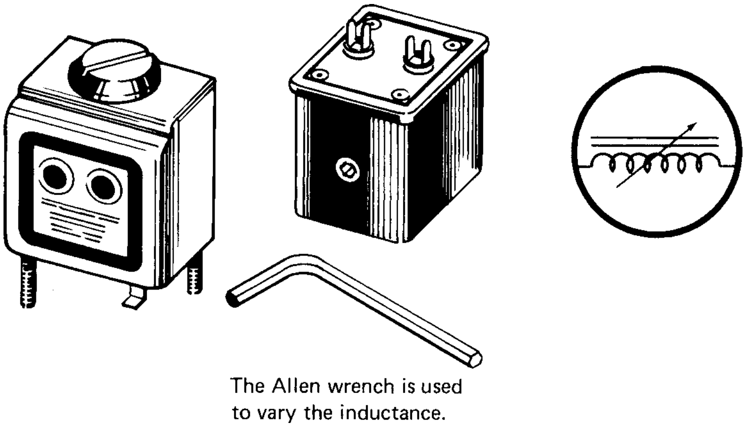

Figure 3-27 Symbol for variable inductors.

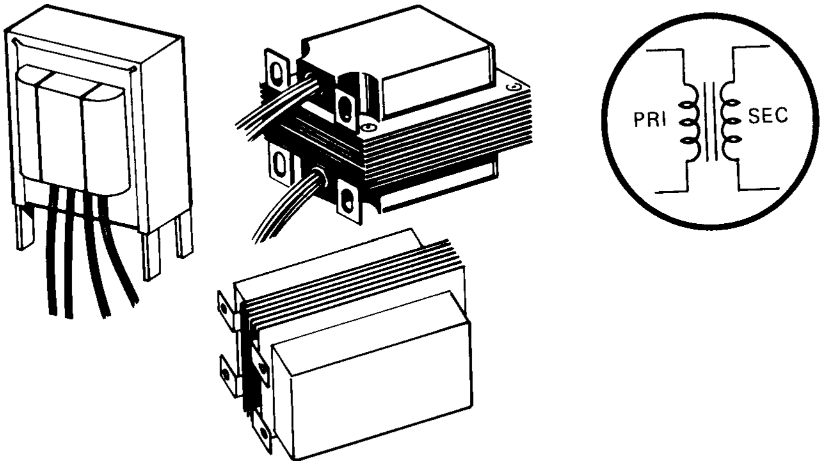

Figure 3-28 Symbol for a transformer.

Semiconductors

You know semiconductors as transistors, diodes, and chips. Silicon material is used to make devices that will conduct a certain amount of current when needed. These devices are made for easy use and with low voltages. You will encounter semiconductor chips in memory devices and computers; transistors are used in many types of circuits, and diodes are used as rectifiers and control devices.

Diodes

Diodes have an anode and a cathode. The cathode end is marked (+) to indicate which polarity it must be connected to in order to work properly. Diodes have many uses. They are found in circuits that are used to change ac to dc for certain control devices. They may also be used as protective devices in circuits. The symbol for a diode is shown in Fig. 3-29.

Transistors

The transistor is used for switching and amplification. It consists of three active elements. There are two basic types of transistors, PNP and NPN (see Fig. 3-30). These terms will be discussed later. E stands for emitter, C stands for collector, and B is used to indicate the base connection.

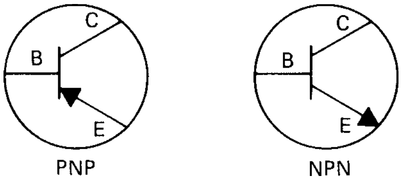

Figure 3-30 Transistor symbols, PNP and NPN.

Switches

Switches are used to turn on or off a circuit. They can be made as a simple on-off device or used to control many functions in a number of circuits.

Switches have names that designate what they can do in terms of turning on or off a circuit or circuits. For instance, there are SPST (single pole, single throw) switches, DPDT (double pole, double throw), DPST (double pole, single throw), single-pole, six-position, and so forth. Symbols for various types of switches are shown in Fig. 3-31.

Relays

Relays are switches that are moved electrically instead of by hand. They can be made in almost any configuration of poles, throws, and construction. The force that operates a relay is magnetic. The magnetic pull is produced by current passing through a coil of wire. The attraction of an armature causes the switch sections to operate.

Some relay types that you may run into in the air-conditioning and refrigeration field are shown in Fig. 3-32. Relays can also be represented by symbols (see Fig. 3-33).

Fuses and Circuit Breakers

Safety devices are needed on a piece of equipment to protect the expensive equipment and the persons who work on it. The fuse is a safety device designed to protect the equipment from itself. The fuse protects the equipment when it develops a condition that causes it to draw too much current.

Figure 3-34 Fuse symbols and circuit breakers.

Many circuits need a device to protect the equipment from shorts. Such devices as a fuse or circuit breaker are called for in most electric circuits. Motors have circuit breakers inserted in their windings that will turn off the motor before it reaches a critically high temperature. Fuses and circuit breakers are represented by a symbol such as that in Fig. 3-34. Typical fuses are shown in Fig. 3-35. They are manufactured in many sizes and values.

Lamps

Indicator lamps come in a variety of shapes and sizes. They may be incandescent, the type used in lamps in the home, or they may be neon types. Light-emitting diodes (LEDs) are also used as indicator lamps. Their symbol is the same as a diode with a couple of arrows pointing away from them to indicate

they emit light. However, the incandescent symbol and the neon lamp symbol are quite different (see Figs. 3-36 and 3-37).

Batteries

Many pieces of electronic equipment use batteries. Some types of programmable thermostats use batteries to keep the circuit operating when there is no power. They are required to keep the memory active in the chip so that the settings for times on and off and temperature are not lost with a power failure.

Batteries are made up of cells. A cell symbol is shown in Fig. 3-38 along with that for a battery. The battery is made up of more than one cell. The way to indicate the voltage is by a number alongside the battery symbol, rather than trying to draw the correct number of cells.

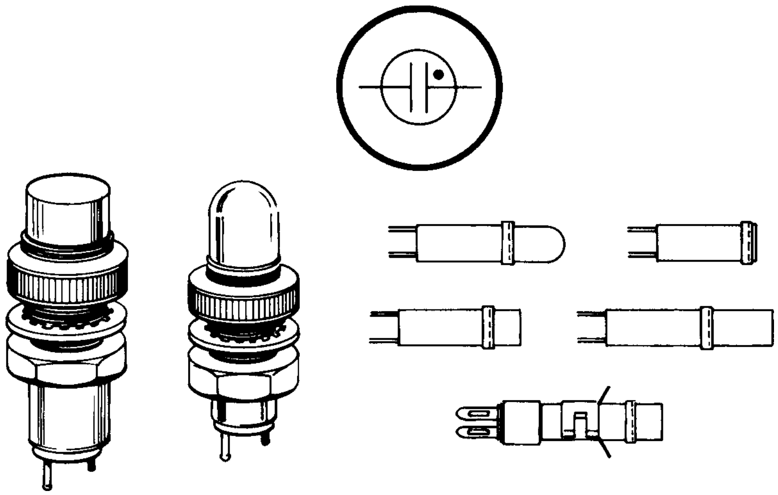

Figure 3-37 Neon lamps with neon-lamp symbols.

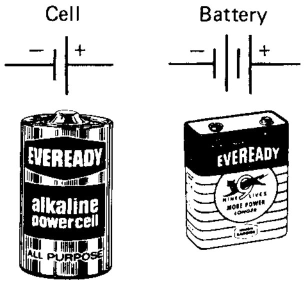

Figure 3-38 Cell and battery symbols.

Meters

Many meters are used in electronic and electric circuits. They are represented by a V or A inside a circle for voltmeter and ammeter, respectively (see Fig. 3-39).

Reading Schematics

As a technician you will be required to read schematics. This is necessary because all air-conditioning and refrigeration equipment use electric circuits for operational control. Study this chapter to be sure you can recognize the various symbols used in schematics. The more you study them, the easier it will be to interpret circuit meanings.

Series and Parallel Circuits

Performance Objectives

- Be able to identify a series circuit.
- Be able to identify a fuse and how it is used in a circuit.
- Be able to identify a parallel circuit.
- Be able to determine the total resistance in a parallel circuit.
- Be able to determine the total resistance in a series circuit.
- Be able to determine the total resistance in a series-parallel circuit.
- Be able to solve problems associated with series, parallel, and series-parallel circuits.

To be able to read a schematic, you have to know the types of circuits used in electrical work. Symbols in series and parallel circuits are the first steps in learning to read a schematic.

Series Circuit

A series circuit consists of resistors or other electrical components connected one after another. If you place cells in series, they form a battery. It takes more than one cell to make a battery (see Fig. 4-1). Cells in series produce a higher voltage. Two 1.5-volt cells in series produce 3 volts. The voltages of each cell are added to produce the total voltage. The 9-volt transistor radio battery is actually composed of six 1.5-volt cells connected in series. In a series connection, – is connected to +. The current is limited to whatever is produced by one cell. If one cell is dead, the whole battery is useless.

Series circuits have some peculiar properties. They are made up of resistors connected one after the other (see Fig. 4-2). If one resistor is open or removed from the circuit, the whole circuit is open (see Fig. 4-3). In this case, no current flows because the electrons do not have a complete path from − to + of a power source.

Resistances in series

If the resistances that form a series circuit are added, their total resistance can be found (see Fig. 4-4). When $R_1 + R_2 + R_3 + R_4$ are added, the total resistance in the circuit is 60 ohms. Or R_1 (10 ohms) + R_2 (20 ohms) + R_3 (5 ohms) + R_4 (25 ohms) is equal to 60 ohms. When this is written as a formula it becomes

$$R_T = R_1 + R_2 + R_3 + R_4$$

Voltages in series

The total voltage needed for a series circuit is found by adding the voltages needed by each resistor. Or, as Fig. 4-5 shows.

E_A = voltage applied [total voltage]

E_{R1} = voltage drop across R_1

E_{R2} = voltage drop across R_2

E_{R3} = voltage drop across R_3

Step 1: $E_A = E_{R1} + E_{R2} + E_{R3}$

Step 2: $E_A = 10 + 20 + 30$

Step 3: $E_A = 60$ volts

In a series circuit, the voltage applied is equal to the sum of the voltage drops across individual resistors. Voltage in series divides according to the resistance.

Current in series

Current in a series circuit is the same through all resistors. There is only one path for electrons to move from − to +. If the current in R_1 (Fig. 4-5) is 3 amperes, then the current through R_2 and R_3 is also 3 amperes.

I_T = total current

I_{R1} = current through R_1

I_{R2} = current through R_2

I_{R3} = current through R_3

Therefore, the formula for current in a series circuit is simply stated as

$$I_T = I_{R1} = I_{R2} = I_{R3}$$

Series circuit rules

Three basic elements must be considered in any circuit: current, voltage, and resistance. Three simple rules for series circuits concern these elements.

Voltage: Applied voltage is equal to the sum of the individual voltage drops around the series loop.

$$E_A = E_{R1} + E_{R2} + E_{R3}$$

Current: Total current in a series circuit is the same as the current in any resistor in the circuit.

$$I_T = I_{R1} = I_{R2} = I_{R3}$$

Resistance: Total resistance in a series circuit is equal to the sum of the individual resistances.

There is a disadvantage in using a series circuit. If one resistor opens, the entire circuit will not operate. An open anywhere in the circuit means the circuit will not function. The path of electrons from − to + terminals of the battery is broken. This feature of a series circuit can be useful. A switch can be used to turn the circuit on-off (see Fig. 4-6).

Fuses

A fuse can also be placed in series to protect the power supply (see Fig. 4-7). If the fuse opens, the circuit is turned off. This means you must locate the trouble. Then you replace the fuse. This safety device (fuse) is very useful.

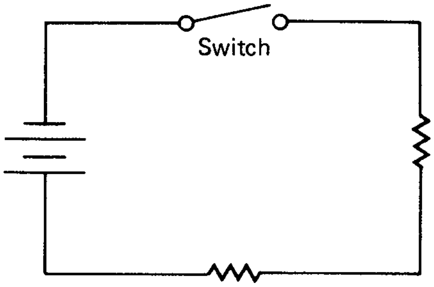

Figure 4-6 A switch controls the flow of electrons.

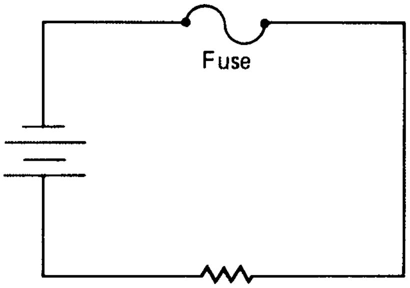

Figure 4-7 The fuse is in series with the load.

A fuse is a safety device. Its symbol is ∿. Fuses are placed in series in a circuit to protect the circuit from excess current. A fuse contains a piece of wire that melts to open the circuit. It melts when too much current flows in the circuit. The size of the fuse determines the amount of current it will safely pass. Fuses are available in a number of sizes and shapes.

Parallel Circuit

Cells in parallel

When cells are connected in parallel, the voltage output from the hookup is the same as from one cell. However, the current available is found by adding the current of each cell. Thus, two cells of 1.5 volts each in parallel produce 1.5 volts output. However, if the current available from each of the two cells is 1 ampere, then the total current available is 2 amperes. The type of material used to make a cell determines its voltage. The physical size of a cell determines its current.

Parallel circuit characteristics

Parallel circuits are used where a number of devices use the same voltage. This is the case in wiring the lighting circuits in your home (see Fig. 4-8). Most appliances

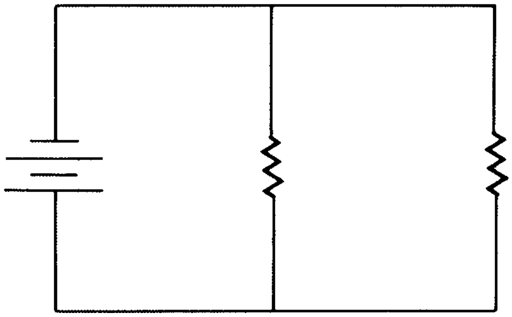

Figure 4-8 Two resistors connected across a battery are in parallel.

in the home are made to operate on the same voltage, and they are connected in parallel to the same voltage, 120 volts.

A parallel circuit has the same voltage applied to each device. However, the current in a parallel circuit will vary with the resistance of the device.

Currents in a parallel circuit

When two resistors are connected in parallel, current can flow through each resistor. Current divides according to the resistance. Two paths for current flow are present. If one path opens, it does not affect the other. The total current in a parallel circuit is equal to the sum of the branch circuits, or

$$I_T = I_{R1} + I_{R2} + I_{R3} + \ldots$$

Resistances in a parallel circuit

Resistances in a parallel circuit cannot be added to yield the total resistance. The following formula must be used to determine the total resistance when more than one resistor is connected in parallel.

$$\frac{1}{R_T} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \ldots$$

For instance, if you have three resistors of 5 ohms, 10 ohms, and 20 ohms in parallel, the total resistance is found as follows:

$$\text{Step 1: } \frac{1}{R_T} = \frac{1}{5} + \frac{1}{10} + \frac{1}{20}$$

$$\text{Step 2: } \frac{1}{R_T} = \frac{4}{20} + \frac{2}{20} + \frac{1}{20}$$

$$\text{Step 3: } \frac{1}{R_T} = \frac{7}{20}$$

$$\text{Step 4: } \frac{R_T}{1} = \frac{20}{7}$$

$$\text{Step 5: } R_T = 2\frac{6}{7}$$

A common denominator is necessary to add fractions. Fractions are produced when resistor values are inserted into a formula.

Another formula is used when there are only two resistors in parallel.

$$R_T = \frac{R_1 \times R_2}{R_1 + R_2}$$

If $R_1 = 10$ ohms and $R_2 = 20$ ohms, then

$$R_T = \frac{10 \times 20}{10 + 20} \quad \text{or} \quad R_T = \frac{200}{30}$$

$$\text{thus } R_T = 6\frac{2}{3} \text{ ohms}$$

Parallel circuit rules

Three elements must be dealt with in parallel circuits. They are voltage, current, and resistance. For a quick review, look at these three rules governing parallel circuits:

Voltage: Voltage across each resistor is the same as the applied or total voltage.

$$E_A = E_{R1} = E_{R2} = E_{R3}$$

Current: Total current is equal to the sum of the individual currents.

$$I_T = I_{R1} + I_{R2} + I_{R3} + \ldots$$

Resistance: Total resistance in a parallel circuit is found by using one of two formulas.

For two resistors only,

$$R_T = \frac{R_1 \times R_2}{R_1 + R_2}$$

For two or more resistors,

$$\frac{1}{R_T} = +\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \ldots$$

To connect power sources in parallel, make sure the polarity is observed. Connect + to + and − to − to make a parallel hookup.

Series-Parallel Circuits

Series-parallel circuits use the properties of both series and parallel circuits (see Fig. 4-9). Note that R_1 is in series with R_2 and R_3 and R_2 and R_3 are in parallel. Total current flows through R_1 but divides to go through R_2 and R_3. This type of circuit uses the properties of both series and parallel circuits. It is a good idea to make sure you understand the three rules of series circuits and the three rules of parallel circuits before moving ahead.

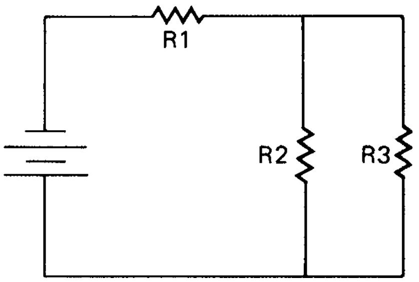

Figure 4-9 Parallel-series circuit.

Series-parallel resistance circuits

It is possible to have circuits that combine series and parallel connections. Within these circuits, some resistors or consuming devices are connected in series. Others are connected in parallel. An example of such a circuit is shown in Fig. 4-10. Another technique for writing a series-parallel circuit is shown in Fig. 4-11. One feature of a series-parallel circuit is obvious from these diagrams. There must be at least three resistors or consuming devices.

Determining resistance

To determine resistance for a series-parallel circuit, follow a simple method: Calculate the resistance for the parallel units first. Then treat the entire circuit as a series circuit. After you have reduced the values of the resistors that are in parallel to a series equivalent, you add all resistance values together. For example, look at the diagram in Fig. 4-12. Both parallel resistors have values of 30 ohms. Thus, the parallel circuit has a total resistance of 15 ohms. Remember the rule: For two resistors of equal value, divide the value of one of the resistors by 2:30 ohms divided by 2 = 15 ohms. In effect, you have a series circuit like the one in Fig. 4-13. You might want to redraw the circuit to aid in figuring the values for series-parallel circuit. Figure 4-13 shows two resistors in series. One has a value of 10 ohms. The other has a value of 15 ohms. So the total resistance of the circuit is 25 ohms. Remember the rule: To determine the total resistance in a series circuit, add the values of all resistors.

To review these steps for a more complex circuit, consider Fig. 4-14. The diagram shows a circuit with five resistors. To figure the resistance for this circuit, follow the steps shown in Fig. 4-15.

Figure 4-14 Schematic of complex series-parallel circuit.

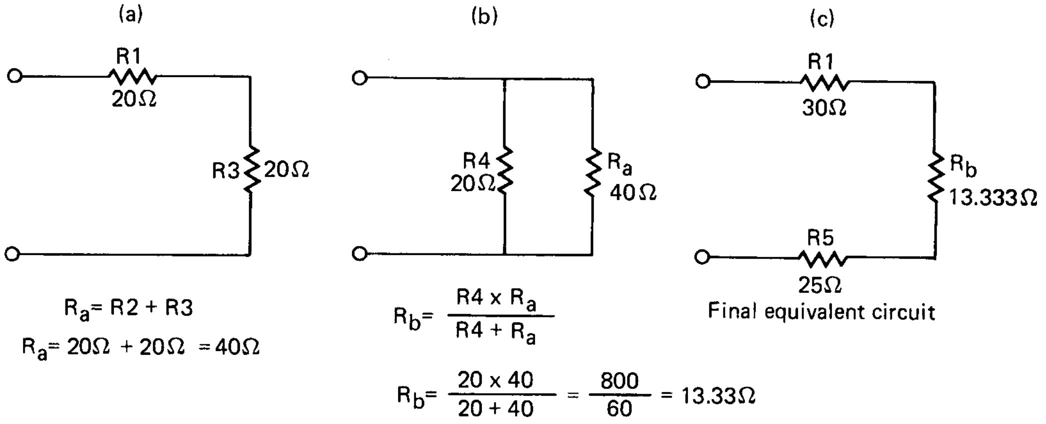

Figure 4-15 Redrawn schematic for determining resistance in series-parallel circuit.

In drawing A of Fig. 4-15, the values of two 20-ohm resistors in series are added together. The total value for these two resistors is 40 ohms. Drawing B then shows this value as part of a parallel circuit. This parallel circuit includes the combined values of the two series resistors. These have been redrawn in parallel with a 20-ohm resistor (R_4). The effect is to combine the series resistors within the parallel portion of the circuit from the original drawing. The 20- and 40-ohm parallel resistors have a total resistance of 13.333 ohms, In diagram C, this value is included as part of a series. The three resistors in the final drawing have values of 30, 13.333, and 25 ohms. Adding these, the total resistance for the circuit is 68.333 ohms. The rules for determining resistance can be summed up as follows:

1. When necessary for clarity, you can redraw the series-parallel circuit.
2. Solve all branches with series resistors first by adding their values.
3. Find the equivalent, or total, resistance of those resistors connected in parallel.
4. After you have series values for all resistors, add all the resistance values.

Determining current in series-parallel circuits

To determine current in a series-parallel circuit, follow the current path through the entire circuit. Remember your rules of current: In a series circuit, current is the same through all resistors. In a parallel circuit, you divide resistance into voltage to determine the current.

Current flow in a series-parallel circuit is shown in Fig. 4-16. The calculations for amperage in this circuit are included in the following section. They are part of the discussion and calculations of voltage values for the same circuit.

Determining voltage in series-parallel circuits

To find the voltage drop across resistors in series-parallel circuits, follow the rules you already know. When resistors are in series, add voltages. When resistors are in parallel, voltage is the same across all resistors.

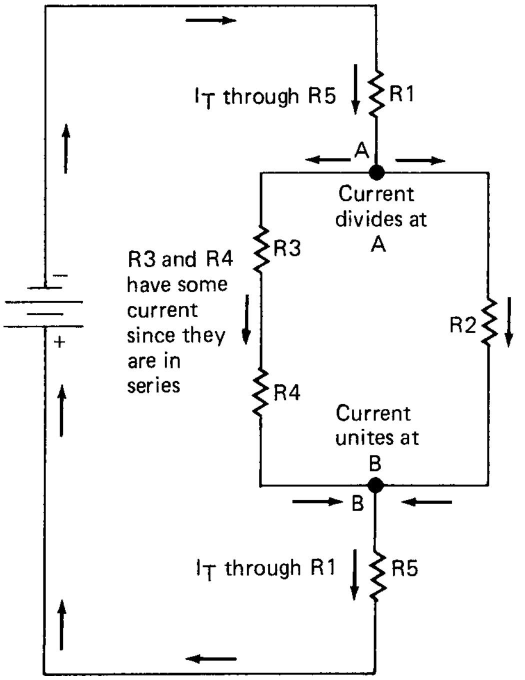

Figure 4-16 Current division in series-parallel circuit.

Examine Fig. 4-16 and see how the current divides; then look at Fig. 4-17. This figure provides total voltage at the source and resistance values for all resistors. To find values for voltage and current, here are the simple steps to follow:

1. Redraw the circuit for clarity, if necessary. Follow the steps illustrated in Figs. 4-18, 4-19, and 4-20.
2. Locate all branches with series resistors. This has been done in drawings 1 and 2 of Fig. 4-18.
3. Locate all branches with parallel resistors. This has been done in drawing 3 of Fig. 4-19.
4. Locate all branches that have series resistors in series with other resistors. Look back at Fig. 4-17. Resistors 1, 2, and 5 are in series. These are shown in loop 1 in Fig. 4-19. Resistors 1, 3, 4, and 5 are also in series. These are shown in loop 2 in Fig. 4-20.
5. Apply the rules for series or parallel circuits to calculate voltage and current.

To figure out current, divide total resistance into total voltage. Total voltage is given as 100 volts. Resistance values are shown in Fig. 4-17. Look at the resistance for the parallel portion of this circuit first. Resistors 3 and 4 are in series. These values of 10 ohms each are added for a total of 20 ohms. This gives the effect of two 20-ohm resistors in parallel. Two 20-ohm resistors in parallel give a total resistance value of 10 ohms. This value (10 ohms) is then added in

series to the values of resistors 1 and 5. The values added are 5 ohms, 10 ohms, and 10 ohms, for a total of 25 ohms. Dividing 25 ohms into 100 volts (using Ohm's law) produces an answer of 4 amperes.

$$R_3 + R_4 = 10\Omega + 10\Omega = 20\Omega$$

$$20\Omega \div 2 = 10\Omega$$

$$\text{Resistance of parallel circuit} = 10\Omega$$

Total resistance for the circuit is 25 ohms. Now, to determine current, divide the voltage (100 V) by the resistance.

$$100\text{V} \div 25\Omega = 4\text{A}$$

The current through the circuit is 4 amperes. This current is divided through the parallel portion of the circuit. So, current at resistors 2, 3, and 4 is 2 amperes. At resistors 1 and 5, the current is 4 amperes.

Note that resistors 1 and 5 are repeated in the series drawings in Figs. 4-19 and 4-20. This is important to remember: In determining voltage in a series-parallel circuit, reduce the branches to an equivalent series value. In doing so, consider all resistors in each series.

To determine voltage for each resistor in a series branch, multiply the current by the resistance (Ohm's law: $E = I \times R$). Resistor 1 has a rating of 5 ohms and a current of 4 amperes. Use Ohm's law again and get $4 \times 5 = 20$. The voltage is 20. Resistor 2 has 20 ohms of resistance and a current of 2 amperes. Using Ohm's law again, you get 40 volts for R_2. Resistor 5 (R_5) has 10 ohms with 4 amperes of current. This produces 40 volts for R_5. R_3 and R_4 each has 10 ohms resistance. These resistors have 20 volts across each.

You have been working with series, parallel, and series-parallel circuits. They are the basic circuits of anything electrical or electronic. Seeing how voltage, current, and resistance behave in these circuits brings about an understanding of circuits and improves your ability to read schematics. Schematics are symbols placed in series or parallel configurations. They are the shorthand of the electrical field. Every technician should be able to read a schematic and be able to identify how the components are connected in a circuit.

Magnetism, Solenoids, and Relays

Performance Objectives

- Know the basics of magnetic induction.
- Know how electromagnets are made.
- Know how a solenoid differs from a relay.
- Know the primary purpose of an electrically operated solenoid valve.
- Know the difference between NC and NO.
- Know what happens when a valve leaks hot gas in a hot-gas defrost system.
- Know the usual voltage ratings for solenoid valves.
- Know what VA stands for and why you need to know it.

Magnetism is something everyone knows about and has worked with, even when very young. Magnetism is the property of certain materials that permits them to produce or conduct magnetic lines of force.

Magnetic lines of force surround a current-carrying conductor or any atomic particles in motion. Even in the atom, magnetic fields result from the spinning motions of the electrons. Such magnetic lines of force can also interact with electric fields or other magnetic fields.

Every time you press a doorbell button, an electromagnet causes it to ring or chime. Electromagnets are created by sending electricity through a coil. Permanent magnets are made from materials that will retain magnetism. That is, they keep their ability to attract iron (and other materials). They do not need electricity to function. Electromagnets lose their magnetism when the electric current is removed. Both permanent and temporary (electromagnet) magnets have their use in heating, air-conditioning, and refrigeration control circuits.

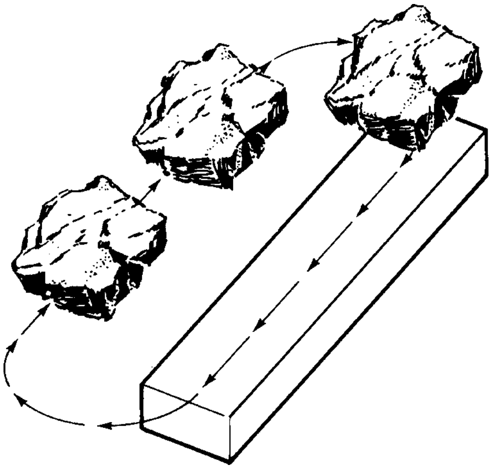

Figure 5-1 Making a permanent magnet by rubbing it with a lodestone.

Permanent Magnets

One type of permanent magnet is the natural magnet, the lodestone. It is also possible to make permanent magnets. For example, if you stroke a piece of high-carbon steel with a lodestone, the steel becomes magnetized (see Fig. 5-1).

Under normal conditions, the steel stroked with the lodestone keeps its magnetism permanently. When this happens, the molecules that form the steel bar line up in the same direction (see Fig. 5-2). The molecules that line themselves up in this way point toward the ends, or poles, of the magnet. Each magnet has two poles, which are identified as north and south.

A permanent magnet can be used to create other magnets. Figure 5-3 shows a permanent magnet used to stroke a bar of high-carbon steel. This creates a second magnet.

Magnets made of high-carbon steel sometimes lose their magnetism. This happens if the magnetized steel bar receives a strong shock, for instance, if the bar is dropped or struck with a hammer. When this happens, the molecules lose their alignment. This leads to a loss of magnetism. Magnetism can also be lost if a magnet is heated to high temperatures.

A magnet may be formed by rubbing a piece of steel with another magnet. This is called *magnetic induction*. This was the only way known of making magnets until electromagnetism was discovered.

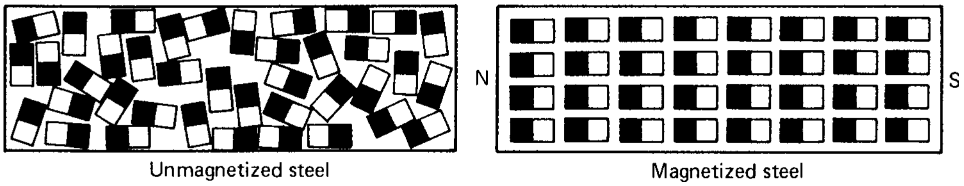

Figure 5-2 A magnetic field aligns iron molecules to produce a permanent magnet.

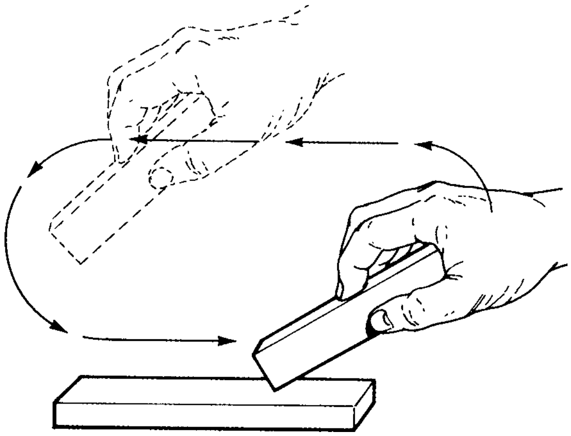

Figure 5-3 Permanent magnet used to make another permanent magnet.

Temporary Magnets

A bar of low-carbon steel attracts iron particles when it is in direct contact with another magnet. For example, you can place a lodestone against one pole of a bar of low-carbon steel as shown in Fig. 5-4. When this is done, the bar attracts iron particles. Removing the lodestone removes the magnetism. Then the iron particles fall away. The same happens if you place a permanent magnet against one end of a bar of low-carbon steel.

Low-carbon steel does not retain, or keep, magnetism. This material can serve as a temporary magnet. But it cannot be used for a permanent magnet.

Electromagnets

Magnetism also results when electric currents are passed through iron materials. Electromagnetism is important to electricity.

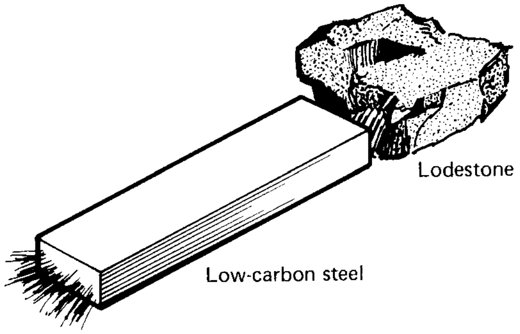

Figure 5-4 A temporary magnet made by placing the lodestone next to a piece of low-carbon steel.

Magnetic Theory

It is important to know the basics about how magnetism behaves for you to understand how certain pieces of equipment operate. Scientists still do not know exactly how magnets behave.

There are no laws or fixed rules for magnetism. Instead, there are a number of theories. These theories explain the behavior patterns that can be observed.

Magnetic Permeability

The ability of a material to become magnetized is called *permeability*. The magnetic force that attracts iron materials is called *magnetic flux*. The greater the permeability of a material, the higher its magnetic flux.

Numbers are used to indicate the permeability of materials. The higher the number, the more easily a material is magnetized. The relative permeabilities of a number of materials are listed in Table 5-1. At lower levels, materials are considered to be nonmagnetic. This applies to aluminum and all materials listed above it in Table 5-1.

Materials with higher ratings, including nickel, cobalt, iron, and permalloy, have high permeability. Permalloy, a combination of materials, has extremely high permeability. When a bar of permalloy is held in a north-south direction, it becomes a magnet. When the bar is turned to face east and west, it loses the magnetism.

Shapes of Magnets

Magnets can be made in a variety of shapes. Some of these are shown in Fig. 5-5. One common shape for magnets is the rod or bar. Another shape is similar to the letter U. This is sometimes called a horseshoe magnet.

Magnets made in a horseshoe shape have an advantage: Their ends, or poles, are close together. Thus, horseshoe magnets have a strong field of magnetic attraction, or flux field (see Fig. 5-6). By comparison, a bar magnet of the same strength has a flux field with less attraction. This is demonstrated in Fig. 5-7.

The horseshoe magnet comes in handy when we start studying electrical measurement instruments.

Poles of magnets

Dip a bar magnet into a pile of iron filings. When it is withdrawn, the filings will gather at the ends of the magnet (see Fig. 5-8). This demonstrates that magnetism is strongest at the ends. These are the poles of a magnet.

Each magnet has two poles. However, there is a difference between the poles. If you suspend a magnet from a string, it turns until one pole points north and the other south (see Fig. 5-9). (This will occur if you do not have any large deposits of steel around, such as steel storage cabinets or a building with a steel framework.) This is the principle behind the operation of a compass: One pole of a magnet is north-seeking. A bar magnet is suspended on a bearing to reduce friction. The north-seeking pole points north and the other pole points south. Therefore, the poles of a magnet are referred to as the north pole and the south pole.

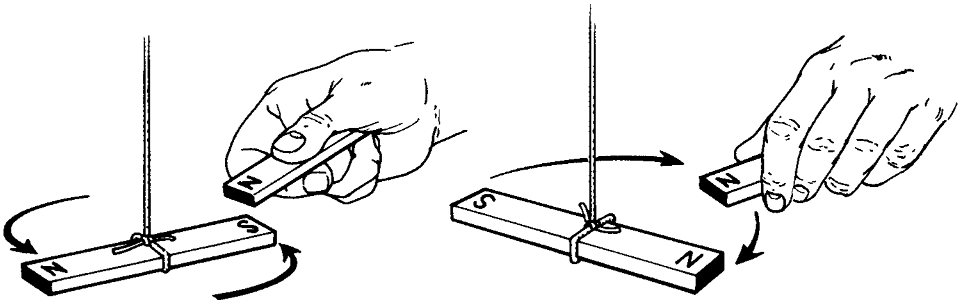

Figure 5-9 Magnetic poles align to north and south.

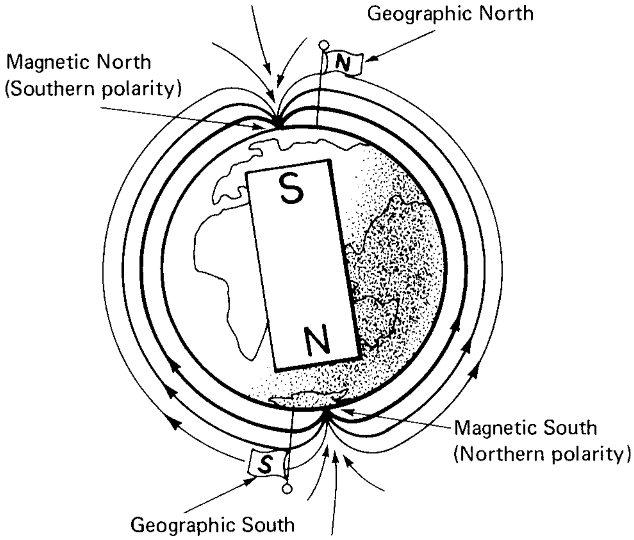

Figure 5-10 Polar attraction of magnets.

If you point the north poles of two bar magnets at each other, they are not attracted. Actually, there is a reverse force pushing the magnets apart. This force repels them from each other. This is a rule of magnetism: Like poles repel.

If you place the north pole of one magnet near the south pole of another, there is a strong attraction. This follows another rule of magnetism: Unlike, or opposite, poles attract. This means that the north-seeking pole of a magnet is actually the south pole (see Fig. 5-10). The pattern of attraction around a bar magnet is shown in Fig. 5-11.

Electromagnetism

The relationship between electric current and magnetism was discovered by Hans Christian Oersted in 1820. This relationship is direct. When current flows through a conductor, there is a magnetic field around the conductor. The direction of the current flow determines the force field of an electromagnet. Currents flowing in the same direction set up connecting fields of force (see

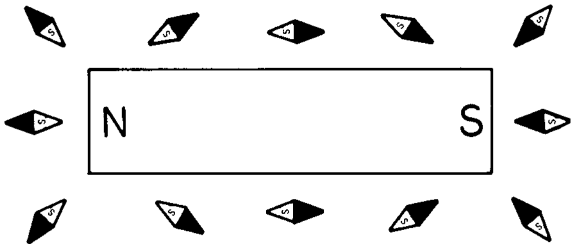

Figure 5-11 Pattern of attraction around a bar magnet.

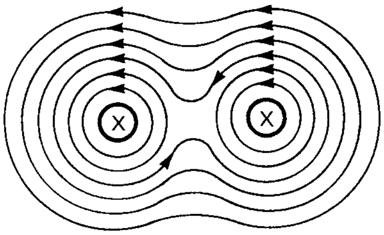

Figure 5-12 Current flow creates an electromagnetic field.

Fig. 5-12). Currents flowing in opposite directions set up repelling force fields (see Fig. 5-13).

The polarity of an electromagnet is determined by the direction of the current (see Fig. 5-14). This is important in an electrical meter.

The strength of an electromagnetic field is proportional to the current flowing through the conductor. More current means more magnetism.

Magnetism in a coil of wire

The magnetic field that surrounds a conductor depends on the form into which the wire is shaped (see Fig. 5-15). The magnetic field surrounding a single loop of wire is shown in Fig. 5-15a. Additional loops are shown in Fig. 5-15b. These loops form a spiral or helix. This shape is also known as a helical coil. Figure 5-15b shows magnetic flux around loops of wire wound next to one another. The more loops in the wire, the stronger the magnetic field becomes. This is shown in Fig. 5-15c.

The strength of an electromagnet or coiled conductor depends on the amount of current flowing in the coil and the number of turns of wire. Keep in mind that the direction of current flow determines the magnetic polarity (see Figs. 5-13 and 5-14).

Electromagnets

The usual form of an electromagnet is a coil of wire wound around a soft iron core. Thus, the core will lose its magnetism when the source of energy is

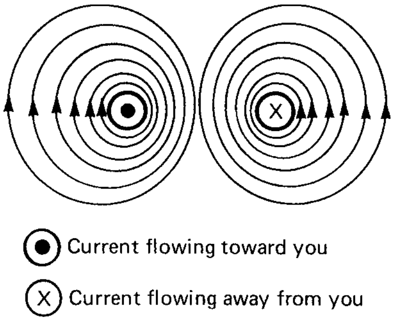

Figure 5-13 Currents in opposite directions create repelling fields.

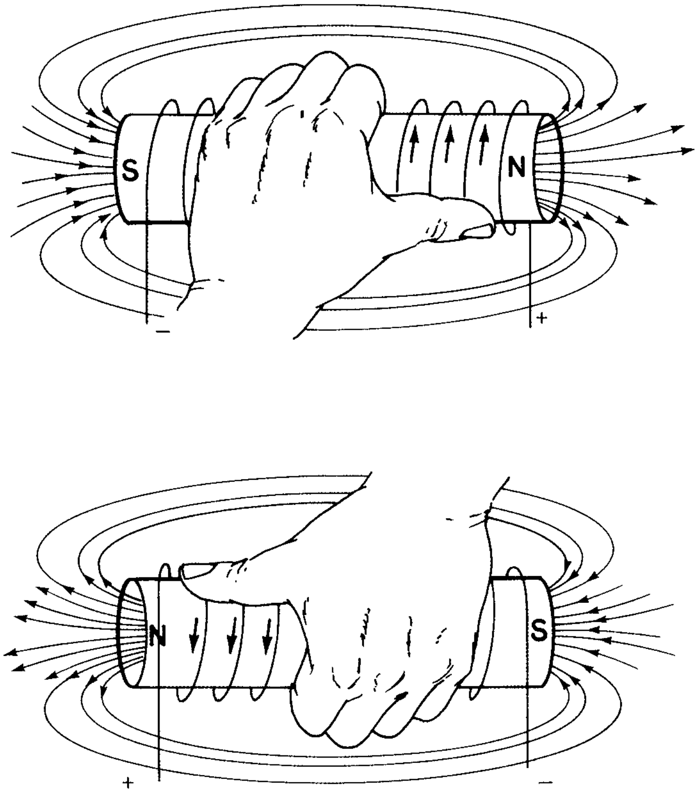

Figure 5-14 The left-hand rule shows how the polarity of an electromagnet is determined by the current flow. Grasp the coil with your fingers pointing in the direction of the current flow: the thumb of the left hand then points toward the north pole.

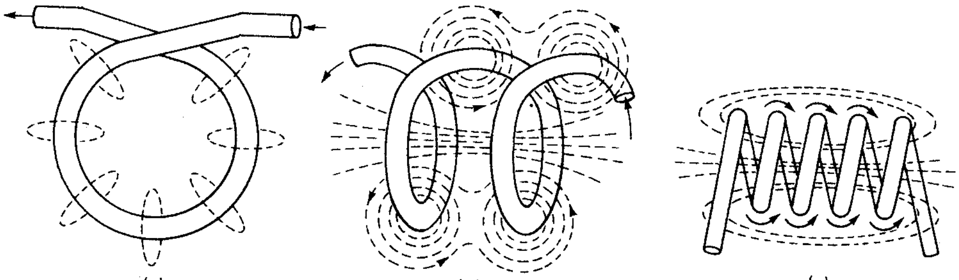
removed (see Fig. 5-16). The iron core provides an easy path for the magnetic field created by the coil. An electromagnet with an iron core forms a stronger magnet than the same coil of wire without the iron core.

The size of the iron core can help determine the strength of an electromagnet. For full strength, the core should be large enough to absorb all the magnetism



(a) (b) (c)

Figure 5-15 Magnetic fields form around various shapes of magnetic coils.

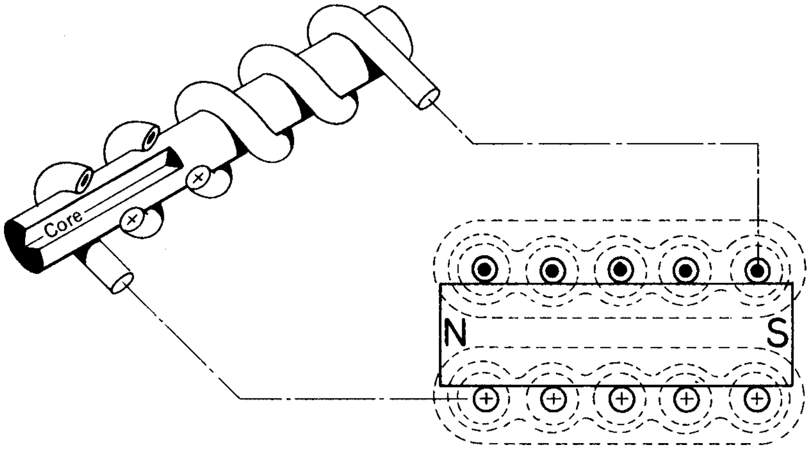


Figure 5-16 Electromagnets can be made by winding wire around a soft iron core.

from the coil. When the coil creates more magnetism than the core can absorb, it is called saturation. If the core is too small, there is too much magnetism to be absorbed. All the magnetism of the coil can be used when the core has a capacity slightly larger than the magnetic flux created.

Using electromagnetism

The generation and use of electricity are directly related to electromagnetism. Some of these uses are in the solenoid and relay. These two items are useful in heating, air-conditioning, and refrigeration equipment control circuits. It is important to understand how they work, since they can be the source of much troubleshooting.

The Solenoids and Relays

A magnetic field seeks the path of minimum reluctance, just as an electric current seeks the path of least resistance. Reluctance and resistance are related. Resistance refers to the opposition to current flow in a circuit. Reluctance refers to the opposition of the flow of a magnetic field. The lower the reluctance, the greater is the attraction of materials to a magnetic field.

A solenoid is a device that uses these principles. A helical coil of wire produces a magnetic field. An iron core fits loosely within the coil of wire. When the current is off, the core rests outside the area of the coil. When the current is applied, the core is sucked into the coil. This is referred to as the sucking effect of a coil (see Fig. 5-17).

The sucking effect is often used in devices that require a small amount of physical movement. One type of solenoid is shown in Fig. 5-18. A common use for solenoids is in devices called solenoid valves (see Fig. 5-19). This valve is a device that opens and closes to permit liquids or gases to flow. In most valves, for

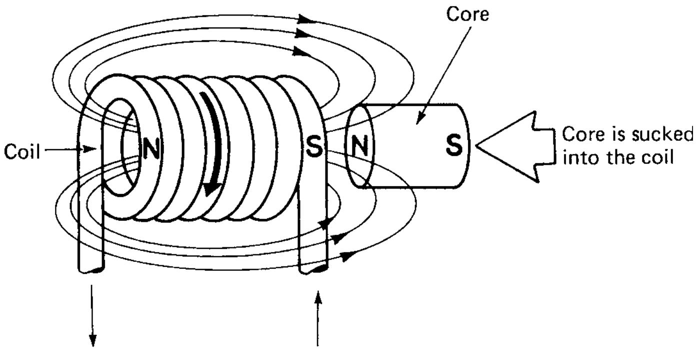

Figure 5-17 The sucking effect of a coil.

example, you turn a handle or knob to start or stop the flow of gas. Solenoid valves are used widely as safety devices. They are found in gas lines, air lines, and water lines. Many types are used in air-conditioning, refrigeration, and heating systems.

The solenoid in the valve in Fig. 5-19 is closed when there is no current through its coil. The valve stem is held in a closed position by a spring that applies light pressure. When the valve is closed, gas cannot flow. Current is applied when a person or thermostat turns on a heater. The current draws the movable core, or plunger, into the coil. This opens the gate to the flow of gas. When the current is turned off, the spring moves the valve system back into a closed position.

This same principle is used widely in solenoid-type relays. A solenoid relay is like an electrically operated switch. The coil in this type of relay pulls a core piece that has a number of electrical contacts. The contacts are designed so that they may either close or open electrical circuits. The relay contacts themselves can be designed to handle large amounts of current. But the coil of the control solenoid may operate on only a fraction of an ampere. The effect is that low-voltage, low-current electricity is used to control the flow of larger amounts of electricity.

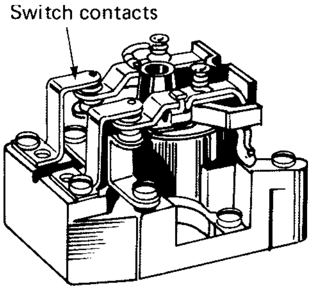

Figure 5-20 Heavy-duty power relay.

Power relays

A heavy-duty power relay that operates from solenoid action is shown in Fig. 5-20. In this device, a spring pulls the solenoid core, or armature, away from the electrical contact when the current is off. When current flows, the armature is pulled toward the coil. An electrical contact connected to the armature is either closed or opened by this action. Note that the electromagnetism can be used either to open or close the relay. The action taken depends on the design of the relay. The relay contacts can be arranged for a variety of functions, such as SPST, SPDT, DPDT, or any other combination.

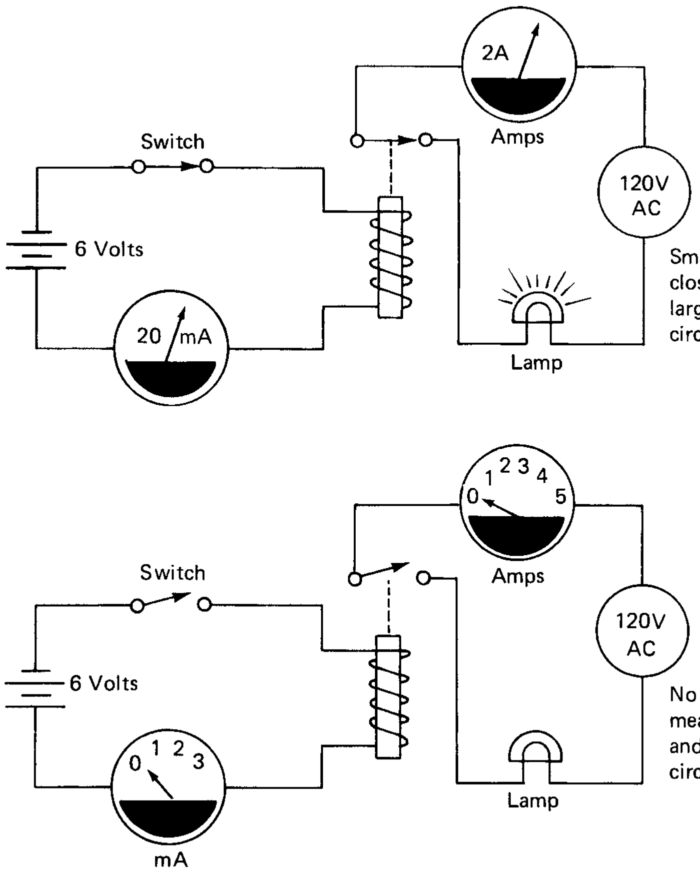
The advantage of a relay is that a substantial pulling power can be developed with a small coil current. The contacts can be made quite large and can handle or switch high values of electrical power. An extremely small amount of control power thus can be used to switch much higher voltages and currents in a safe manner (see Fig. 5-21).

Solenoid valves

The primary purpose of an electrically operated solenoid valve is to control automatically the flow of fluids, liquid, or gas. There are two basic types of solenoid valves. The most common is the normally closed (NC) type, in which the valve opens when the coil is energized and closes when the coil is de-energized. The other type is the normally open (NO) valve, which opens when the coil is de-energized and closes when the coil is energized (see Fig. 5-22).

Principles of operation

Solenoid valve operation is based on the theory of the electromagnet. The solenoid valve coil sets up a magnetic field when electrical current is flowing through it. If a magnetic metal, such as iron or steel, is introduced into the magnetic field, the pull of the field will raise the metal and center it in the hollow core of the coil. By attaching a stem to the magnetic metal plunger, this principle is used to open the port of the valve. When the electrical circuit to the coil is broken, the magnetic field collapses and the stem and plunger either fall by gravity or are pushed down by the kick-off spring.



Small current in relay coil closes contacts that control large current in higher voltage circuit.

No current through the coil means relay contacts are open and no current flows in the circuit.

Figure 5-21 Relay in a circuit.

Some solenoid valves are designed with a hammer-blow effect. When the coil is energized, the plunger starts upward before the stem. The plunger then picks up the stem by making contact with a collar at the top. The momentum of the plunger assists in opening the valve against the unbalanced pressure across the port.

Applications

In many cases, valves are used for controlling the flow of refrigerants in liquid or suction lines or in hot-gas defrost circuits. They are equally suitable for many other less common forms of refrigerant control.

Liquid line service

The primary purpose of a solenoid valve in a refrigerant liquid line is to prevent flow into the evaporator during the off cycle. On multiple systems, a solenoid valve may be used in each liquid line leading to the individual evaporators.

The application of a liquid line solenoid valve depends mainly on the method of wiring the valve with the compressor control circuit. It may be wired so the valve is energized only when the compressor is running. This type of application is shown in Fig. 5-23.

Another application, known as pump-down control, uses a thermostat to control the solenoid valve (see Fig. 5-24 for a wiring and valve location schematic). When the thermostat is satisfied, the valve closes and the compressor continues to run until a substantial portion of the refrigerant has been pumped from the evaporator. A low-pressure cutout control is used to stop the compressor at a predetermined

evaporator pressure. When the thermostat again calls for refrigeration, the solenoid valve opens, causing the evaporator pressure to rise and the compressor to start. This arrangement can be used on either single or multiple evaporators.

Suction line service

There are several applications, particularly on suction lines, where pressure drops in the range of 2 to 4 pounds per square inch (psi) cannot be tolerated. Therefore, only valves that are capable of opening at very low pressure drops are suitable for this type of use. Some valves incorporate the floating disc principle and are ideally suited for such special applications. They are capable of opening full at pressure drops of 0.1 psi and below.

Larger-capacity valves are suitable for suction service when supplied with internal parts that are mechanically connected. With this arrangement, the piston is connected to the stem and plunger assembly, and when the coil is energized, the plunger assists in supporting the piston. As a result, the pressure drop through the valve is reduced to a bare minimum. Valves with the direct-connected assembly are designated usually with a prefix D to the type number.

When these valves are required for suction service, they are supplied with a spring support under the piston. The spring counterbalances the major portion of the piston's weight, and therefore the valve will open with far less pressure drop than normal. Valves with the counterbalance spring are identified by the prefix S added to the type number.

High-Temperature Applications

In some high-temperature applications, a high-temperature coil construction is required. The temperature of the fluid or gas flowing through the solenoid valve will generally determine whether a high-temperature coil is necessary.

Hot-gas defrost service

Several piping arrangements are used for hot-gas defrost systems, one of which is shown in Fig. 5-25. A portion of the compressor discharge gas is passed through the solenoid valve into the evaporator. The solenoid valve may be controlled either manually or automatically for this duty.

Hot-gas defrost valve selection requires a slightly different approach from the simple pressure drop versus tonnage. Be sure to consider the evaporator temperature correction factors to make certain that the valve selected has adequate capacity.

Normally open solenoid valves have many uses. Perhaps the most popular is their adaptation to heat-reclaiming systems. The use of one normally closed valve and one normally open valve to shunt the discharge gas to either the outdoor condenser or the indoor heat-reclaiming coil provides positive opening and closing action.

This eliminates the problem found in some three-way valves which have a tendency to leak hot gas into the heat-reclaiming coil when not required. When this leakage occurs during the cooling season, it imposes an extra load on the cooling system that wastes energy, rather than conserving it.

If leakage occurs during the heating season when all the discharge gas should be going to the reheat coil, a good portion of the liquid charge could become logged in the inactive condenser. For a simple schematic of a heat-reclaiming cycle, see Fig. 5-26. Many original equipment manufacturers (OEMs) have developed their own reheat cycle, which may be completely different from the one illustrated. In addition, some may incorporate head pressure control as well, so it is always advisable to consult the manufacturer's bulletin regarding its particular design.

Transformers for Low-Voltage Controls

The use of low-voltage control systems is becoming more widespread as the demand for residential air conditioning increases. This necessitates the use of a transformer for voltage reduction, normally to 24 volts. The selection of a transformer is not accomplished by merely selecting one that has the proper voltage requirements. The volt-ampere (VA) rating is equally important. To determine the VA requirements for a specific solenoid valve, refer to the manufacturer's data. Insufficient transformer capacity will result in reduced operating power or a lowering of the maximum operating pressure differential (MOPD) of the valve. MOPD and safe working pressure (SWP) are usually noted on the valve nameplate (see Fig. 5-27).

If more than one solenoid valve and/or other accessories are operated from the same transformer, the transformer VA rating must be determined by adding the individual accessories' VA requirements.

Electricity

Electricity cannot be seen, heard, tasted, or smelled. That is why it is necessary to use some type of device to detect its presence. Once you have detected its presence, you need to know how much of it is present. This is the function of electrical measuring instruments. Another reason for using an instrument is to allow you to detect the presence of electricity without having to feel it. The sense of feel is the only one of our five senses that can be used to detect the presence of electricity. This can be deadly also; therefore, a measuring device is much more reliable and safer.

It takes a meter to measure electricity. It takes a meter to determine the three properties of a circuit: voltage, current, and resistance. The main reason for using meters in heating, refrigeration, and air-conditioning work is to aid

in troubleshooting defective equipment. With this in mind, we will examine a number of types of meters. By looking a little closer at what is under the meter cover, you will better understand how to treat the device to make it last longer and produce the accuracy needed to do your job.

The most frequently used meter is the multimeter (see Fig. 6-1). It can be used to measure voltage, current, and resistance.

Types of Meter Movements

There are many types of meter movements. One of the most often used in the analog configuration is the d'Arsonval meter movement, named after its designer, Arsene d'Arsonval. Actually, it is a revision of the galvanometer. The galvanometer is a measuring device that detects the presence and direction of current flow in a circuit.

Edward Weston made some improvements on the design that d'Arsonval produced and the results are still seen in today's meters.

D'Arsonval meter movement

The d'Arsonval meter movement has a small, rectangular coil of wire. The coil is suspended in a magnetic field created by a permanent magnet. When current is applied to the coil, it becomes an electromagnet. The energized coil then lines up with the poles of the permanent magnet. The amount of current applied to the coil controls its movement. An electromagnet that is free to move will align its axis with the magnetic axis of a fixed magnet. The axis of an electromagnet is a straight line between its poles (see Fig. 6-2).

The coil must be free to rotate in order to align itself with the magnetic axis. The coil in the meter is mounted on pivots that permit easy rotation. Two small springs are mounted on the top and bottom. These springs offer slight resistance to the rotation of the coil. The springs control the position of the coil when there is no current flowing.

When current flows in the coil, it produces a magnetic field around the coil. This magnetic flux overcomes the force of the springs and moves the coil. A pointer on top of the coil rotates to mark the amount of movement. The greater the current through the coil, the more it turns, and the further the pointer moves. The pointer then stops in front of a marked scale on the face of the meter. The position of the pointer indicates the meter measurement (see Fig. 6-3).

A typical meter scale is shown in Fig. 6-4. Note the even divisions between each line on the scale. This is a linear-type meter. Every space indicates the same amount of voltage.

As you look closer at the d'Arsonval meter movement, you will find that it can be extremely sensitive to small currents. For instance, a relatively inexpensive meter can give a full-scale deflection of 10 microamperes (μA). Full-scale deflection is the total range of a meter scale. A microampere is one-millionth (0.000001) of an ampere.

Meter deflection is determined by three factors:

1. The number of turns of wire in the coil and the amount of current flowing in the coil.
2. The strength of the magnetic field produced by the permanent magnet affects the positioning of the coil.
3. The tension of the springs and the friction of the bearings determine the sensitivity of the meter movement.

The amount of current flowing through the meter determines its pointer deflection since it is the only variable in the meter movement circuit. The scale of the meter is calibrated (marked) to show the type of reading (volts, ohms, or amperes). The scale in Fig. 6-4 is calibrated to read dc (direct current) volts.

Before you use a meter, check its instruction manual. Each meter is a little different and you should be aware of any important instructions in the instruction manual.

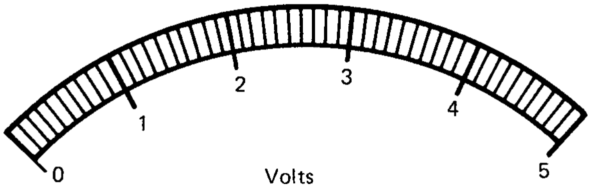

Figure 6-5 Linear scale.

Analog meters

An analog-type meter has a scale that uses a pointer to indicate its reading. The digital meter uses digits similar to a digital watch to indicate the voltage, current, or resistance. There is a place for both types. At this point, it is best to concentrate on the analog type since many of them are still in use and they are still made for all types of applications.

A scale with four separate readings is shown in Fig. 6-5. This shows what is known as a linear scale. A linear scale has marks spaced equally. The full-scale deflection is 5. This could mean 5 amperes, 5 volts, or 5 milliamperes, or 5 of any other value of voltage or current. The information on what is being measured usually appears below the scale. In this case (Fig. 6-5), it is volts.

A nonlinear scale is shown in Fig. 6-6. This particular scale is referred to technically as a square-law scale. The lines in this scale increase in squares. That is, each larger scale marking indicates that the measured value is multiplied by itself or squared. The spacing of nonlinear scales can be easily spotted since they are uneven.

Take a look at a multimeter scale (see Fig. 6-7). A multimeter usually has a number of scales. Each scale on a multimeter is defined individually.

Parallax Error

A parallax error results from the fact that there is a distance between the pointer and the scale behind it. If you look at the pointer from an angle, you will get an incorrect reading. From the side, the reading will be different than from directly in front. It is also possible to have a parallax error if you use both eyes. The best practice is to use one eye. Make sure your view is from directly in front of the pointer. Some meters have a small mirror attached to the scale to reduce parallax error (see Fig. 6-8). You minimize parallax error when you line up the pointer with the reflection in the mirror.

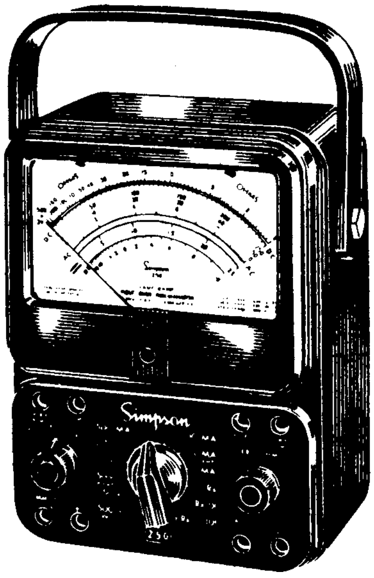
Ammeters

The ammeter is used to measure current. It measures current in microamperes (μA), milliamperes (mA), or amperes. The microampere is very small (0.000001 ampere). The milliampere is also very small (0.001 ampere). In most instances, you will be working with milliamperes and amperes. Microamperes are usually found in circuits that use transistors and other semiconductor devices.

It is important to fit the meter to the job. You select a meter to fit the work you are doing and the range of currents you will be encountering on the job. Keep in mind that the 1-milliampere meter is used for measuring direct current (dc)



Simpson

Figure 6-8 Meter with mirrored scale.

of up to 1 milliampere. Such a meter does not have sufficient sensitivity to measure currents of less than 100 microamperes or 0.1 milliampere.

Keep in mind also that meters are most accurate in the middle 80% of their range. Accuracy falls off in the lowest and highest 10% of the scale.

Extending the range of an ammeter

The 1-milliampere meter movement can be used to measure direct currents that are larger than 1 milliampere. To do this, a resistor is connected in parallel with the meter movement. This resistor is called a shunt. To measure 2 milliamperes, the shunt requires a resistor that can pass 1 milliampere around the meter movement. Thus, 1 milliampere goes through the meter and 1 milliampere through the shunt (see Fig. 6-9).

Various-sized shunts can be connected, by switching, across the meter movement to increase its range from 1 milliampere to 1 ampere, 10 amperes, or even 100 amperes (see Fig. 6-10).

Connecting an ammeter in the circuit

An ammeter is always inserted in a circuit in series with the load.

Clamp-on ammeters

The clamp-on ammeter is shown in Fig. 6-11. It is inserted over a wire carrying alternating current (ac). The magnetic field around the wire induces a small amount of current in the meter. The scale is calibrated to read amperes or volts. Because the wire is run through the large loop extending past the meter movement, it is possible to read ac or current, without removing the insulation from the wire or opening the circuit to install the meter. This meter is very useful

when working with ac motors and compressors. Leads are provided so that the meter can be used as a voltmeter by connecting the leads across whatever voltage source is being checked.

AC ammeters

DC meters can be modified to measure ac current. This is done by connecting a rectifier in series with the meter movement (see Fig. 6-12). A rectifier is a device that changes ac to dc. An ac scale and rectifier are shown in Fig. 6-12. Today, most rectifiers are semiconductor diodes. In the past, vacuum tubes were often used for this purpose.

Voltmeters

The voltmeter measures electrical pressure, or volts. It is nothing more than an ammeter with a resistor added to the meter circuit. The high resistance of the voltmeter makes it possible to place it across a power source (in parallel) (see Fig. 6-13). A number of resistors, called multipliers or scaling resistors, can be switched into a meter circuit to increase its range to make it capable of measuring higher voltages.

A voltmeter circuit is shown in Fig. 6-14. It has 100-volt full-scale deflection. The resistor indicated in the illustration is the meter multiplier. The multiplier's resistance rating is 99.9 kilohms (kΩ). The notation k represents 1000. So the resistance is 99,900 ohms. Meter multipliers are usually precision-type resistors with a ±1% accuracy.

Connecting a voltmeter

A multirange voltmeter uses a switch to select among multipliers. Scales are arranged so that voltage is measured near the center of the meter scale. The center portion of a meter scale is always the most accurate part of the deflection range.

AC Voltmeters

The ac voltmeter is nothing more than the dc meter movement with a diode inserted in series with the meter movement and the multiplier resistor (see Fig. 6-15).

Ohmmeters

It is sometimes necessary to troubleshoot a piece of equipment when no electricity is available. Also, in some cases, the application of power to the circuit may cause some damage. Therefore, you need to be able to troubleshoot the circuit without having to turn on the power and maybe burn up something. This is when an ohmmeter is used to check a circuit because it has its own power source (batteries).

Two types of ohmmeters are made for use in the field: the series ohmmeter, for measuring high resistances and the shunt ohmmeter for measuring low resistances like motor windings and checking for continuity of wiring.

The ohmmeter is most convenient when it comes to measuring resistance in a circuit. It has two probes that can be placed across an unknown resistance. The value of the resistance is displayed on the meter scale (see Fig. 6-16).

The ohmmeter has its own voltage source or batteries. It is never connected to a live circuit (one with the power on). Full-scale deflection on the series ohmmeter indicates 0. This means that when the probes are shorted, the meter pointer goes to the right and indicates no resistance or zero. When the probes are apart with nothing in between, they indicate infinity (∞), which means too much resistance to measure. Note how the scale is nonlinear. The series ohmmeter measures high resistances and the meter scale reads from right to left.

The shunt ohmmeter is designed to measure low resistance, usually below 200 ohms. See the scale in Fig. 6-17. Note, too, that the scale reads from left to right, with the zero being on the left and infinity on the right. An important thing to remember about the shunt ohmmeter is to be sure you turn it off when you have finished using it. It will run down the batteries if left in the on position. The shunt ohmmeter can be identified because it requires an on-off switch. If it is part of a multimeter, then switching it to amperes or volts will turn it off.

Multimeters

Voltmeters, ammeters, and ohmmeters are often combined into a single instrument. Such an instrument is called a multimeter (see Fig. 6-18). Multimeters have a range switch that selects the scale. Another control is a function switch to control its use as an ohmmeter, ammeter, or voltmeter. Multimeters also have a zero adjust knob for the ohmmeter circuits. There are also jacks for the probes. The functions and ranges of a multimeter are determined by selector switches.

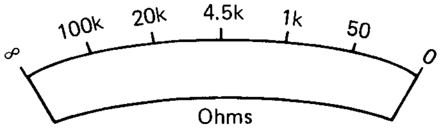

Figure 6-16 Series ohmmeter scale.

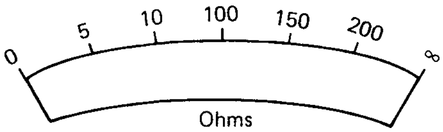

Figure 6-17 Shunt ohmmeter scale.

Meggers

The megger (see Fig. 6-19) is a device that is used for very high resistances. It is used to check for insulation breakdown in motors and compressors. A handcrank is attached to a coil inside the megger. The coil is placed inside a permanent magnet field. A high voltage is produced when the crank is rotated. This high voltage is required to drive small amounts of current through extremely high resistances. The meter movement has to be very sensitive.

The megger can produce a shock if the leads are touched while the handle is turned. Be careful while using a megger. Do not attach the leads to anything that will be easily damaged by high voltage.

Digital Meters

Figure 6-20 shows a digital meter. There are no coils or magnets in digital meters. The meter presents its reading in numbers on a liquid crystal display. This is the type of digital readout found on many instruments, clocks, and watches.

This type of meter can be used to measure ac and dc voltages and currents with great accuracy. In fact, most digital meters can measure voltages to one-hundredth of a volt. They can also measure resistances within one-tenth of an

ohm. They are sometimes more accurate than needed for the job. They are also presently more expensive than the analog type. This, of course, is subject to change, as is the case with all electronics.

Other Instruments

If you are going to be working with heating, air-conditioning, and refrigeration circuits, you will need some other types of instruments to do the job properly and, most of all, efficiently. Electronics is being used today to make the job of recharging refrigeration systems easier and more accurate. A few of these newer electronic devices now available to refrigeration and air-conditioning technicians are described next.

Automatic halogen leak detector

A number of halogen leak detectors are available. However, some of the newer electronic detectors are very sensitive. Figure 6-21 shows an automatic type that has a permanently sealed, miniature battery-operated pump that produces a computer-like beeping signal that changes in both speed and frequency as the leak source (halogen or vapor) is approached. It can detect leaks as small as 0.5 ounce per year. An additional feature is that this instrument is capable of calibrating itself automatically while in use. It operates on two C cells. The detector sensor is not ruined by large doses of refrigerant.

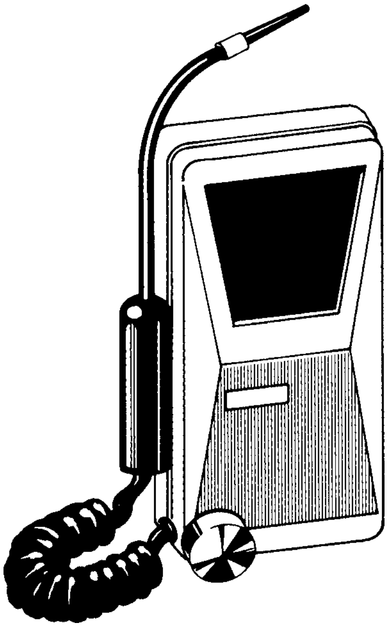

Figure 6-21 Electronic halogen leak detector.

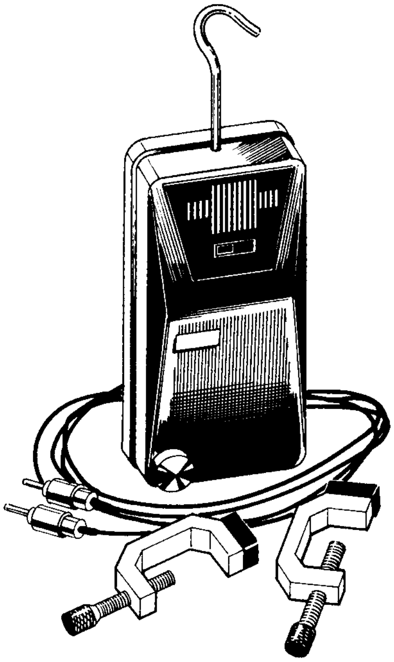

Figure 6-22 Electronic sight glass.

Electronic sight glass

The electronic sight glass emits an audible signal indicating that the refrigeration system being charged is full (see Fig. 6-22). It uses sonar to look inside refrigeration tubing and, in effect, can be considered an "electronic sight glass." It is very handy for capillary systems, which have no sight glass. It is also helpful when charging household and commercial refrigerators and freezers. It is also valuable when checking automobile systems and window air conditioners. This instrument detects flash gas and bubbles in the liquid line. It detects droplets in the suction line and starved evaporators. It can also be used to check for refrigerant flood-back and becomes very useful for multiple evaporator balancing and for adjusting thermostatic expansion valves.

Electronic charging meters

The electronic charging meter is a new tool for dispensing refrigerant into a system in fractions of an ounce without limit from a standard 30-pound cylinder. The charging meter measures the charge dispensed into the system by weight, but it is totally different from a bathroom-type scale. It reads directly like a service station pump. No more wasted time refilling a charged cylinder; no more recorrecting for temperature or type of refrigerant. The refrigerant charge appears on a liquid crystal display, which is easily read even in bright sunlight. There are no controls or adjustments. It is operated at the touch of a

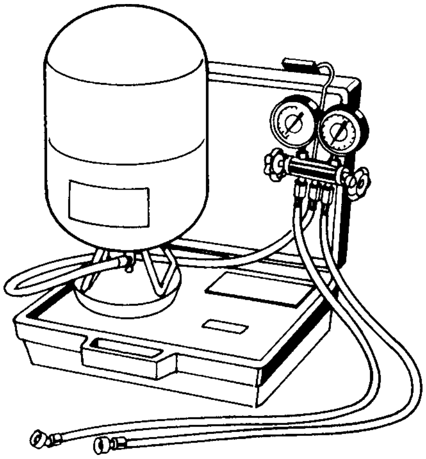

Figure 6-23 Electronic charging meter.

button. It can also be used as a conventional weight scale so that your cylinder can be weighed to ascertain the amount of refrigerant remaining for other jobs. It operates on six C cells (see Fig. 6-23).

Using an Ohmmeter

The basic unit for measuring resistance is the ohm. An ohmmeter is a device used to measure resistance or ohms. It is an ammeter (or milliammeter or microammeter) movement, modified to measure resistance (see Fig. 6-2). The ohmmeter is easily damaged if not properly connected to the circuit under test. Most multimeters are capable of measuring ohms with at least three different ranges: R × 1, R × 10, and R × 10,000. Thus, it is capable of measuring up to 20 million ohms when on the R × 10,000 scale. The meter scale has to be multiplied by the 100 or 10,000 number to obtain the proper value. The R × 1 scale is used to check for shorts and very low resistances, such as in compressor motors, relay contacts, and motor windings and switches.

Warning

An ohmmeter has a battery in it, so it does not use power from the circuit under test. In fact, do not connect it to a live circuit (one with the power on). To do so will result in destruction of the meter movement.

Adjusting the meter

Adjust the ohmmeter so that the meter reads zero before starting to use it to measure resistance. This means that you have to adjust the meter circuit to compensate for the battery voltage changes. Battery voltages decrease with shelf life. It doesn't matter whether or not the battery is used. It will, in time, lose its voltage.

The ohmmeter can be used to test compressor windings for opens or shorts. An open means the meter does not move or reads infinite. A short means the meter reads zero. If you read the same resistance between the three pins of the compressor, it means the motor is three phase and will not run on single-phase power.

One important thing is to obtain an ohmmeter that can measure very low resistances, such as 1 to 10 ohms, with some degree of accuracy. This calls for a digital meter that is somewhat expensive or a multimeter with a shunt ohmmeter capability. The shunt ohmmeter has a scale for low resistance that reads from left to right (see Fig. 6-17). Since, in some instances, a 1-ohm reading can indicate a short, you will probably need a good digital ohmmeter to be sure. The common readings for a compressor are 1, 5, 10, 15, and 20 ohms resistance.

Check Fig. 6-24 for the layout of compressor terminals. Note that the resistance from R to S is 11 ohms. This means that both windings (start and run) are in series and are being added at this point. The reading from R to C is 1 ohm. This means that the run (R) winding has 1 ohm of resistance and is normal. If the reading is less than 1 ohm, it means you have a short in the start winding. The reading from C (common) to S (start winding terminal) is normally 10 ohms. If you obtain infinite for any of these readings, it means the winding is open.

If you read less than 3 ohms for the run winding, it means the winding is shorted. If you get a reading from any one of the three terminals to the case of the compressor, it means the winding is shorted to the case.

Other steps in troubleshooting will be explained in following chapters.

Power Sources

Today's electronics require sources of direct current to operate the semiconductor devices associated with their control circuits. Direct current can be generated with any number of battery types. However, only the more familiar types are presented here. The heating, air-conditioning, and refrigeration technician must learn to choose the right battery for the job.

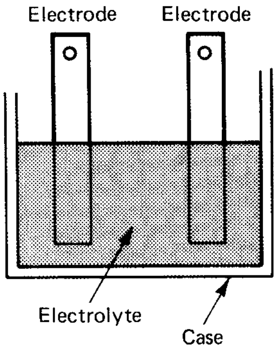

Figure 7-1 Makeup of a cell.

Types of Batteries

A single cell produces a voltage between 1.2 and 2.2 volts (see Fig. 7-1). Two or more cells connected either in series or parallel make a battery. The number of cells in a battery is related to its voltage and current requirements. Cells connected in series produce higher voltages. Cells connected in parallel produce higher current.

Primary cell

A cell is a device that converts chemical energy into electrical energy. The primary cell cannot be recharged. Once the primary cell is discharged, it is thrown away. The chemical action that discharged the primary cell cannot be reversed (see Fig. 7-2).

Secondary cell

The secondary cell can be recharged. The chemical action is reversible. The electrodes and electrolyte that make up the cell can be restored to the same makeup that existed before the discharge (see Fig. 7-3).

The secondary cell, such as the one used in your automobile battery, can be discharged and charged many times. However, the secondary cells that make up such a battery deteriorate. The number of times a secondary cell can be charged and discharged depends on its design, construction, use, and how well it is maintained. During discharge, electrons flow from the − (negative) terminal of the cell or battery to the + (positive) terminal by way of a load (see Fig. 7-4). When the cells are charged, the process is reversed and electrons flow from + to −. This reversal of electron flow causes a chemical action to take place that produces a charged condition when completed.

Dry Cells

The dry cell is a primary cell. It is so named because the electrolyte is not a liquid but a dry, paste-like compound. The many types of dry cells differ mainly in the types of electrodes and electrolyte used. Three types of dry cells in popular use are the carbon-zinc cell, the alkaline cell, and the mercury cell.

The alkaline cell will last longer than the carbon-zinc because it has a lower internal resistance and higher current output. This is due to the potassium hydroxide used as an electrolyte. Potassium hydroxide has a higher conductivity than the sal ammoniac used in the carbon-zinc cell.

The mercury cell has a positive electrode of mercuric oxide. The negative electrode is made of amalgamated zinc. The entire assembly is mounted in a sealed steel container. It is produced in flat and cylindrical shapes. With the use of pressed powder electrodes, the mercury cell can be made very small. This is an advantage for use in hearing aids and other miniature electronic devices, such as watches and timers used with electronic temperature controls (see Fig. 7-5).

Battery Specifications

Batteries are made in many sizes and shapes. Figure 7-6 shows the standard cell sizes. Batteries come in even larger sizes. They may be as small as the 9-volt transistor battery and as large as a submarine battery that measures over 6 feet high.

Batteries are rated according to voltage. They are also rated according to the recommended current range or in terms of ampere-hour capacity.

Higher current demands and longer operating hours than the specifications call for will shorten the life of the battery. Higher current and longer operating hours will reduce the ampere-hour capacity of the battery. The ampere-hour rating is good for a reasonable range on each side of the point used to establish the rating. Alkaline batteries are made for continuous-drain and high-current operation. Their service life may be 10 times greater than a comparable carbon-zinc battery. For light loads, the service life may be only a limited number of times longer. For light loads, then, alkaline batteries may not be practical because of the higher initial costs. Lithium batteries are becoming commonplace for many electronic devices. They are, however, very expensive.

The mercury battery is expensive in comparison to the alkaline and carbon-zinc. The lithium battery or cell is more expensive than alkaline.

Connecting Cells

Cells can be connected in series or parallel to obtain a desired voltage or current rating. When cells are connected in series, the individual voltages add. Four 1.5-volt cells connected in series provide 6 volts. The 9-volt transistor battery is made up of six 1.5-volt cells connected in series.

Cells are connected in series by putting the − terminal to the + terminal of the next cell. They are connected, − to +, − to +, and − to +, for as many cells as you need to produce the voltage needed (see Fig. 7-7).

Cells connected in parallel, as in Fig. 7-8, provide more current. They are connected by placing the − to − terminals together and the + to + terminals together.

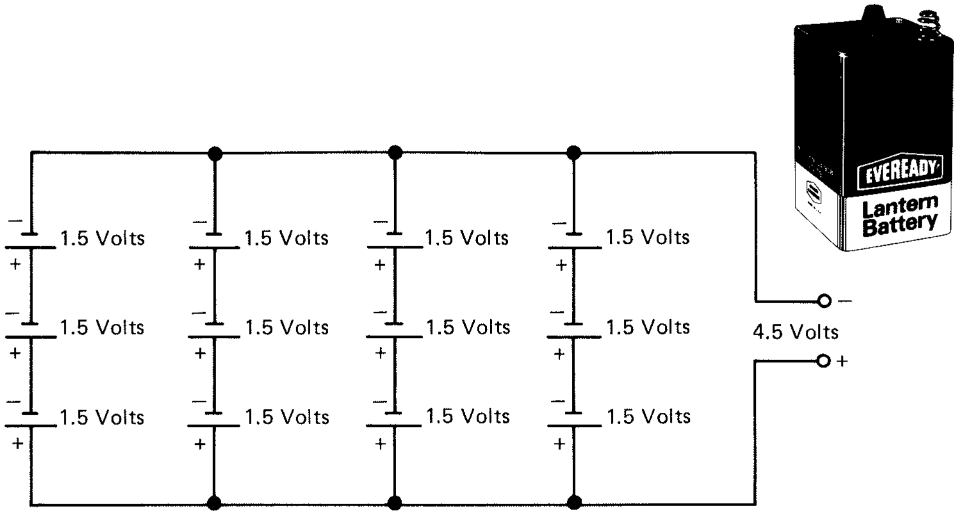

Figure 7-9 Cells in series-parallel.

You obtain the same voltage as from one cell, but the current available from all the cells is added. Do not connect cells with different voltages in parallel. They have a tendency to quickly drain when not in use.

Higher voltage and current batteries such as lantern batteries can be obtained by using cells connected in series-parallel (see Fig. 7-9).

Battery Maintenance

Batteries that have been properly treated will last longer. Two of the most important elements working against batteries are overheating and sulfation. The formation of lead sulfate on the battery plates is normal during the discharge cycle of the lead-acid battery. The lead-acid type is used in the automobile and elsewhere when high currents are needed for an extended period of time. If a battery is allowed to stay in a discharged state for a period of time, the deposit hardens and no longer responds to recharging. The battery is said to be sulfated and cannot be restored to full capacity. Sulfation extended over a long period makes the battery useless.

Other practices that can cause shortened battery life are frequent undercharging, too high a specific gravity, long idle periods in a discharged condition, and defects caused by rapid cycles of high-current discharge and high-current charge.

Charge and discharge currents should not be allowed to overheat the battery. Overheating can cause bending of the battery plates and excessive sulfation. Avoid rapid discharge and keep the proper water level. There is a normal loss of water from the electrolyte, and it is important that the water be replaced. Reasonably pure water should be added when necessary to maintain the proper level and the correct specific gravity range. Overheating tends to encourage faster water evaporation. Whenever the battery is on charge, there is some release of hydrogen and oxygen gas at the electrodes. These gases bubble through the electrolyte to the surface and then through the vent hole in the cell. Indirectly, this also means a loss of water, which must be replaced. However, recent battery technology has improved the battery to such a point that maintenance-free operation is possible for the life of the battery if it is cared for and used for its intended purpose. The sealed battery does not call for the addition of water inasmuch as there is no evaporation.

Nickel-Cadmium Cells

The nickel-cadmium cell comes in a variety of sizes. It can be sealed and made very compact. Figure 7-3 shows the nickel-cadmium construction. It is a high-efficiency cell made so that it can deliver high current at a constant-voltage output. It can be recharged often and still have a long active life. Storage life is not critical and long idle periods, charged or discharged, have no bad effects. It can also be completely discharged without damage.

The voltage output of the nickel-cadmium cell is usually 1.25 volts or a little less than the 1.5 volts of the carbon-zinc cell.

Alkaline Cells

The alkaline cell can be either a primary or secondary cell. It has characteristics comparable to a similar sized nickel-cadmium battery. The number of times that the alkaline battery can be charged and discharged is less. However, the initial cost is much less than a similar sized nickel-cadmium. In some cases, overall economic considerations favor the alkaline type of battery.

The alkaline rechargeable cell should never be discharged below 0.9 volt per cell because the battery life will be shortened. If an alkaline rechargeable cell is completely discharged, it is impossible to recharge it.

When an alkaline secondary battery is discharged for the maximum recommended time and then recharged for the maximum recommended time, it may be cycled as many as 50 times before the battery falls below the rated cutoff voltage at the end of the recommended discharge period. The alkaline cell output voltage is 1.5.

Proper battery care is needed to make sure that electronic and electrical equipment operate properly and when needed. Also, be sure to dispose of the batteries and cells properly according to manufacturer's recommendations.

Alternating Current

Direct current has electricity flowing in one direction. Another type of electricity that you must understand to be able to troubleshoot equipment is alternating current (ac). Most motors and other control devices on refrigerators, air conditioners, and heating units operate on alternating current, or ac as it is most commonly called.

Alternating current is constantly changing in direction and amplitude. In as much as dc was discovered first, the formulas and mathematical equations for working with electricity were developed for dc. However, after the introduction of ac, around the beginning of 1900, a number of changes had to be made in the way electricity was handled mathematically. Alternating current was equated to dc. This was for the sake of making previous formulas work and, at the same time, to produce an understanding of what ac could do when applied to motors and other devices.

Sine Wave

The shape of the ac waveform is that of a sine wave. There are many other types of waveforms, such as the pulse, sawtooth, and square. However, these other waveforms are considered combinations of sine waves of different amplitude, frequency, and phase. Thus, the forms other than sine waves are usually discussed in terms of their sine-wave (sinusoidal) makeup. The basic sine-wave current is a single frequency, and it is this sine wave of single frequency (60 Hz) that we are interested in for our use (see Fig. 7-10).

The sine wave is unique. It can take many shapes. The sine wave has a very special relation to time and motion. Take a close look at Fig. 7-11. Assume that a point at the end of the radial (r) takes one second to travel at a constant speed around the circle, as shown in Fig. 7-11a. How long would it take the point to move 90° or 180°? Since the radial rotates at a constant speed, it would require 0.25 second to rotate 90° (from a horizontal position to a vertical position). At this instant, the point at the end of the radial (on the circumference of the circle) would be at the highest point with relation to the horizontal line. At 180° the point will have been in motion for 0.5 second and will have reached the horizontal line. At 270°, or 0.75 second, the point at the end of the radial line will be at the lowest point with relation to the horizontal reference line. Finally, in 1 second the point at the end of the radial comes back to its starting position, and one cycle (called 1 hertz) has been completed. Keep in mind that time can be stated in degrees of rotation, and the horizontal reference line is time.

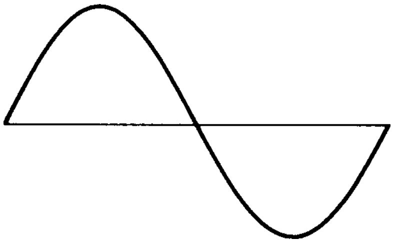

Figure 7-10 Sine wave.

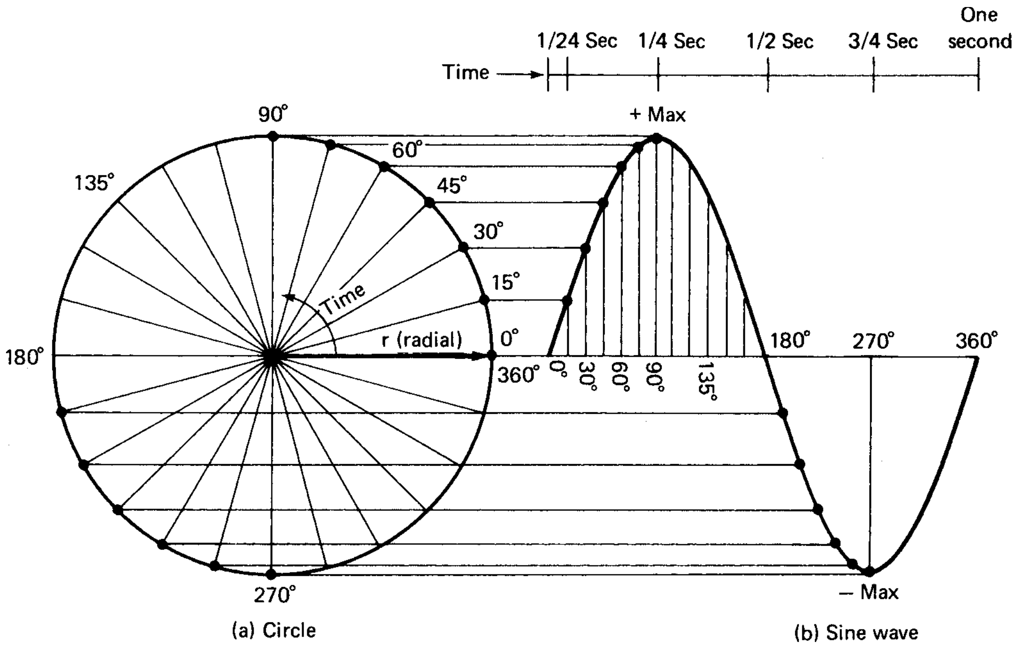

Figure 7-11 Sine wave showing how it is generated by a point rotating in a circle, that point being one coil on a generator rotating in a magnetic field.

Electricity available for home use in the United States is 60 hertz. Thus, the generator must turn 60 times per second to produce 60 hertz. One hertz is one cycle per second. Thus, one sine wave is produced every sixtieth of a second.

Sine-Wave Characteristics

Figure 7-12 shows the output of two cycles of the generator. These two cycles (hertz) of alternating current have a negative alternation and a positive alternation. Each sine wave has a positive alternation that swings above the zero axis and a negative alternation that swings below the zero axis. Unless otherwise marked, it is normal for the alternation that swings above the zero axis to be positive, and the alternation that swings below the zero axis to be negative. Thus, a complete cycle (hertz) is made up of a positive and negative swing.

Two important characteristics of a sine wave are period and frequency. It takes time for the sine wave to go through its positive and negative alternations and return to the origin or zero reference line. The time required for a single cycle (hertz) is called the *period of the sine wave.*

The number of complete cycles (hertz) made each second is called the *frequency of the sine wave.*

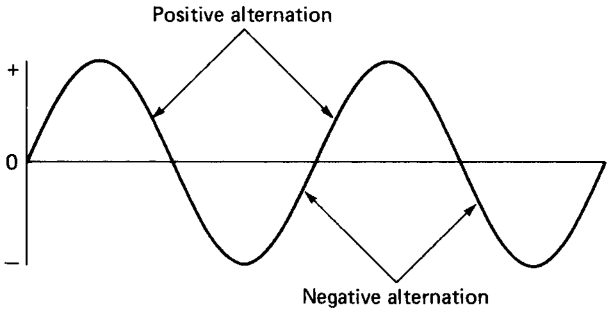

Figure 7-12 Two hertz (cycles) of a sine wave.

Phase

In electrical work it is often necessary to relate one sine wave to another. Two sine waves are shown in Fig. 7-13. This relation between two sine waves, known as phase, can be a comparison between a sine-wave voltage and a sine-wave current. Or it can be a comparison between two sine-wave voltages or between two sine-wave currents. This phase or difference in time is another important characteristic of a sine wave.

Average, RMS, and Peak Values of AC

Three values are used to describe ac:

1. Peak value
2. Average value
3. Root-Mean-Square (rms) value

Peak value. The maximum point on a sine wave is its peak value. Both peaks of a single hertz may be included in a reference. If so, it becomes a peak-to-peak (p-p) value. A peak value of 100 volts means that the peak-to-peak value is 200 volts. This is shown in Fig. 7-14.

Average value. The average of all instantaneous values of a generator is measured at regular intervals (see Fig. 7-11). Instantaneous values are taken

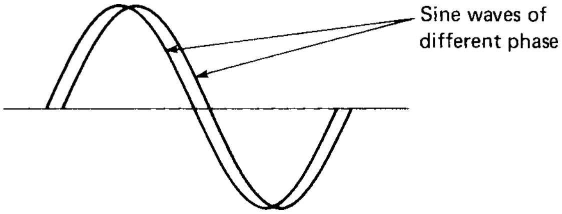

Figure 7-13 Phase difference between two sine waves.

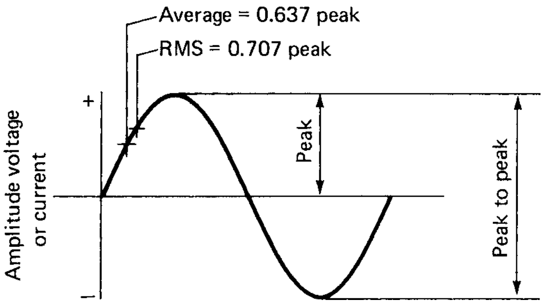

Figure 7-14 Sine-wave values of average, rms, and peak.

at selected points in the generating process. The average of these is the average value of ac current or voltage.

The half-hertz is used to compute this value. This is because the average value for full-hertz (cycles) would be zero. The zero average would come from the fact that half the values are positive and half are negative.

To compute the average value, sine-wave values for angles between 0° and 180° are added. The total is then divided by the number of values taken. As seen in Fig. 7-14, the average is equal to 0.637 of the peak. For example, suppose the peak voltage of a sine wave is 100 volts. The average voltage is 63.7 volts ($100 \times 0.637 = 63.7$).

Root-Mean-Square (RMS) value. A value equivalent to effective voltage or effective current is known as the Root-Mean-Square (rms) value. It is calculated mathematically. Imagine one-quarter of the sine wave broken down into 90 parts. This is one part for each degree of a hertz. The value of each degree is squared, or multiplied by itself. All the squared values are added together. Then the total is divided by 90. This produces the average of the squares. A square root is then figured for this average. This is the rms value.

Polyphase Alternating Current

The armature coils of a single-phase alternator (ac generator) are connected in series. At any given instant, the voltage induced is the sum of the voltages induced separately in each coil. If the coils were not connected in series, and if their connections were brought out separately, the voltages induced would vary in phase with relation to each other. This is because each coil is in a different position with respect to the flux lines of the field (see Fig. 7-15).

When windings, identical in size and of the proper phase relationships, are added to the single-phase alternator, a voltage output is obtained from each coil added. These voltages differ in phase but not in amplitude. The output from such a generator is known as a polyphase-output system. Systems of this type are generally two- or three-phase systems with the three-phase the most widely used. In fact, all the power generated by the large utilities is three-phase. Large air-conditioning and refrigeration installations use three-phase power.

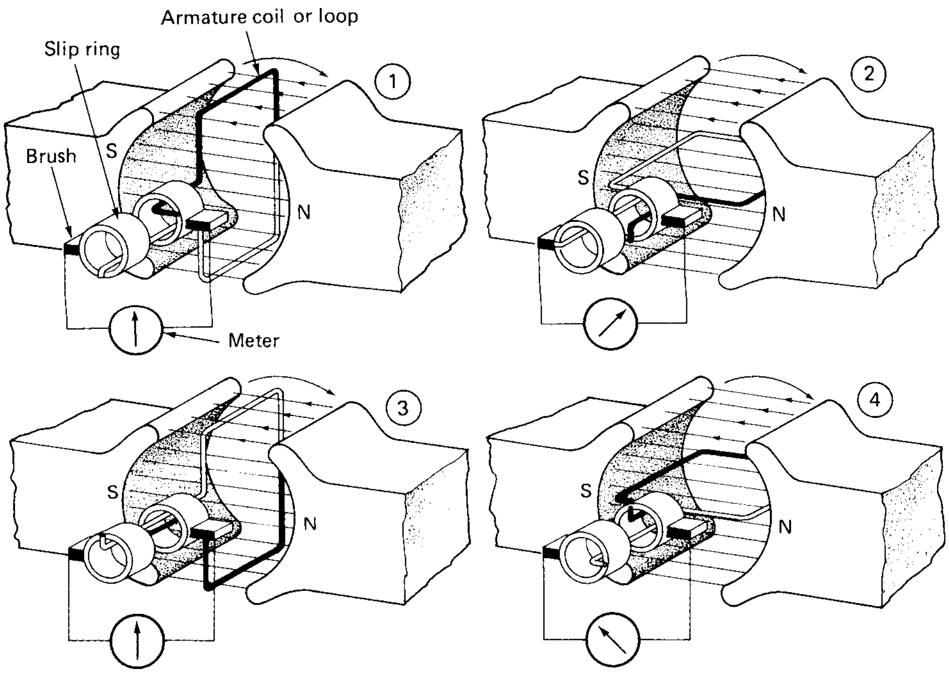

Figure 7-15 Generation of an ac voltage.

Three phase

A three-phase system is one in which the voltages have equal magnitudes and are displaced 120 electrical degrees from each other (see Fig. 7-16). The three windings are placed on the armature 120° apart (Fig. 7-17). As the armature is rotated, the outputs of the three windings are equal but out of phase by 120° (see Fig. 7-18).

Three-phase connections

Three-phase (3ϕ) windings are usually connected in either a delta or wye configuration. Each of these connections has definite electrical characteristics from which the designations delta and wye are derived (see Figs. 7-19 and 7-20).

Electrical Properties of Delta and Wye

Delta connection (Δ)

In a balanced circuit, when the generators are connected in delta, the voltage between any two lines is equal to that of a single phase. The line voltage and the voltage across any winding are in phase, but the line current is 30° or 150° out of phase with the current in any of the other windings (see Fig. 7-21). In the delta-connected generator, the line current from any one of the windings is found by multiplying the phase current by the square root of 3, which is 1.73.

Wye connection (Y)

In the wye connection, the current in the line is in phase with the current in the winding. The voltage between any two lines is not equal to the voltage of a single phase, but is equal to the vector sum of the two windings between the lines. The current in line A of Fig. 7-22 is the current flowing through the winding L_1; that in line B is the current flowing through the winding L_2; and the current flowing in line C is that of the winding L_3. Therefore, the current in any line is in phase with the current in the winding that it feeds. Since the line voltage is the vector sum of the voltages across any two coils, the line voltage E_L and the voltage across the winding E_ϕ are 30° out of phase. The line voltage may be found by multiplying the voltage of any winding E_ϕ by 1.73.

Delta and wye summarized

The properties of delta connections may be summarized as follows: The three windings of the delta connection form a *closed loop*. The sum of the three equal voltages, which are 120° out of phase, is zero. Thus, the circulating current in the closed loop formed by the windings is zero. The magnitude of any line current is equal to the square root of 3 (1.73) times the magnitude of any phase current.

Properties of the wye connection do not form a closed loop. The magnitude of the voltage between any two lines equals the magnitude of any phase voltage times the square root of 3, that is,

$$E_L = \sqrt{3} \times E_\phi$$

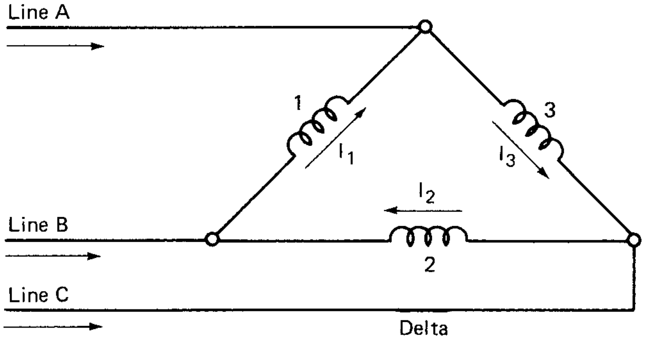

Figure 7-21 Delta-connected currents.

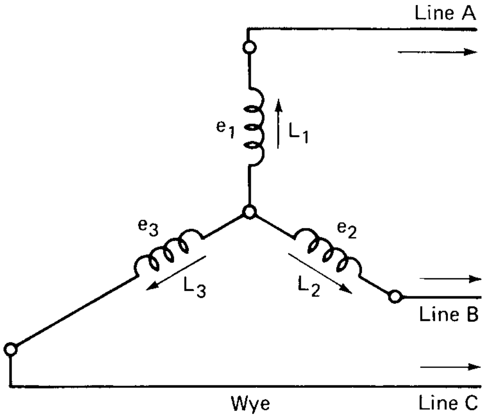

Figure 7-22 Wye-connected currents.

The current in any winding equals the current in the line.

Applications of three-phase power to motors will be discussed in more detail in Chapter 12. Connections of power supply transformers to furnish three-phase power are discussed in Chapter 8. As previously mentioned, three-phase power is used in commercial and industrial air-conditioning and refrigeration equipment and in some heating units.

- Know what self-inductance is.
- Know what mutual inductance is.
- Know the effects of a counter emf.

The magnetic field that surrounds a coil produces an opposition to a change in current in that coil. This opposition is not the same as resistance is to direct current. A coil has an opposition to alternating current because the ac is constantly changing its direction and amplitude. The opposition that a coil presents to ac is called *inductive reactance*. Inductive reactance must be taken into consideration when a motor or transformer is in an electrical circuit. It is also very important in the design of start circuits for compressors. Coils are used for filter circuits in electronic power supplies. There are many uses for inductors and for inductive reactance.

Coils are also referred to as inductors and chokes. The inductor is used in a circuit to retard the flow of ac and to allow dc to pass. Inductors are diagrammed in circuits through the use of the symbol shown in Fig. 8-1.

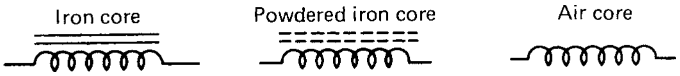

Figure 8-1 Symbols for inductors.

The property of a coil that opposes any change in circuit current is known as *inductance*. The symbol for inductance is L. Inductance is measured in *henrys*, abbreviated H. Since the henry may be too big for most electronic circuits, it is broken down further into millihenrys (mH) and microhenrys (μH). Motors and transformers have inductance and therefore inductive reactance when ac is applied.

Changing Inductance

The inductance of a coil depends on four factors:

1. *Number of turns:* The more turns a coil has, the greater its inductance.
2. *Diameter of the coil:* The wider the cross-section of a coil, the higher the inductance is.
3. *Permeability of the core:* The more permeable the core, the better are the magnetic properties and the higher the inductance.
4. *Length of the coil:* The shorter the coil, the higher the inductance is. Coil length and inductance are said to be inversely proportional.

Figure 8-2 shows how the inductance of a coil can be increased by adding turns, by adding a core, and by the way layers are wound.

Self-Inductance

The ability of a conductor to induce voltage in itself when the current changes is called *self-inductance*. This ability can be valuable. Self-inductance is also measured in henrys.

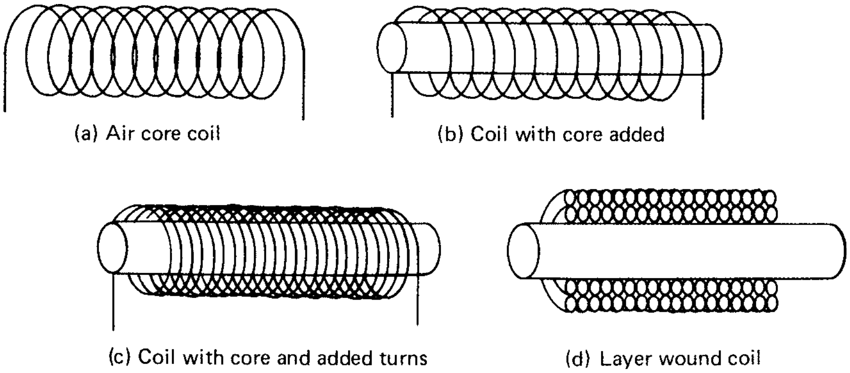

Figure 8-2 Changing the inductance of a coil.

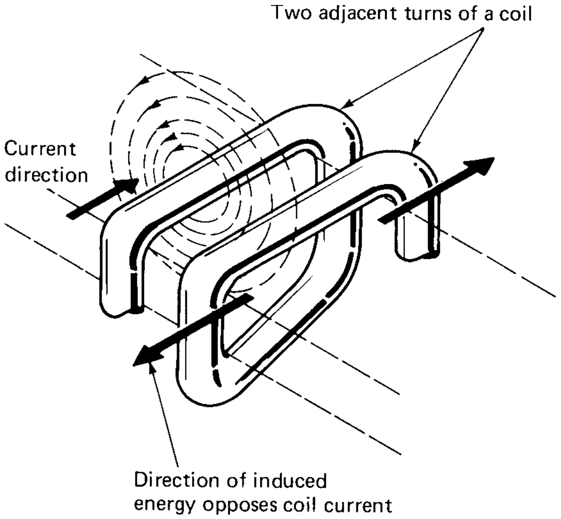

Two adjacent turns of a coil
Current direction
Direction of induced energy opposes coil current

Figure 8-3 Self-inductance created by placing coils adjacent to one another. Note how the magnetic field cuts adjacent turns.

Self-inductance is produced by varying current in a coil. The current produces a magnetic field around each turn of the coil. The field around each turn then cuts across other turns (see Fig. 8-3). A changing current in the turns of a coil produces a changing magnetic field. Self-induced voltage occurs when the changing magnetic field cuts the turns of the coil and induces a voltage across the coil.

The amount of induced voltage depends on the rate of change of current. The faster the current changes, per unit of time, the higher is the self-induced voltage. Take a look at Fig. 8-4 and see how two points on a sine wave demonstrate the difference in ratio of current change.

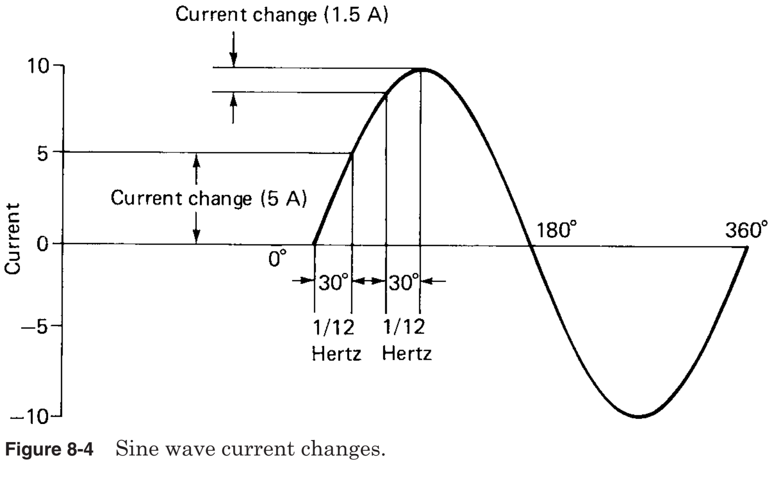

Figure 8-4 Sine wave current changes.

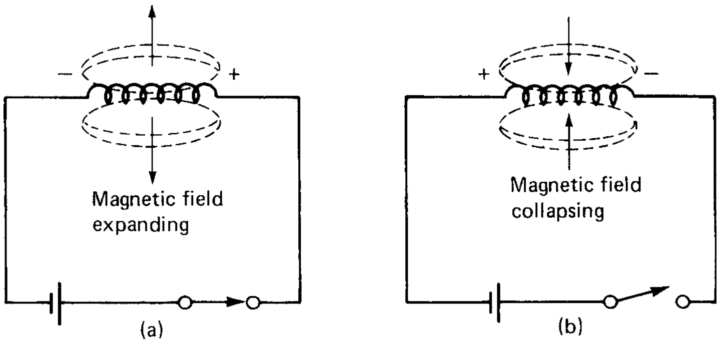

Figure 8-5 Counter emf.

The self-induced voltage is in the opposite direction to the magnetic field that produced it. This voltage is called a *counter emf (cemf).*

The cemf is shown in Fig. 8-5a. A current increases rapidly from zero to maximum. This causes the magnetic field to expand. The expanding magnetic field produces cemf that moves away from the input current. The cemf cuts across windings in the path of the current. The increasing cemf opposes the increase in current in the circuit.

Now take a look at Fig. 8-5b. The circuit is broken by a switch. When this happens, the magnetic field collapses. At this time, the current in the circuit changes from its maximum value to zero. The collapsing field induces voltage across the coil. The induced voltage opposes the decrease in current. The current is thus prevented from dropping quickly to zero. The gradual decline in current level due to self-inductance is shown in Fig. 8-6.

In an inductor, the lag created between current and voltage is 90°. Thus, in a purely inductive circuit the voltage will lead the current as shown in Fig. 8-7. The coil opposes—increases or decreases—in current. This is valuable in filter circuits. In such a situation, inductance protects devices against sudden increases or drops in electrical current. An inductor, then, creates a lag or delay between the voltage and current. To show this, consider a purely inductive ac circuit, one with an inductor only. In such a circuit, current lags voltage by 90°. When this condition exists, the voltage and current are said to be out of phase.

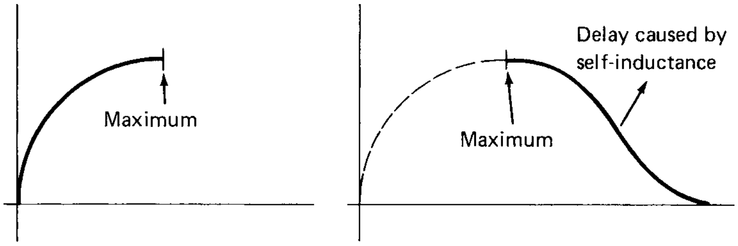

Figure 8-6 Time lag in an inductor.

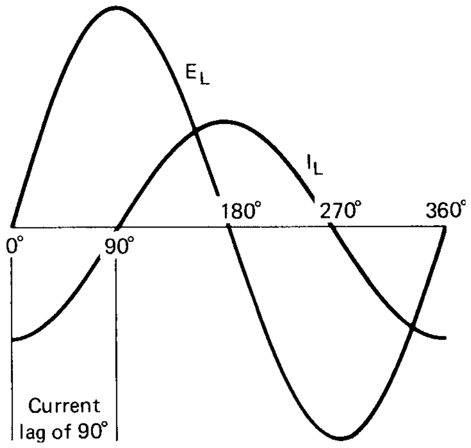

Figure 8-7 Voltage leads current by 90°.

Mutual Inductance

A condition in which two circuits share the energy of one circuit is called *mutual inductance*. The energy in one circuit is transferred to the other circuit. The two coils have a mutual inductance of 1 henry if a current change of 1 ampere per second in one coil induces 1 volt in the other coil. Magnetic lines of flux cause a coupling between the circuits.

A mutual inductance circuit is shown in Fig. 8-8. The symbol at the left of this diagram indicates an ac source. Coil L_2 is placed near coil L_1. The magnetic flux surrounds the wires making up L_2. This induces a voltage across coil L_2.

As soon as the magnetic field is built up by the ac, the current flow is reversed. The magnetic field begins to collapse. As the magnetic field collapses, it also induces a voltage in L_2. This induced voltage moves in the opposite direction from when it built up to a maximum.

L_2 is part of a circuit with an electrical load. Current flows through the load. Current in the circuit of L_2 also produces a magnetic field. This is in opposition to the field that induced the current in L_2. If a heavier load is placed in the circuit with L_2, a greater opposition is presented to the induced current. Thus, L_1 must draw more current for its source. It needs this additional current to make the increased opposition provided by the increased load across L_2. There is no load on L_1 until L_2 has a load connected across its terminals. This is the basis of how the transformer operates.

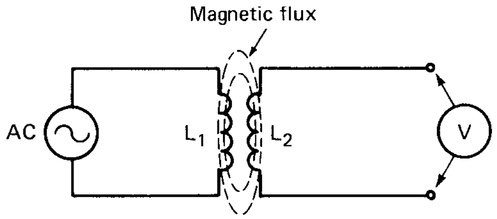

Figure 8-8 Mutual inductance.

Inductive Reactance

As we have already seen, an inductor reacts to a changing magnetic field produced by a changing current. When alternating current passes through an inductor, a phase shift occurs. Voltage and current that were in phase become out of phase. Phase shifting occurs repeatedly. This results from the opposition to ac by an inductor. This opposition is referred to as reactance. X is the symbol for reactance. Since the opposition takes place in an inductor, it is called *inductive reactance* and is represented by X_L. It is an opposition so it is measured in ohms.

This type of opposition, or reactance, does not affect dc. The only opposition to dc comes from the resistance of the conductor (wire) that makes up the coil.

Measuring X_L

A number of factors determine X_L. One is the frequency of the alternating current. Another is the size of the inductor. The formula used to calculate X_L is

$$X_L = 2\pi f L$$

Inductive reactance is not measured by an ohmmeter, but is arrived at by mathematical calculation. In this equation, f is for frequency, measured in hertz. L is inductance, measured in henrys. π is a standard mathematical term with a value of 3.14. So 2π equals 6.28. Thus, if either frequency (f) or inductance (L) is increased, inductive reactance (X_L) also increases. If either of these factors is reduced, inductive reactance also becomes smaller.

Power in an Inductive Circuit

In an inductive circuit, power is absorbed by the coil during the time that current is increasing. This power is stored in the generated magnetic field. However, all the power absorbed during the current rise is returned to the source by the collapse of the magnetic field. This means that the average power consumed by the inductance is zero. Whatever it takes, it puts back.

The current, voltage, and power in a purely inductive circuit are shown in Fig. 8-9. During the first quarter-hertz of the sine wave (0° to 90°), the current is rising and power is being supplied from the source. The instantaneous power, which is represented by the shaded areas in the illustration, is the product of the instantaneous voltage and instantaneous current.

The areas on the positive side of the zero axis represent power being transferred to a magnetic field from the electrical source. The areas on the negative side of the zero axis represent power being returned to the circuit. This occurs when the current decreases from its peak value toward zero on the 90° to 180° part of the hertz or cycle. The magnetic field then decreases in intensity and delivers power back to the source. There is now a transfer of magnetic energy back to electrical energy (the magnetic field is said to be collapsing). The source is now receiving power from the collapsing magnetic field. Since the power supplied and the power taken back are identical, the average power is zero.

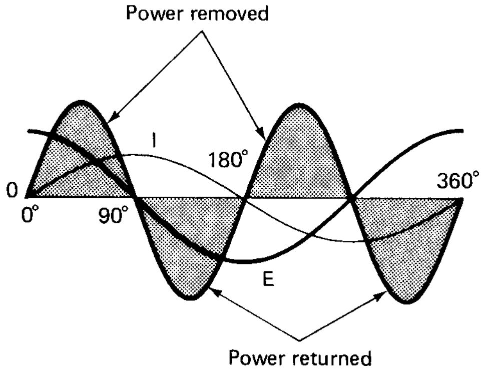

Figure 8-9 Power in an inductive circuit.

Before you think an electric motor or fluorescent lamp can be operated without consuming energy, you have to bear in mind that there is no pure inductor. There is always some resistance associated with any practical coil, because the conductors (wires) that make up the turns of the windings have resistance. It is this resistance that consumes power.

Uses for Inductive Reactance

Inductive reactance can be very useful. It holds back the current in an ac motor and makes sure it does not draw too much from the line. A transformer is able to sit on the line without having a load on it due to inductive reactance. Filters also use the properties of coils to aid in the selection of the proper frequencies for cross-over networks in stereo speaker systems and for making sure the right station is tuned in on the television and the radio. In refrigeration, air-conditioning, and heating work, you will be primarily concerned with what inductance can do when it is present in a solenoid, relay, motor, or transformer.

Transformers

So far you have looked at the terms inductance, mutual inductance, and self-inductance. Inductance is the opposition to current flow presented by a coil or inductor. A changing magnetic field produced by a changing electrical current can also be used in making what is referred to as a transformer. When the magnetic field produced by one coil is allowed to cut the windings of another coil nearby, it produces the transformer effect, or it introduces a voltage in the second nearby winding. This voltage and the amount of current available can be controlled by utilizing knowledge gleaned from years of experience and from some simple mathematical formulas.

Mutual inductance in a transformer

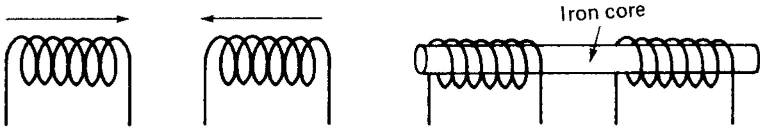
Two coils placed close to one another will allow the magnetic flux from each coil to be linked to the other. This is the basis of mutual inductance. A change in the current in one coil produces a magnetic field that cuts the turns of the second coil and induces a voltage. A mutual inductance thus exists between the two coils. This mutual linkage causes the effective inductance of each coil to be different from that of the self-inductance. The unit of mutual inductance is also the henry and is designated by the symbol L_M. A mutual inductance of 1 henry exists when a current change of 1 ampere per second in the first coil (primary) induces 1 volt into the second coil (secondary).

The mutual inductance between two coils depends on the closeness of the two coils, the way in which the coils are wound, and the reluctance of the mutual magnetic path. Three ways to increase the mutual inductance of two coils are shown in Fig. 8-10. Two coils that are coupled by a magnetic core have a higher mutual inductance. When the magnetic core makes a complete loop, as seen in Fig. 8-8, nearly all the magnetic flux of one coil is coupled to the other coil, and the mutual inductance is maximum. The amount of flux linkage between two coils is called the *coefficient of coupling*.

Iron-core transformer

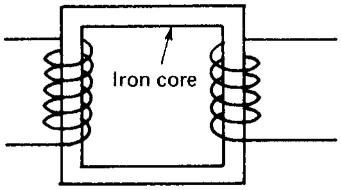
A device that transfers electrical power from one coil to another is called a *transformer*. Transformers may also change the value of voltage during the transfer. A transformer functions with no physical connection between the source and the receiving conductors. The principle used is mutual inductance.

Current flows into a transformer primary coil. This current creates a magnetic flux. The magnetic flux, in effect, couples the primary coil with the secondary coil. Voltage is induced in the secondary coil. The induced voltage may be varied by increasing or decreasing the magnetic field. The result of a transformer's operation is the induction of emf in the secondary coil. This is transferred to a conductor connected to the secondary coil.



(a) Move the coils closer together.

(b) Use a magnetic core to couple the coils.



(c) Use a closed magnetic path.

Figure 8-10 Three ways to increase mutual inductance.

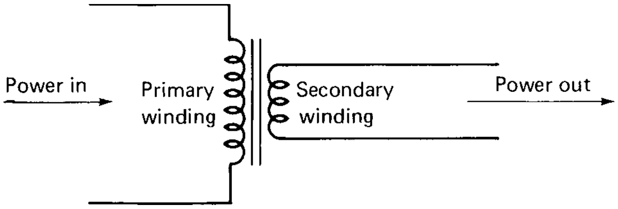


Figure 8-11 Step-down transformer.

Iron-core transformers use the mutual inductance principle to transform power between primary and secondary windings. An iron core provides a low reluctance path for the magnetic flux, and the coefficient of coupling between primary and secondary is so near unity (1) that it is considered as such in the designing of the transformer. The transformer is a highly efficient device since it has no moving parts; only current variations cause the transformer action to occur.

Changing magnetic fields are generated by ac so a transformer can be used to transfer ac power from primary to secondary (see Fig. 8-11). The two windings of a transformer are not connected, and the only means of transferring energy from the primary winding to the secondary winding is by way of the mutual coupling of a magnetic field.

Construction

Every transformer is built with at least two coils. One is a primary coil and the other is a secondary coil. The primary coil is called the *input*. This means that it brings electrical power into the transformer. The secondary coil is the *output*. It carries electrical power out of the transformer.

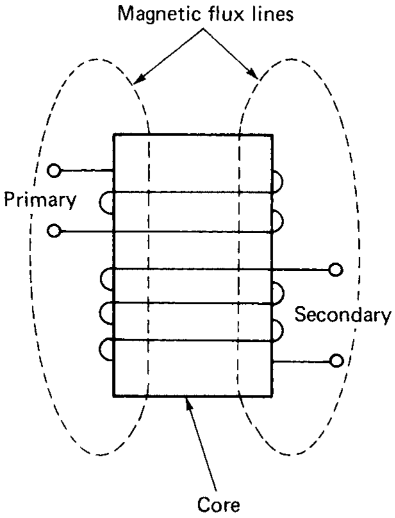
The transformer's iron core aids in the concentration of the magnetic field. The size of the core is the major determiner of the amount of current that can be drawn from the transformer, along with the size of the wire to handle the current. Wire size and core size determine the weight and physical size of the transformer. The higher the wattage rating or power output of the transformer, the larger the transformer is.

Refrigeration, heating, and air-conditioning circuits utilize a 24-volt transformer in most of the control circuits. This transformer steps down 120 volts to 24 volts. The National Electrical Code classifies this low-voltage control circuit as class 2.

Types of iron-core transformers

There are three basic types of iron-core transformers:

1. *Open-core:* This type is used in power transformers (see Fig. 8-12).
2. *Closed-core:* This type is more efficient than the open-core type. Figure 8-13 shows that the flux path is contained within the core. This increases the strength of the magnetic field. The transfer of energy is improved.



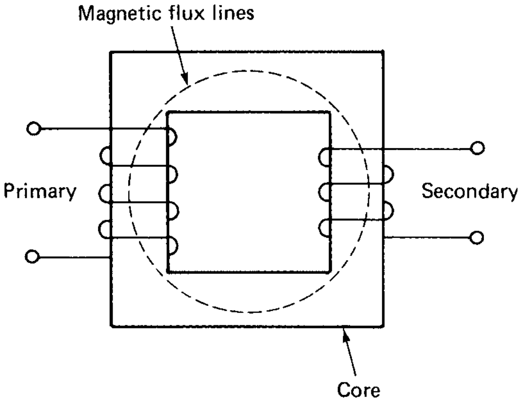
Magnetic flux lines
Primary
Secondary
Core

Figure 8-12 Open-core transformer.

3. *Shell-core:* This is the most efficient type of transformer. Figure 8-14 shows the design characteristics. Note how the magnetic flux pattern containment improves the efficiency.

Voltage Transfer

The transformer is a power transfer device. Power that goes into the primary is transferred to the secondary. Also, power required by the secondary is reflected back as a power requirement to the primary. The rule is simple: Power in is equal to power out, less any losses.



Magnetic flux lines
Primary
Secondary
Core

Figure 8-13 Closed-core transformer.

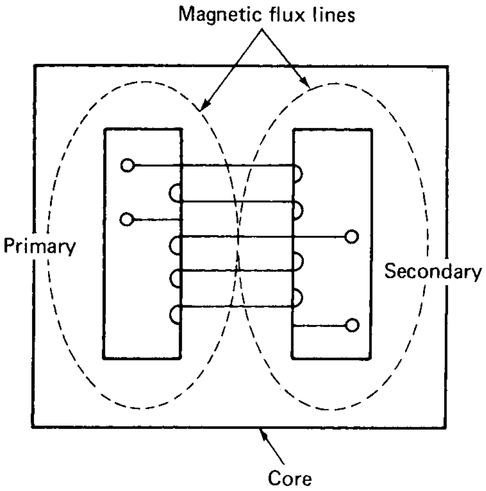


Figure 8-14 Shell-core transformer.

Thus, if no load is connected to the secondary coil, the current flowing into the primary is virtually zero. The only current required is the amount necessary to support part of the losses. This is almost zero. Current flows in the primary only when the secondary is connected and there is output current to a load.

Step up, step down

Transformers are either step up or step down. If input voltage is higher than output voltage, the device is known as a step-down transformer. In the step-up transformer, the output voltage is higher than the input.

Turns ratio

The input and output voltage relationship of a transformer depends on the turns ratio. The turns ratio describes the relationship of the windings of the primary and secondary coils. The first number in a given ratio is for the secondary. The second number is for the primary.

To find the turns ratio of a transformer, divide the number of turns of the secondary by the number of turns of the primary. For example, if there are 1000 turns in the secondary and 100 turns in the primary, divide 1000 by 100. This produces a ratio of 10 to 1. This is written as 10:1. The formula used to find the turns ratio is

$$\text{Turns ratio} = \frac{1000}{100} = \frac{10}{1} \quad \text{or} \quad 10{:}1$$

If the transformer has a turns ratio of 10:1, the voltage ratio is 10:1. If 100 volts is applied to a 10:1 transformer primary, the secondary would have an output of 1000 volts.

There are other types of transformers that you should be familiar with. This will make it possible for you to make some substitutions, if needed, and give you some idea as to which transformers cannot be used for control circuits such as you will experience in refrigeration, air-conditioning, and heating equipment.

Power Transformers

Power transformers use multiple secondary coils. These can deliver a number of secondary voltages. Examples of the power transformer are shown in Figs. 8-15 and 8-16. These transformers are used for a wide variety of jobs. They may provide power for factories. They may power broadcast stations. Or they may be built into special equipment such as the power supply of a transmitter, television set, or electronics equipment. As you can see from the schematic, there are both step-up and step-down transformers. They have one primary coil with various ratios of secondary coils wound on top of the primary. They can be easily identified since they will have more than the usual four leads coming out of the case.

Audio Frequency and Radio Frequency Transformers

Audio transformers change voltages for use in the audio range of frequencies. Audio frequencies are from 16 to 16,000 hertz. An audio transformer is shown in Fig. 8-17.

To deliver voltage at higher frequencies, no core is used. This is because an iron core consumes too much power above 16,000 hertz. Air-core transformers, therefore, are usually used in radio frequency circuits and are called

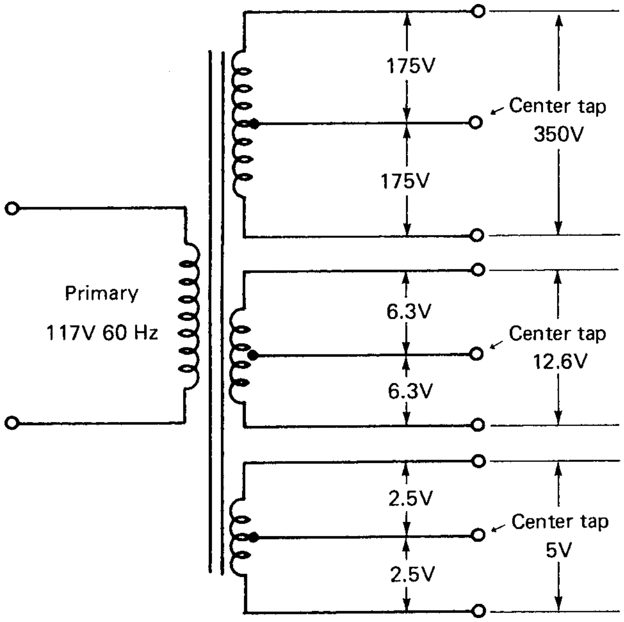

Figure 8-15 Schematic of a power transformer.

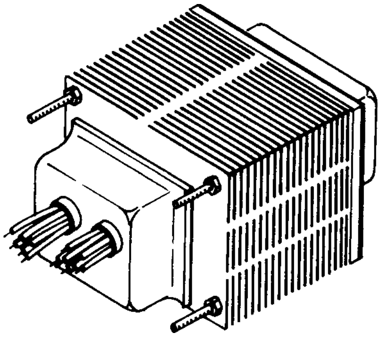

Figure 8-16 Power transformer used in electronic devices.

rf transformers. Electronics equipment have special miniature transformers to do certain jobs.

These are not usable on line frequencies such as 60 hertz for control circuits in heating and air-conditioning equipment.

Autotransformers

Autotransformers have only one coil. Input and output come from a single coil. The amount of voltage output is determined by the position of the secondary tap (connection point). Placement of the secondary tap changes the turns ratio.

When an autotransformer is used to step up the voltage, part of the single winding is used as the primary. The entire winding acts as the secondary (see Fig. 8-18). Power is transferred from the primary to the secondary by the changing magnetic field that is concentrated by the core material. The turns ratio determines the voltage output.

An autotransformer does not provide isolation, as do the regular primary coil and secondary coil types that are not physically connected. The autotransformer will not serve to remove the ground found in most home and industrial wiring systems because the primary and secondary use the same turns. This type of

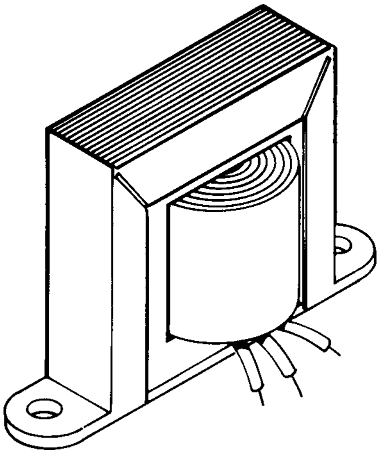

Figure 8-17 Audio-type transformer.

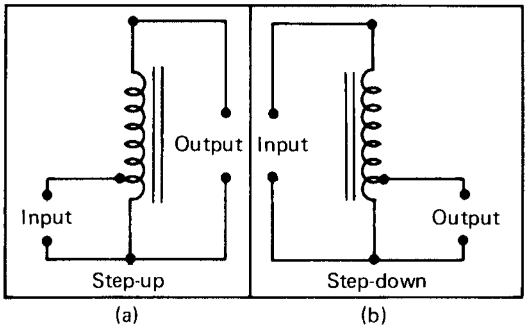

Figure 8-18 Autotransformer.

unit can be made into a variable transformer. A variable transformer can produce differing output voltages. A slider arm is placed over the windings. The slider makes contact with points where the insulation on the wire has been removed. This type of variable transformer is called a *variac*.

Transformer Losses

There are transformer losses, even though most of them can be minimized. Nevertheless, there are some that must be taken into consideration when designing a transformer for maximum efficiency. Three types of losses take power away from the output in a transformer and must be dealt with when the transformer is designed.

1. *Copper losses:* These are due to the resistance of the wire in the primary and secondary coils. Large size wire helps to minimize these losses.
2. *Hysteresis losses:* These are due to the properties of the iron core. Iron is slow to change polarity. The delay is known as hysteresis, or slowness to change properties (see Fig. 8-19). The magnetic domains (or molecules) of the iron core are facing in one direction. The domains (or molecules) are mixed in the middle illustration. This is in response to a change in magnetic fields. In the last illustration, the domains (or molecules) are lined up in the opposite direction. This happens when the magnetizing force of ac is at its peak. Hysteresis losses in

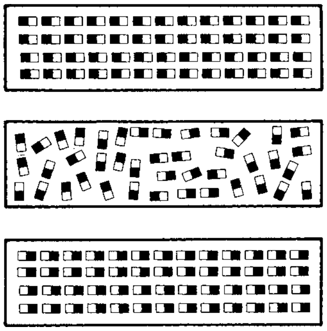

Figure 8-19 Hysteresis losses due to alignment of domains (or molecules) in an iron core.

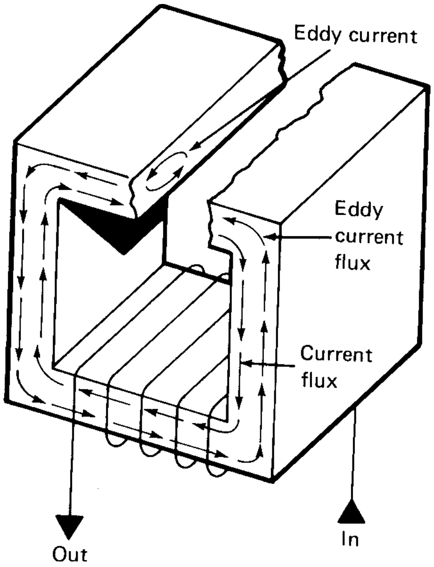

Figure 8-20 Eddy currents in a transformer core.

transformers are minimized by using silicon steel for the iron core. This type of metal offers very little opposition to changing polarity.

3. *Eddy currents:* These are very small but create losses in the transformer core. They are small currents created in the core when the magnetic fields change (see Fig. 8-20). Eddy currents generate heat. They flow in a direction opposite to the current that induced them. The effect is to resist the flow of current in the core. Eddy currents can be minimized by using laminations. Laminating is the building of an object through the use of several layers of material. When this method is used, each lamination is varnished. Varnishing insulates the layers from each other. This increases resistance to eddy currents. Figure 8-21 shows how a solid core has high eddy current losses and a laminated core practically eliminates current losses.

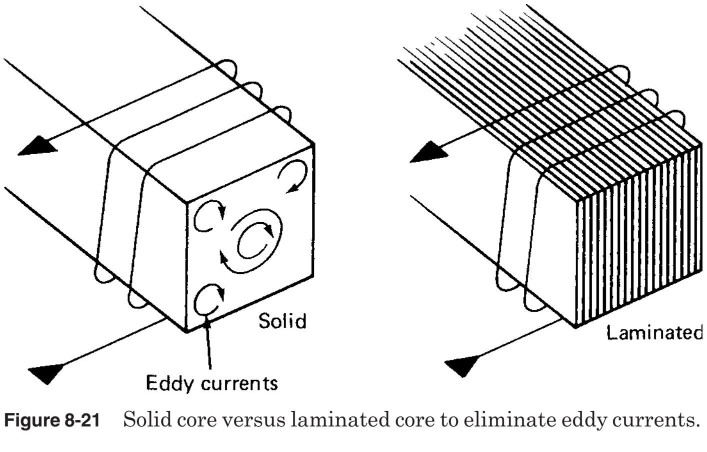

Figure 8-21 Solid core versus laminated core to eliminate eddy currents.

Inductive Circuits

Inductors have a definite effect on the operation of the circuits in which they are located. Inductors, remember, can be a coil of wire, the windings of an electric motor, or the ballast from a fluorescent lamp. Relay coils and solenoid coils have inductance, as dc transformers. These devices have definite functions in circuits used in heating, air conditioning, and refrigeration. Their reaction to one another and to resistors in the same circuit is very important. They can cause some interesting problems that need to be understood for you to be able to properly and safely troubleshoot them.

The response of an inductor to dc is quite different from its response to ac. In ac circuits, the inductor responds to the changing current by producing a self-induced voltage that tends to prevent any change in the amplitude of the current. In a dc circuit, there is no inductive opposition to the current because the current is unchanging. Therefore, in a dc circuit the amount of current depends entirely on the total resistance in the circuit. This includes resistors, wiring, and coil winding resistance.

The dc current in an inductor is determined by the dc resistance. Assume that an ac and a dc voltage of the same value are applied to identical inductors. Will there be a difference in the values of the dc and ac currents? The current is higher for the dc circuit because it is determined by the resistance of the coil windings. This value is usually very small. For the ac circuit, the current is determined by the impedance (impedance is the combination of resistance and reactance). Furthermore, as the frequency of the alternating current is increased, the coil current decreases because of the increasing reactance of the inductor.

Figure 8-22 shows how the coil reacts with dc applied. When the switch in the circuit is closed, a certain time is required for the magnetic field to expand to the maximum value determined by the current in the circuit. During this interval, the magnetic flux is changing, and the counter emf prevents the current from rising immediately to the final value determined by the resistance. The graph in Fig. 8-22b shows what happens. At time zero, the switch is closed and the current begins to increase. When the switch is first closed, the rate of flux change is maximum, and, as shown by the voltage curve E_L, a maximum voltage appears across the coil.

However as the current I rises, the rate of flux change slows down. The voltage across the coil decreases as the current rises.

This process continues until the current builds up to the maximum value determined by the dc resistance of the circuit. At this point, the magnetic field that has built up around the coil becomes stationary and unchanging, and the voltage drop across the coil, assuming the coil has no resistance, falls to zero. This is the steady state condition. As long as the switch remains closed, this amount of current will be present in the circuit. The initial buildup period is brief, and in most dc circuits the time required to reach a steady state is very short. The delay can be witnessed in some circuits where it takes some time for the current to build up to its maximum value.

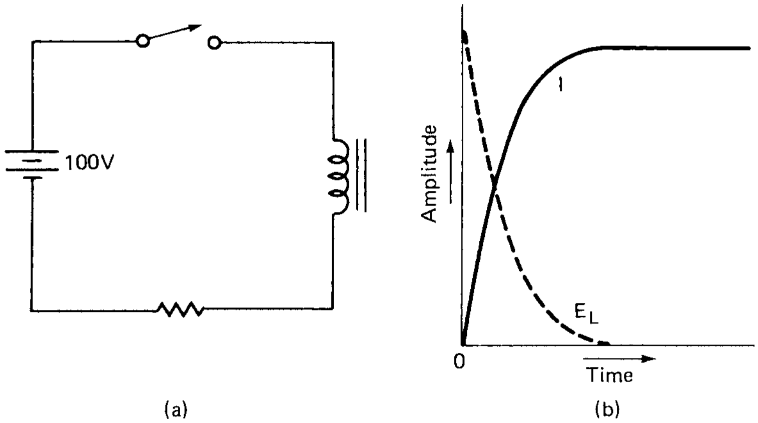

Figure 8-22 Current rises from zero to maximum. Maximum is determined by resistance in the circuit. The voltage across the coil drops from the applied voltage to zero.

Keep in mind that the maximum amount of current is dumped back into the circuit when the switch is opened. This collapsing magnetic field induces an emf of large amounts across the switch when it is opened. This is one reason why switches must be rated for inductive loads. This inductive kickback can cause an arc over and damage the switch if it is not properly rated to handle motors or inductive loads.

In ac resistor-inductor circuits, the current is determined by the impedance of the circuit. The higher the reactance and resistance of the circuit, the lower is the series current. The voltage drop across the inductor is determined by its reactance. Reactance is determined by both frequency and inductance. In a dc resistor-inductor circuit, a short but definite time is needed for the current to rise to its maximum value. This maximum current value is determined by the resistance of the circuit. The higher the resistance in the circuit, the lower the current is. However, assuming that the same two components are used in an ac and a dc circuit, the current present with the application of a dc voltage will be higher than the current present when an ac voltage of the same value is applied to the circuit. The dc voltage drop across the inductor in the dc circuit depends on the winding resistance of the inductor. If the winding resistance is assumed to be zero, the voltage drop across the inductor will be zero in a dc circuit.

Special handling

In handling circuits of this nature, remember the inductor in the circuit can cause a mild shock when you use an ohmmeter to check its continuity. The ohmmeter has a dc power supply that can excite the windings of a motor, solenoid coil, or relay coil. If you get across the terminals being tested, it is possible to obtain a mild shock from a circuit you may assume to be de-energized.

Utilizing the Inductive Delay

When a start capacitor is used in series with a compressor motor to cause it to start, it is taken out of the circuit within a few seconds. This is so that the capacitor does not explode from having ac applied to it. The delay in energizing the relay to remove the capacitor from the circuit is caused by the inductance of the relay coil and the inductance of the motor winding. The delay is caused by inductive reactance and the normal delay caused by a coil to a changing current. This is one practical use for the inductive reactance of a coil.

- Know why a capacitor can cause a lagging voltage.

To cause electric motors to start when single-phase power is applied, it is necessary to make it two phase or more. The split-phase motor was developed to utilize the single-phase power source, but it also needed an additional component in its start circuit to get it moving from a standing condition.

With the development of high-quality and high-capacity electrolytic capacitors, a variation of the split-phase motor known as the capacitor-start motor, has been made. Almost all fractional-horsepower motors in use today on refrigerators, oil burners, washing machines, table saws, drill presses, and similar devices are capacitor start. A capacitor motor has a high starting current and the ability to develop about four times its rated horsepower if it is suddenly overloaded.

In this adaptation of the split-phase motor, the start winding and the run winding have the same size and resistance value. The phase shift between the currents of the two windings is obtained by means of capacitors connected in

series with the start winding. Capacitor-start motors have a starting torque comparable to their torque at rated speed and can be used in places where the initial load is heavy. One such application is a compressor in an air conditioner or refrigerator. A centrifugal switch is required for disconnecting the start winding when the rotor speed is up to about 25% of the rated speed. See Fig. 9-1 for a disassembled capacitor-start motor. Note in Fig. 9-2, which also shows a capacitor-start motor, the centrifugal switch arrangement with the governor mechanism. The capacitor on this motor is shown on top in the motor frame. It is enclosed in the metal housing on top of the motor. More about motors will be presented in Chapter 11.

Now that you can see how important the capacitor is in air-conditioning, heating, and refrigeration circuits (especially motor circuits), you can see why you need a better understanding of how they operate in order to be able to make decisions about replacement, repair, and testing of the equipment using them.

The Capacitor

A *capacitor* is a device that opposes any change in circuit voltage. The property of a capacitor that opposes voltage change is called *capacitance*.

Capacitors make it possible to store electric energy. Electrons are held within a capacitor. This, in effect, is stored electricity. It is also known as an *electrostatic field*. Electrostatic fields hold electrons. When the buildup of electrons becomes great enough, the electrical potential is discharged. This process takes place in nature when clouds build up electrostatic charges; their discharge is seen as lightning.

Figure 9-3 shows the diagram of a simple capacitor. Two plates of a conductor material are isolated from one another. Between the plates is a dielectric. The dielectric material does not conduct electrons very easily. In fact, the dielectric is an insulator. The larger the surface area of the conductive material (the plates), the larger is the capacitor's capacitance.

How the Capacitor Works

If a capacitor has no charge of electrons, it is uncharged. This happens when no voltage is applied to the plates. An uncharged capacitor is shown in Fig. 9-4. Note the symbol for the capacitor in this drawing. This is the preferred way to show a capacitor: a straight and a curved line facing each other. Figure 9-4b shows the switch closed to position 1. This causes current to be applied to the capacitor. A difference in potential is created by the voltage source (the battery). This causes electrons to be transferred from the positive plate to the negative plate of the capacitor. This transfer continues as long as the voltage source is connected to the two plates and until the accumulated charge becomes equal to the voltage of the battery. That is, charging takes place until the capacitor is charged.

In Fig. 9-4c, the voltage has been removed. The switch is open. At this point, the potential difference, or charge, across the capacitor remains. That is, there

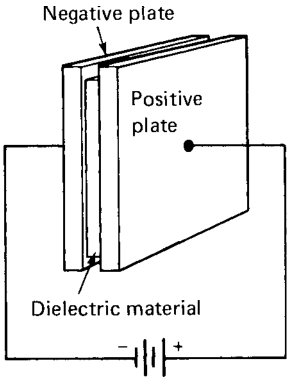

Figure 9-3 Simple capacitor.

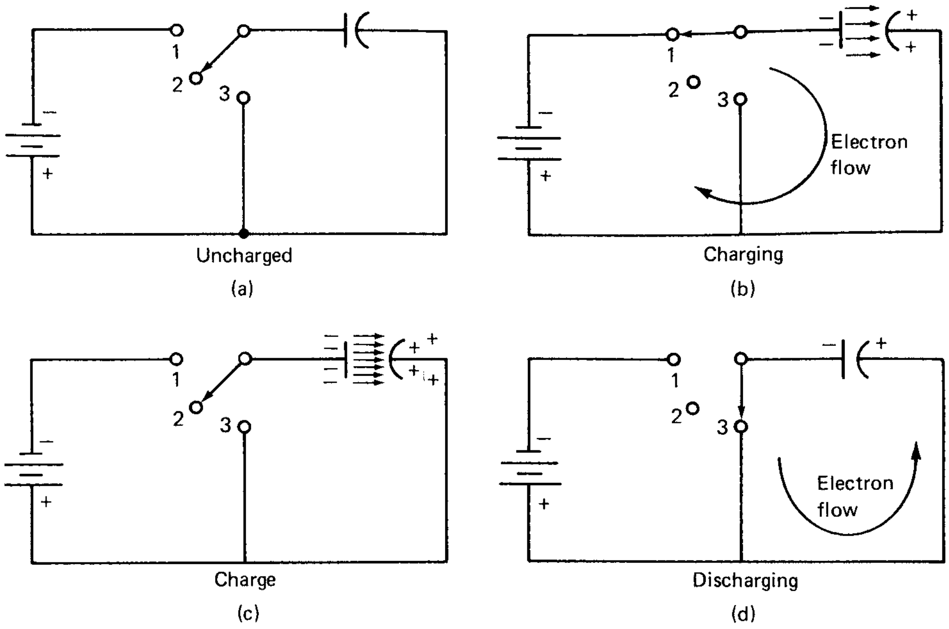

Figure 9-4 Charge-discharge action of a capacitor.

is still a surplus of electrons on the negative plate of the capacitor. This charge remains in place until a path is provided for discharging the excess electrons.

In Fig. 9-4d, the switch is moved to its third position. This opens the path for discharging the surplus electrons. Notice that the discharge path is in the opposite direction from the charge path. This demonstrates how a change in circuit voltages results in a change in the capacitor charge. Some electrons leave the excess or negative plate. They do this to try to keep the voltage in the circuit constant.

Capacity of a Capacitor

The two plates of a capacitor can be made from almost any material. The only requirement is that the material must allow electrons to collect on its surface. The dielectric between the plates of a capacitor is an insulating material. Some dielectrics are air, vacuum, plastic, mica, wood, Bakelite, paper, and oil.

Three factors determine the capacitance of a capacitor:

1. Area of the plates
2. Distance between the plates
3. Material used as a dielectric

The area of the plates determines the ability of a capacitor to hold electrons. The larger the plate area, the greater the capacitance is.

The distance between the plates determines the effect that the electrons on the plates have on one another. There is an electrostatic charge around each electron. Electrons on the plates store energy when voltage is applied. Capacitance increases as the plates are brought closer together. Capacitance decreases as the plates are moved apart.

The material used as a dielectric also determines the charge also. The thickness of the material means the plates are separated more or less by this dimension. But the type of material in the dielectric determines how much the electrostatic charges in the dielectric material react with one another. Some materials have the ability to increase the difference between the negative and positive plates.

Breakdown Voltage

The voltage at which the dielectric of a capacitor no longer functions as an insulator is the *breakdown voltage*. At this level, the capacitor permits the free flow of electrons through the dielectric. The result is known as a *shorted capacitor*. If the breakdown is partial, the result is a *leaky capacitor*. Thus, the dielectric strength of the material used is important to the functioning of a capacitor.

Basic Units of Capacitance

The basic unit for capacitance is the *farad* (F). A 1-farad capacitor stores 1 coulomb of electrons. It has a potential difference of 1 volt between its plates.

In most cases in electronics and electrical applications, the farad is too large a unit to be practical. It is broken down into the microfarad (μF) and the picofarad (pF), formerly called the micromicrofarad. The microfarad has been abbreviated UF, MF, MFD, Mfd. Today's standard abbreviation is μF.

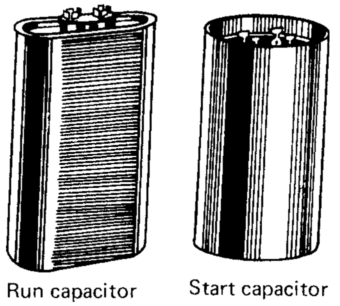
The micromicrofarad was once used as the smaller unit of measurement of capacitance. Some older capacitors may be marked with a MMF, MMFD, UUF, or μμFD. Today's standard abbreviation is pF for picofarad.

The microfarad is one-millionth of a farad (0.000001). The picofarad is just what it says, one-millionth of one-millionth. The pico is today's accepted way of saying one-millionth of one-millionth. The Greek letter mu (μ) is used to represent micro. Micro is used universally as a prefix to indicate one-millionth.

Types of Capacitors

Six general types of capacitors are the most widely used:

1. Air
2. Ceramic
3. Mica
4. Electrolytic



Run capacitor
Start capacitor

5. Paper
6. Tantalum

The electrolytic capacitor is marked with + and − and has polarity that must be observed when it is connected in a circuit. The other types do not need a polarity marking. Figure 9-5 shows an electrolytic capacitor that may be found in air-conditioning, refrigeration, and heating applications. It is used as ac motor run and start capacitors (see Fig. 9-6).

Air capacitors. Air capacitors have air for a dielectric. They are usually variable capacitors used in the tuning circuits of radios.

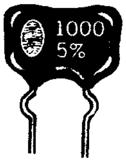

Figure 9-7 Mica capacitors.

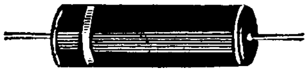

Figure 9-8 Paper capacitors.

Mica capacitors. Aluminum foil is used as the plate material in mica capacitors. Between the aluminum foil plates is a thin sheet of mica. Sometimes the mica is sprayed with a conducting paint. The paint then forms the plate on one side of the mica. Mica capacitors are usually sealed in Bakelite or some type of plastic (see Fig. 9-7).

Paper capacitors. Aluminum is also used as the plate material in paper capacitors (see Fig. 9-8). However, the plates are separated by a paper dielectric. The materials (paper and aluminum) are rolled into a cylindrical shape. A wire is connected to alternate ends of the foil and it is encased in plastic.

Ceramic capacitors. Ceramic dielectric materials make high-voltage capacitors. They have very little change in capacitance due to temperature changes. These small capacitors usually consist of a ceramic disc coated on both sides with silver. They are made in values from 1 picofarad up to 0.05 microfarad. Breakdown voltages of ceramic capacitors run as high as 10,000 volts and more.

Oil-filled capacitors. Oil-filled capacitors are paper capacitors encased in oil. They are sometimes referred to as bathtub capacitors (see Fig. 9-9). The main advantages of these capacitors are sturdy construction and high voltage breakdown ratings. They are used in places where grease and oil are likely to be encountered.

Electrolytic Capacitors

Electrolytic capacitors are very important to people working in the air-conditioning, refrigeration, and heating field.

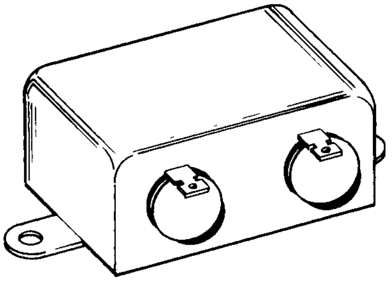

Figure 9-9 Oil-filled capacitor.

There are two types: wet and dry. The wet type uses a liquid electrolyte. It is rather large in physical size. But it has high capacitance. Wet electrolytics are generally used in transmitters and other large, stationary electronic equipment.

The dry electrolytic capacitor is used for capacitances above 1 microfarad. It can be made in sizes up to 1 farad. These units can be kept rather small in physical size for such large capacitances. This is done by using an oxide film as a dielectric (see Fig. 9-10). Very large sizes are used in computer power supplies for filtering the dc power supply.

Making an electrolytic capacitor

The way an electrolytic capacitor is made is very important because it also affects the way in which the capacitor is used in a circuit. To produce a capacitor of this type, dc voltage is applied to the electrolytic capacitor as part of the manufacturing process. This produces an electrolytic action. As a result, a molecule-thin layer of aluminum oxide with a thin film of gas is deposited. This gas is at the junction between the positive plate and the electrolyte.

The oxide film is a dielectric. There is capacitance between the positive plate and the electrolyte through the film. The negative plate provides a connection to the electrolyte. This film allows many layers of film to be placed in a case. Thus, large capacitances can be placed in smaller containers since the insulating film between the plates is so thin that the plates are very close together. And remember, the closer the plates are, the greater the capacitance.

Connecting electrolytics

Electrolytics have polarity (− and +). If these capacitors are not connected in a circuit properly, the oxide film is not formed. If connections are improper, no capacitance is available. Reverse electrolysis forms a gas when the capacitors are connected to opposite polarity. These capacitors become hot and may

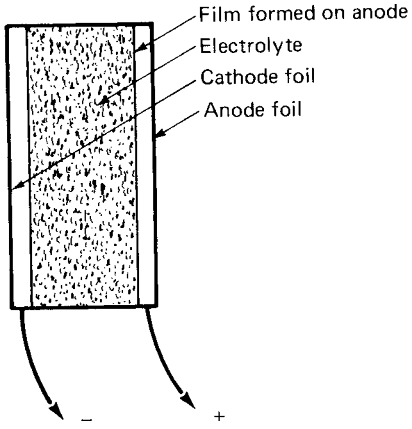

Figure 9-10 Electrolytic capacitor construction.

Figure 9-11 Back-to-back connection of electrolytics to provide a nonpolarized capacitor.

explode. Electrolytic capacitors may dry up and become leaky. These cause all kinds of problems since they may re-form to their rated capacitance once the power has been turned on for some time. So, the problems they present may be intermittent. These are the hardest types to pin down when troubleshooting. Electrolytic capacitors should be used in circuits in which approximately 75% of their working voltage is available. This keeps the capacitor formed.

If a refrigerator or air-conditioning unit has been left out of service for a year or more, it is possible for the electrolytic capacitor to present problems. It may have dried up or become leaky. Nonpolarized electrolytic capacitors are available. They do not have − and + polarity. They use two capacitors in series in the same case and connected in what is called a back-to-back configuration. This means that the two negative terminals are connected internally and the positive terminals are brought out of the case to be connected in the circuit. Nonpolarized electrolytics are used for ac circuits since the normal electrolytic capacitor would explode when ac is connected (see Fig. 9-11).

Working Voltage, Direct Current (WVDC)

The maximum safe operating (working) voltage of a capacitor in a dc circuit is identified as working voltage, direct current, or WVDC. When higher voltages are applied, the dielectric will deform and allow electrons to pass through, thus ruining the capacitor.

Capacitive Reactance

The degree to which a capacitor opposes the flow of current is called *capacitive reactance* (X_c). The capacitive reactance of a circuit is determined by capacitance and frequency. These two factors are used in a formula to determine the capacitive reactance of any given circuit. The formula is:

$$X_c = {}^1/_{2}\pi f C$$

In this formula, X_c is the symbol for capacitive reactance in ohms, C is the symbol for capacitance in farads, and f is the frequency in hertz.

You can see, then, that the changing of the frequency from 60 to 50 hertz would make a difference in the operation of the capacitor. To make the capacitors usable for both frequencies, they have been designed for about 55 hertz so they will operate on both frequencies. This means that the electrolytic capacitors you use for motors have to be properly sized for 50/60 hertz to prevent overheating. In most instances today, the capacitors are made for 50/60 hertz operation.

Note also that the size of the capacitor is very important with respect to the size of motor. In most instances, the electrolytic capacitors will be marked with a range of capacitances:

8–106 μF at 110/125 volts, 50/60 hertz

108–130 μF at 110/125 volts, 50/60 hertz

540–648 μF at 110/125 volts, 50/60 hertz

88–106 μF at 220/250 volts, 50/60 hertz

108–130 μF at 220/250 volts, 50/60 hertz

This type of electrolytic is equipped with two quick-disconnect terminals or some variation (see Fig. 9-12).

The main use for electrolytic capacitors in motor or compressor circuits is for providing starting torque for the device. If a motor must start under load, such as a compressor, it is usually a capacitor-start type.

Capacitor Causes a Lagging Voltage

In a circuit with a capacitor only, the voltage lags, or follows the current by 90°. This is because a purely capacitive circuit has no resistance (a condition that is never found in a practical circuit).

In a purely capacitive circuit, current and voltage are said to have a phase relationship. The phase difference is 90° (see Fig. 9-13).

The current and voltage relationships of capacitance and inductance are found in circuits with motors providing the inductance. By the proper use of capacitance, it is possible to bring the circuit back into phase and reduce the cur-

rent drain from the power source. Run capacitors have this effect since they are left in the circuit at all times. This aids in keeping down the operating costs for electricity.

Checking Capacitors

Start capacitors and run capacitors have a tendency to become open, leaky, and short. These conditions can cause a variety of symptoms that the troubleshooter must become familiar with, to quickly recognize what to do to correct a problem. To check for these conditions, it is necessary to use an ohmmeter.

1. Set the ohmmeter to read its highest resistance range.
2. Sort the leads together and adjust the zero-adjust knob until you get a zero reading on the meter (the battery in the meter will charge the capacitor and, in so doing, a keen observer can detect any malfunctioning of the capacitor).
3. Use a piece of insulated wire with insulation removed at the ends to sort out the capacitor by placing it across the capacitor terminals. You may or may not get a spark. Do this five times to make sure you have discharged the capacitor. If the capacitor has a resistor across its terminals (see Fig. 9-14), remove one end by desoldering or pulling it loose from the connector. This must be done to prevent damage to the meter movement.

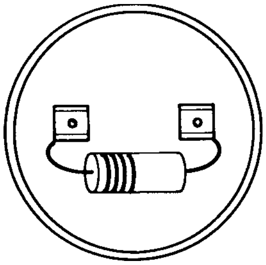

Figure 9-14 Bleeder resistor across capacitor terminals.

TABLE 9-1 Capacitor Troubles

Trouble	Probable cause	Remedy
Compressor will not start. However, it hums intermittently. Cycles with the protector.	Start capacitor open.	Replace start capacitor.
Compressor starts. Motor will not speed up enough to have start winding drop out of circuit.	Start capacitor weak. Run capacitor shorted.	Replace the capacitor. Disconnect run capacitor and check for short.
Compressor starts and runs. However, it cycles on the protector.	Run capacitor defective.	Check capacitance. Replace if found defective.
Start capacitors burn out.	Short cycling.	Reduce number of starts. They should not exceed 20 per hour.
	Prolonged operation with start winding in circuit.	Reduce the starting load. Install a new crankcase pressure limit valve. Increase low voltage if this is found to be the condition. Replace the relay if it is found to be defective.
	Wrong relay or wrong relay setting.	Replace the relay.
	Wrong capacitor.	Check specifications for correct sized capacitor. Be sure the MFD and WVDC are correct for this compressor.
	Water shorts out terminals of the capacitor.	Place capacitor so terminals will not get wet.
Run capacitors burn out. They spew their contents over the surface of anything nearby. This problem can usually be identified with a visual check.	Excessive line voltage.	Reduce line voltage. It should not exceed 10% of the motor rating.
	Light load with a high line voltage.	Reduce voltage if not within 10% overage limit.
	Voltage rating of capacitor too low.	Replace with capacitor of correct WVDC.
	Capacitor terminals shorted by water.	Place capacitor so the terminals will not get wet.

4. Place the meter probes across the capacitor and hold them there for at least 15 seconds. Watch the action of the meter at this time. The needle on the meter should swing all the way to the right or zero. Then it will gradually move back toward infinity and stop. This indicates that the capacitor is taking a charge and is probably all right to put in the circuit.

If the needle goes to zero and stays, the capacitor is shorted. Replace it. There are other ways of finding if a capacitor is doing its job. You may also check from each terminal of the capacitor to its metallic case. If you get a zero reading, replace the capacitor. The meter should read infinity from each terminal to the case to be usable. A troubleshooting guide for capacitors is given in Table 9-1.

Single-Phase and Three-Phase Alternating Current

Performance Objectives

- Know the meaning of impedance.
- Know what a vector is and how it works.
- Know what the term kilowatt-hour means.
- Know what is meant by true power.
- Know the difference between apparent power and true power.
- Know what reactive power is.
- Know how most electrical power is generated.

Single-Phase and Three-Phase AC

Alternating current (ac) affects capacitors and inductors differently than direct current. The reactance of inductors and capacitors to ac creates a phase shift between the voltage and current in the circuit. This phase shift causes the kilowatt-hour meter that measures the power consumed in a home, business, or industrial plant to read higher than the power that is actually being used. In as much as compressors for air conditioners and refrigerators are motors, they are also known as inductors and cause a phase shift.

In some cases it is possible by using the right combination of capacitance to lower the power being measured on the kilowatt-hour meter and, of course, lower the cost of operation of the unit. This is why service technicians need to know about power factor and how it affects the equipment they work with.

Resistance, Capacitance, and Inductance

The total opposition to the flow of current within a circuit is called *impedance* (Z). It impedes or resists the flow of current. Since it impedes the flow of current in a circuit, impedance is measured in ohms.

In dc circuits, the only opposition is resistance. In ac circuits, opposition to voltage and current comes from a combination of factors. These include resistance (R), capacitance (C), and inductance (L).

The effect of combining these elements (R, L, and C) in a circuit is best examined in steps. Start with resistance. Then add inductance and/or capacitance. When combined in a circuit, a resistor and inductor and/or capacitor produce impedance. Impedance is a combination of effects. It consists of resistance and reactance provided by an inductor and/or a capacitor.

Keep in mind that voltage leads current across an inductor and lags current across a capacitor. This is a phase angle of 90°. The effect on current is of special interest in this situation. The reactance effect is 90° out of phase with the resistive effect. The voltage and current, remember, are in phase in a resistor. To combine these, it is necessary to obtain the vector sum of the two quantities (resistance and capacitive reactance).

Impedance is the vector sum of resistance and reactance. A vector is a line segment used to represent a quantity that has both direction and magnitude. Vectors are used to represent current. A single vector line, or curve, can show two dimensions of current. It can show the direction of flow and it can also show the magnitude or amount of current flowing. A vector sum is a line representing the total of two or more vectors. Impedance is stated in terms of a vector sum (see Fig. 10-1). In this illustration you can see how vectors represent X_L and R. The Z is used to represent the sum of the two acting together to produce the impedance. By measuring the angle made by CAD, you can also find the phase angle produced by the inductor and resistor being in the same circuit. The phase angle is directly related to the power factor. Power factor is important in ac circuits because it tells the ratio of power being consumed to power that appears to be consumed and is actually read by watt-meters. More about power factor will be presented in this chapter as we develop the concepts needed to understand it.

Power is represented by the letter P. It is measured in watts. We also see it represented as kilowatts (kW). The kilo means 1000. Therefore, a kilowatt means 1000 watts. When power is consumed at home or in industry for a period of a month, it is likely to be measured in terms of kilowatts, rather than in watts.

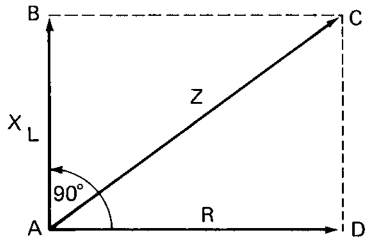

Figure 10-1 Vectors showing impedance.

An ac circuit consumes power differently than a dc circuit or an ac circuit with resistance only. The addition of a capacitor or inductor makes a difference in the actual power consumed. When power is consumed in a dc circuit or an ac circuit with resistance only, the power is found by $P = E \times I$. Or the power is equal to the product of volts and amperes. Once a capacitor or inductor is added to an ac circuit, all this changes because the difference between voltage and current or phase shift has to be taken into consideration to get an accurate reading of what is actually consumed in the way of power. Power that is actually consumed is referred to as true power. True power is that which a dc circuit or ac resistive circuit consumes.

In a purely resistive circuit, energy is dissipated in the resistance as heat, and the resistance does not care in which direction the current is moving at any given instant. As a result, the power cycle looks like the upper waveform in Fig. 10-2. This resistive power cycle is always positive, indicating that power is always being drawn from the circuit. The average power for the cycle is one-half of the maximum value.

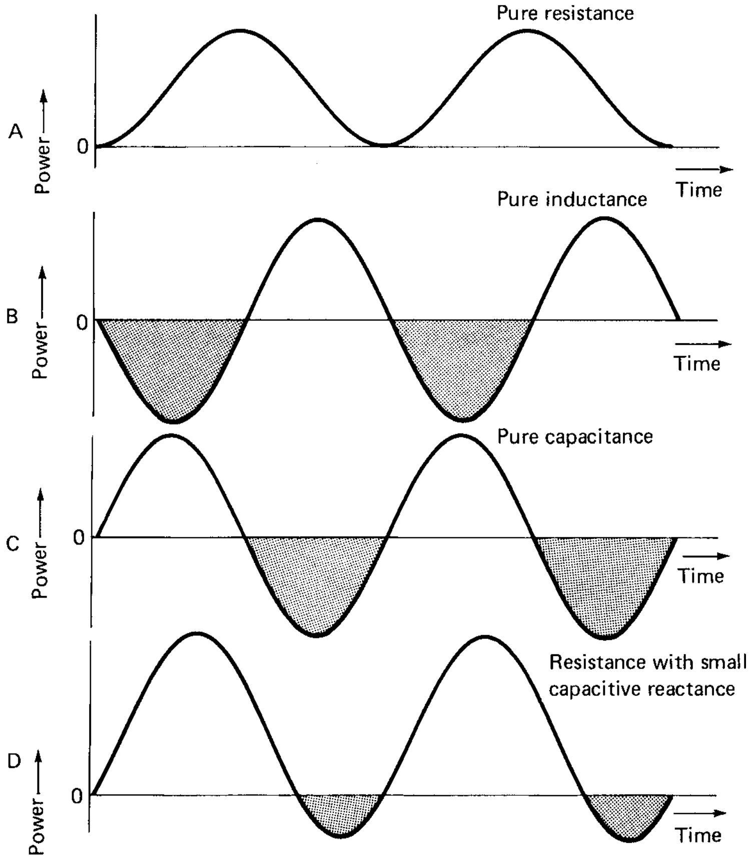

Figure 10-2 Power waveforms.

In a purely inductive or capacitive reactance, the situation is quite different. During parts of the voltage cycle, when the magnetic field is building up around the inductor in either direction or when the capacitor is being charged in either direction, power is being drawn from the circuit. This energy is stored in the magnetic field of the inductor or the electrostatic field of the capacitor. During the remaining parts of the cycle, the magnetic field of the inductor collapses and the capacitor discharges, returning the stored power to the circuit. In these cases, we have a reactive power cycle that is sinusoidal about the zero line, with twice the voltage cycle frequency. The average power consumed for the cycle is zero. The capacitive cycle is 180° out of phase with the inductive cycle, as seen in Fig. 10-2b and c.

The power cycle in any real circuit lies somewhere between the extremes of pure resistive and pure reactive, with more power being drawn from the circuit than is returned to it (see Fig. 10-2d). The circuit is predominantly resistive but slightly capacitive. A slightly inductive power cycle would be similar, except that the negative parts of the cycle would precede the positive parts.

Power Factor

The measure of the relative reactivity of an ac circuit is its power factor. Power factor is defined as the net resistance (*R*) divided by the total impedance (*Z*) of the circuit, or

$$\mathrm{PF} = \frac{\mathrm{R}}{\mathrm{Z}}$$

Power factor is given in both percentage form and in decimal form. That is, 100% is 1.00, or 90% is 0.900.

In a purely resistive circuit, the impedance is made up only of resistance. That means the power factor is unity (100%). In a purely reactive circuit, the impedance comprises only reactance with no resistance, and the power factor is zero (0%). To find the apparent power (AP), you multiply the voltage *E* by the current *I*. This produces what is called *volt-amperes* (VA). Note that this is different from watts. The difference in volt-amperes and watts is significant. The term watt is used to designate a purely resistive circuit or one with only dc resistance. The term volt-ampere designates that the circuit is ac and that there is an inductor or capacitor in the circuit. In other words, it is a reactive circuit when it has volt-amperes. Volt-ampere is also used when referring to the capacity or ability of a transformer to supply a certain amount of volts and amperes. For instance, a door chime transformer may put out 16 volts, but is limited to a maximum of 1 ampere. This means that the volt-ampere rating of the transformer is 16 volt-amperes: $16 \times 1 = 16$. If you want to have two door bells or chimes operate on a transformer, it must be larger, in terms of current available. Thus, if you buy a transformer with the ability to furnish 2 amperes and 16 volts, you have to ask for one that is rated at 32 volt-amperes: $16 \times 2 = 32$.

If you want to know the true power (*W*) instead of the volt-amperes (VA), you have to multiply by the power factor (pf). In other words, if you have 150 volt-amperes and a power factor of 0.5, you will have a true power of 75 watts: $150 \times 0.5 = 75$.

Reactive power averages out to zero. It can be a nuisance in most cases for it puts an instantaneous load on the equipment for part of the cycle, just as if it were a reactive power demand. For this reason, large industrial consumers of power from ac sources will deliberately introduce the opposite kind of reactance into a circuit. That is, they will put a capacitor into an inductive load to reduce the level of reactive power and bring the power factor closer to 100%. This is also the reason why ac generators are always rated in terms of the total apparent power, in kilovolt-amperes (kVA), that they can produce. For loads, on the other hand, it is important to know the two individual components of the apparent power: reactive power in kilovolt-amperes reactive kVAR and the true power in kilowatts (kW).

By adding a capacitor in parallel with an electric motor, the power factor can be improved. This is why some large consumers of electrical power try to reduce the power factor as much as possible. It means they have to pay for the apparent power. Apparent power is always more than true power when there is an inductor or capacitor in the circuit.

Keep in mind, though, that the capacitors used in compressor circuits are not there for power factor correction, but for improving starting torque. The power factor is a secondary consideration. Note that some motors are capacitor start and capacitor run. There are some advantages to having a capacitor in the run circuit. These advantages will be discussed in Chapter 12.

Power factor considerations are not the responsibility of the service technician. Power factor is presented here to give you a better understanding of all aspects of the electrical circuits you will encounter while working on refrigeration and air-conditioning equipment.

Distributing Electric Power

Most electric power is generated as three phase (3ϕ). It is stepped up to 138,000 volts, 345,000 volts, or even to 750,000 volts. The frequency is 60 hertz. Sometimes, however, 25 hertz ac is generated for use by some consumers who may have older equipment that uses this frequency. Motors and other equipment using this power frequency would be very expensive to replace. However, most 25-hertz equipment, when worn out, is replaced with 60-hertz equipment. A separate distribution system is necessary to send 25-hertz power to its destination. This is expensive, but we mention it here so that you will be aware of the fact that it exists in some places where there is a nearby very old generating plant.

Don't make the mistake of connecting 60-hertz equipment to 25-hertz power (Fig. 10-3).

Polyphase

The use of more than two wires for a circuit delivering electrical energy offers advantages in economy and in the ways in which the energy can be utilized. As a result, all types of circuits using more than two conductors have been developed and are in common use. These may be either single phase or polyphase (poly means more than one).

In a single-phase system having more than two wires, the voltage between any two pairs of wires will be substantially in phase with the voltage between any other pair of wires. Voltages added in series may be added numerically (taking into account polarity). In the single-phase, three-wire circuit shown in Fig. 10-4, for instance, if the line-to-neutral voltages are each 120 volts, the line-to-line voltage is 240 volts.

In a polyphase system, such voltages are usually not in phase. In a three-phase system (by far the most common polyphase system), three voltages are generated that are equal in magnitude, but 120° apart in phase. Plotted against time,

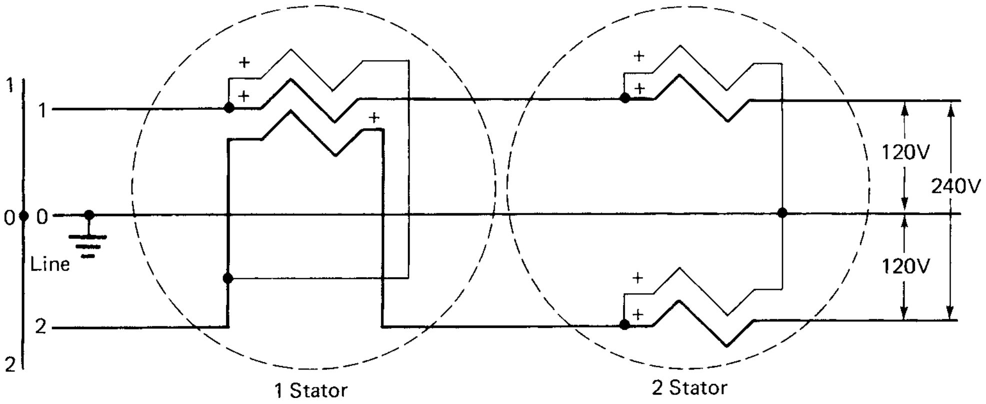

Figure 10-4 Single-phase, three-wire, 240-volt kilowatt-hour meter hookup. The zigzag lines represent the meter coil.

these voltages look like Fig. 10-5. Note that all of the voltages are equal in magnitude, but lag each other by 120°.

Figure 10-6 is a three-wire network being metered with a kilowatt-hour meter. Note how the voltages are distributed. In a conventional three-phase, three-wire system, all line voltages are equal in magnitude, usually at 240 or 480 volts; or for primary metering, at higher distribution voltages, a two-stator meter is required, which is accurate regardless of voltage unbalance. Such a system, usually employed for large commercial or industrial loads, may or may not be grounded. If one line is grounded, the current coils must be in series with the ungrounded lines (see Fig. 10-7).

If a center tap is brought out from one leg of a three-phase delta, the system becomes a three-phase, four-wire delta, such as that frequently used to supply polyphase power at 240 volts for motors and 120 volts, single-phase for lighting. The three-stator kilowatt-hour meter (Fig. 10-8) is rarely used, partly because of the complicated testing procedure. Instead, the two-stator, four-wire delta meter shown in Fig. 10-9 is almost universally used in this service.

Although a four-wire delta system is normally used only for 240/120-volt service, the three-phase (3ϕ), four-wire system covers a wide range of voltages from 208/120-volt service up to the highest transmission voltages (see Fig. 10-9). The neutral is usually grounded. It is measured with either a three- or two-stator meter, depending on the importance of the load and the degree of accuracy required. Note the distribution voltages between any two of the conductors.

These meter hookups are shown to aid in identifying the type of power supplied to various equipment.

Circuit Breakers

A circuit breaker is a device that, after breaking a circuit, can then be reset by turning the handle to past the off position and then to on (see Fig. 10-10). The circuit breaker is mounted in a distribution box by snapping it into place. The hot wire (black or red) is attached by inserting it under the screw and tightening. A knockout blank in the distribution box must be removed to allow for the handle and top of the circuit breaker to be exposed (see Fig. 10-11).

A number of types of circuit breakers are used in home and industrial applications. However, most of them snap in place much as shown in Fig. 10-12. This illustration shows the snap in action without the sides or top of the box in place. Keep in mind that the circuit breakers are snapped into place in the panel board. The wires are connected before the circuit breakers are snapped into place. Make sure the circuit breaker is in the off position while installing or reinstalling if it becomes necessary. Note there is a difference in the three types of circuit breakers shown here. Types A and C must have a notch so the formed rib fits properly. Type B can be used only where there is no formed rib in the mounting plate.

Semiconductors

The word semiconductor identifies a type of electronic device. Transistors and diodes are semiconductors. These units are part of the field of electronics. They have been used over the past years in every aspect of control circuits on every type of equipment. Electronic controls for air-conditioning, refrigeration, and heating equipment have been upgraded to use transistors, diodes and computer chips as well, and other types of semiconductor devices (see Fig. 11-1).

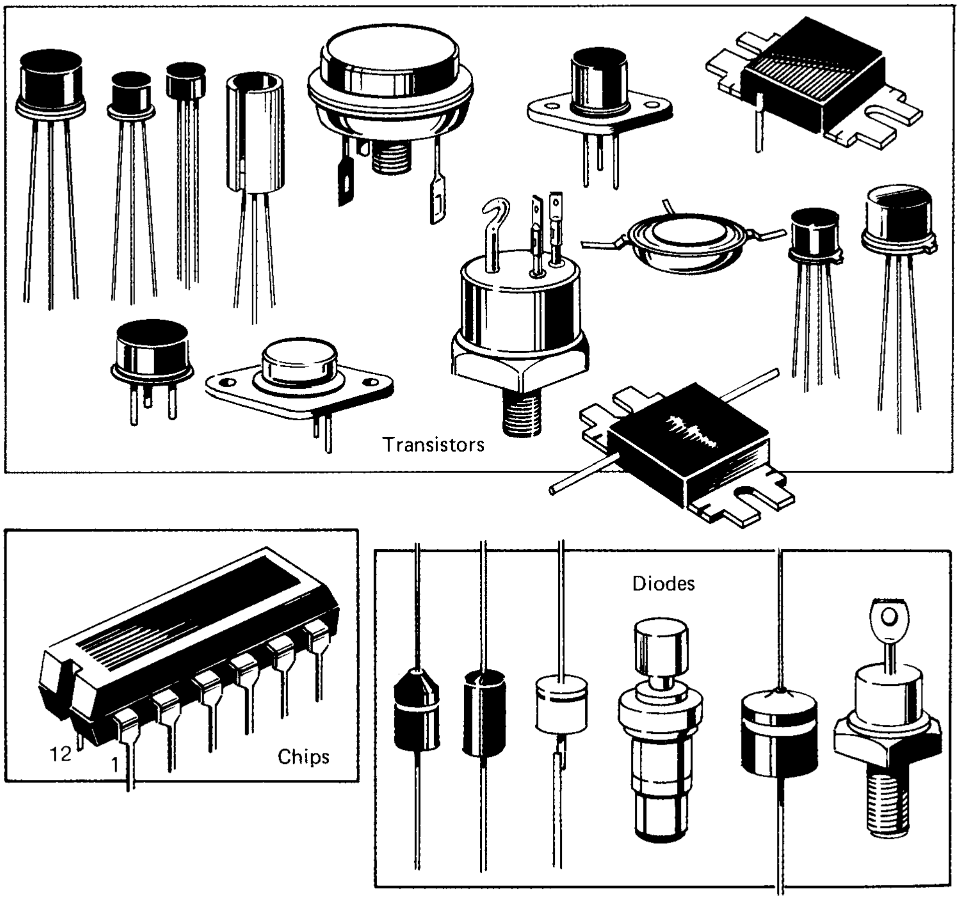

Figure 11-1 Transistors, diodes, and chips.

Semiconductor Principles

Semiconductor technology is usually called *solid state*. This means that the materials used are of one piece. This is in contrast with the vacuum tube, which consisted of a series of assembled parts. Of course, the substances from which semiconductors are made are not really solid. They have atomic structures consisting largely of empty space. The spaces are essential for the movement of electrons.

Many materials can be classified as semiconductors, but two have been used extensively for electronic circuits. They are silicon and germanium. Germanium was used originally for diodes and transistors, but has since been largely replaced by silicon.

Both silicon and germanium are hard, crystal-type materials that are very brittle. They can be made pure to 99.999999999%. Doping agents or impurities

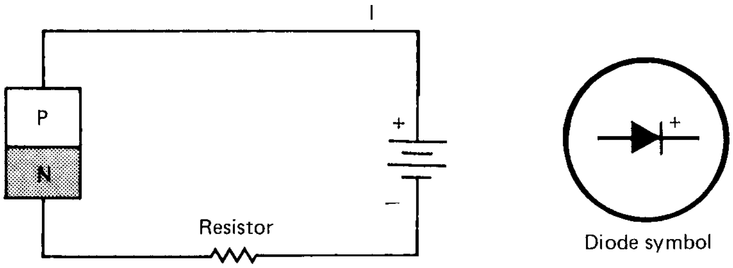

Figure 11-2 PN diode in a circuit. Note the symbol for a diode.

are added in controlled amounts. Impurities used may be boron, aluminum, indium, gallium, arsenic, and antimony.

By doping silicon, it is possible to allow the electrons added by doping (in N-type material) to move easily. In P-type material, the holes or places where an electron should be are moved along by the voltage applied. The addition of arsenic or antimony makes an N-type semiconductor material. The material will have an excess of electrons. Electrons have a negative charge.

When gallium or indium is used as the impurity, a P-type semiconductor material is produced. This means it has a positive charge, or is missing an electron.

Diode

The semiconductor diode is used to allow current to flow in only one direction. It can be used to change alternating current to direct current. It is made by using N-type and P-type semiconductor materials.

When N-type and P-type materials are joined, they form a diode (see Fig. 11-2). The diode is also called a rectifier since it can change (rectify) ac and make it dc. The PN junction (diode) acts as a one-way valve to control the current flow. The forward or low-resistance direction through the junction allows current to flow through it. The high-resistance direction does not allow current to flow. Thus, only one-half of an alternating current hertz is allowed to flow in a circuit with a diode (see Fig. 11-2). The diode used in this circuit is forward biased and allows current to flow. Figure 11-3 indicates the arrangement in the reverse-biased configuration. No current is allowed to flow under these conditions. Also, note the polarity of the battery.

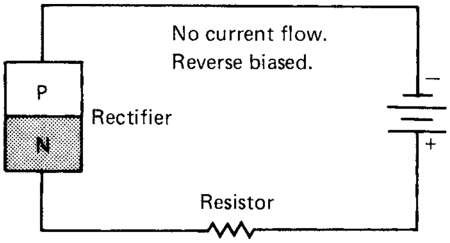

Figure 11-3 Reverse-biased diode in a circuit. Note how this differs from Fig. 11-2.

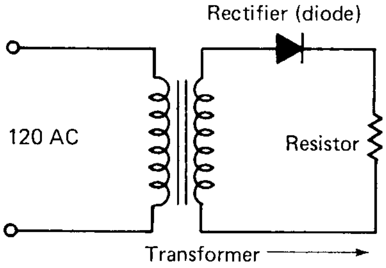

Figure 11-4 Circuit showing how a diode is used to rectify ac to produce dc.

Diodes are used in isolating one circuit from another. A simple rectifier circuit is shown in Fig. 11-4. The output from the transformer is an ac voltage, as shown in Fig. 11-5. However, the rectifier action of the diode blocks current flow in one-half of the sine wave and produces a pulsating dc across the resistor (see Fig. 11-5b).

A number of factors affect the voltage and current ratings of a PN junction diode. As you work with them, you will learn that they have ratings for peak and inverse ac currents. This information is available for both germanium and silicon diodes in transistor handbooks produced by their manufacturers.

Figure 11-6 shows a number of specialized diodes. This illustration demonstrates that diodes are designed for specific jobs. Both internal and external construction is determined by circuit requirements. For example, Fig. 11-6a shows diodes used for radar and computer circuits. The diodes in Fig. 11-6b are designed to carry large currents. So their cases are heat conductors. As the diodes become warm, the generated heat is transferred to the air. Figure 11-6c shows zener diodes. These units protect sensitive meter movements and regulate voltage.

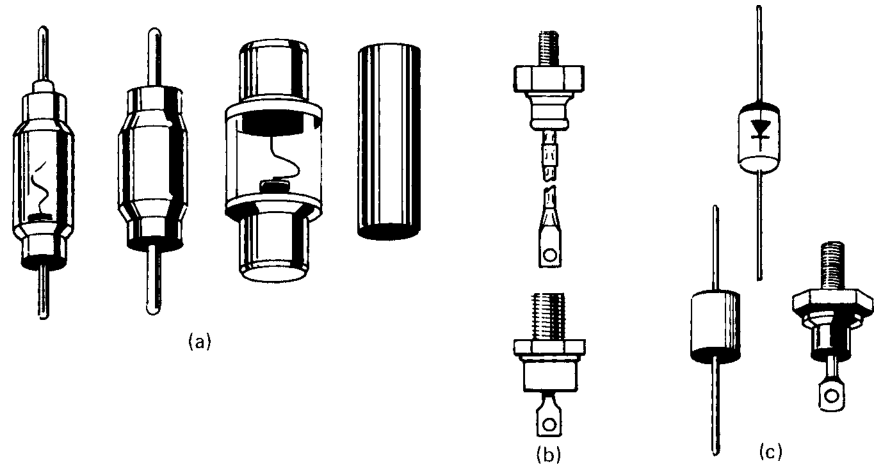

Figure 11-6 Diodes for special circuits. (A) Radar and computer circuits. (B) Large-current circuits. (C) Low-current circuits.

Silicon-Controlled Rectifiers

The silicon-controlled rectifier (SCR) is a specialized type of semiconductor used for control of electrical circuits. This is a four-layer device. The structure can be either NPNP or PNPN.

An SCR conducts current in a forward direction only. The symbol for an SCR is shown in Fig. 11-7. Current always flows through an SCR from the cathode (C) to the anode (A). The illustration indicates that the SCR also has a gate (G).

The function of an SCR is shown in the circuit diagram in Fig. 11-8. The typical use of an SCR is for a controlled circuit. Examples include a light dimmer or a speed control for a motor. This type of circuit is shown in Fig. 11-8. The resistor in the circuit, R_1, is a rheostat, or adjustable resistor: This is used to control the amount of voltage delivered to the gate of the SCR.

The more voltage delivered, the greater the flow. Thus, adjusting the rheostat will control the circuit. If the circuit illuminates a lamp, lowering the voltage to the rheostat dims the bulb. If the load is a motor, its speed is lowered. Figure 11-9 shows typical SCRs.

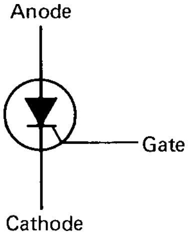

Figure 11-7 Symbol used for representing an SCR in a circuit.

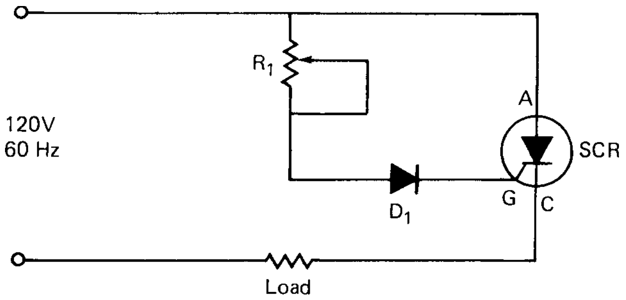

Figure 11-8 Schematic of an SCR-controlled circuit.

Transistors

Transistors are made from N- and P-type crystals. Once joined, the two different types of crystals produce junctions. Transistors are identified according to emitter junction and collector junction. Thus, they are either PNP or NPN types.

A PNP transistor is formed by a thin N region between two P regions (see Fig. 11-10). The center N region is called the base. This base is usually 0.001 inch thick. A collector junction and an emitter junction are also formed. Note the emitter is represented by an arrow either going toward the vertical line or away from it. The collector is the line without an arrow. The third line, the one that has the other two contacting it, is the base. These are usually abbreviated C, B, and E.

Transistors can be used for amplification of signals or they can be used for switching. There are three common configurations for transistor circuits. They are the common base, common collector, and common emitter. The common-emitter circuit is the most often used (see Fig. 11-11). In this type of circuit, the current through the load flows between the emitter and collector. The input signal is applied between the emitter and the base. In normal operation, the collector junction is reverse biased by the supply voltage, B_1. The emitter junction is forward biased by the applied voltage, B_2. Electrons flow across the forward-biased emitter into the base. They diffuse through the base region and flow across the collector junction. Then they flow through the external collector circuit.

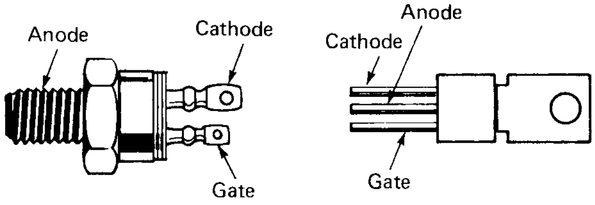

Figure 11-9 Two types of SCRs. Both types are used for control circuits, depending on the amount of current involved.

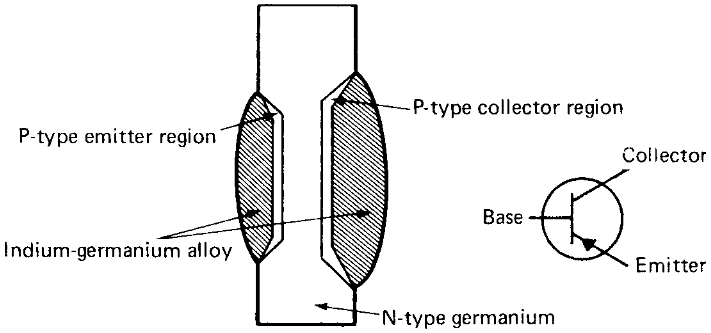

Figure 11-10 Transistor junction using germanium and indium.

Battery B_2 voltage is applied in the forward direction. This means the voltage is positive to the emitter P-type crystal. It also means that voltage is negative to the N-type crystal. Thus, the emitter-base junction has low impedance.

The voltage of battery B_1 is applied in the reverse direction. This means the voltage is positive to the N-type crystal. It also means that voltage is negative to the P-type crystal. This, then, produces a collector-base junction with high impedance.

Transistor impedances

The impedance of the emitter junction is low. Thus, electrons flow from the emitter region to the base region. At the junction, the electrons combine with the holes in the N-type base crystal. If the base is thin enough, almost all the holes are attracted to the negative terminal of the collector. They then flow through the load to B_1.

The collector current is stopped by applying a positive voltage to the base and a negative voltage to the emitter. In actual transistors, however, this cannot be done because of several basic limitations. Some of the electrons in the base region flow across the emitter junction. Some combine with the holes in the base region. For this reason, it is necessary to supply a current to the base. This makes up for these losses.

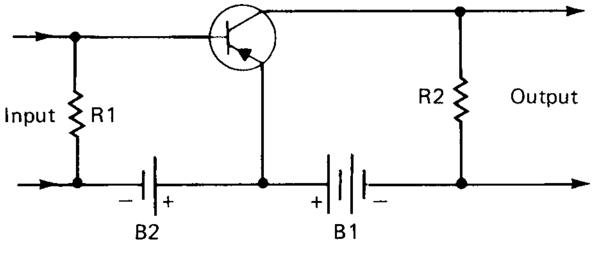

Figure 11-11 Schematic diagram of a common emitter circuit using a PNP transistor.

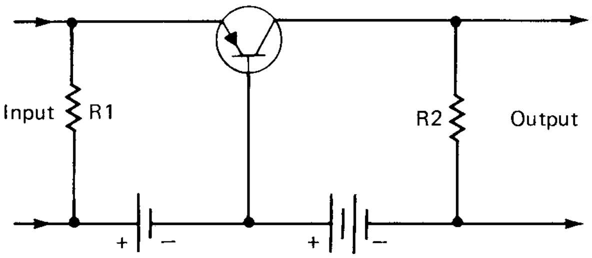

Figure 11-12 Common base circuit using a PNP transistor.

The ratio of the collector current to the base current is known as the current gain of the transistor. Current gain, called beta (β), is found by dividing base current into collector current. At high frequencies, the fundamental limitation is the time for carriers to diffuse across the base region. They move from the emitter to the collector. This is why the base region width or thickness is so important. The thinner the base region, the less time is required for the carriers to diffuse across it. This causes the transistor to operate faster.

Figure 11-12 shows a schematic for a common-base PNP circuit. The signal is injected into the emitter-base circuit. The output signal is taken from the collector-base circuit. An important advantage of the transistor is its ability to transfer impedances. This is where the transistor gets its name. The word transistor comes from *transfer resistor*.

The emitter circuit has low impedance. This low impedance allows current to flow. This current flow then creates a current through the collector circuit. The emitter has low impedance and low current. The collector has high impedance and even slightly less current than the emitter. However, more power is the result in the collector. This is because $P = I^2R$ or, in this case, $P = I^2Z$. Impedance (Z) is high and the current is squared. Thus, the collector circuit has more power than the emitter circuit with its low impedance.

A common-emitter circuit has about 1300 ohms of input impedance. This is compared to an output impedance of about 50,000 ohms. Thus, there is an increase in impedance from emitter to collector of about 39 times. The junction transistor amplifies in this way. It acts as a power amplifier. A small change in emitter voltage causes a large change in the collector circuit. The different impedances cause this reaction.

The power transistor is shown in Fig. 11-13. Along with the power transistor is the much smaller signal amplifying and switching transistor normally seen in electronics equipment.

Integrated Circuits

The semiconductor monolithic chip was developed in 1958 by J.S. Kilby. Active and passive circuit components were successively diffused and deposited on a single chip. Shortly after, Robert Noyce made a complete circuit on a single

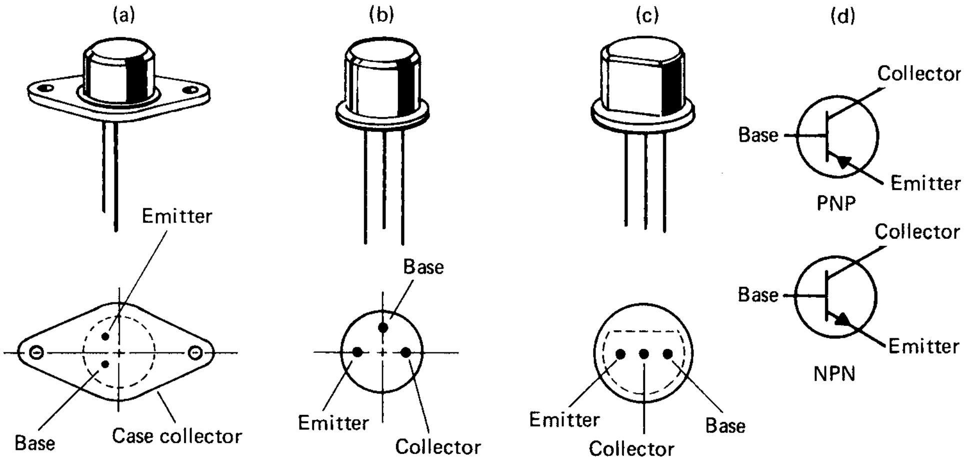

Figure 11-13 Three types of transistor packages. (a) Power transistors. (b) TO-5 case. (c) Small-signal transistors. (d) Transistor symbols.

chip. This was the beginning of the modern, inexpensive integrated circuit (IC or chip). Resistors, capacitors, transistors, and diodes can be placed on a chip. These chips are available in three standard packages, as follows:

Flat pack. The flat pack is hermetically sealed. This means it is vacuum packed. The ceramic flat pack has either 10 or 14 pins. This type of packaging is no longer used. It may be seen in some older-model equipment with chips (see Fig. 11-14).

Multipin circular. This type of packaging is no longer in common use. It was originally used because it fit into the same type of container as a transistor. It had more than three leads coming from a TO-5 case originally made for transistors (see Fig. 11-15).

Dual in-line package (DIP). This is the most commonly used type of integrated circuit today. When you think of a "chip," you think of this type. It may have many leads from each side (see Fig. 11-16). This is an easily used type of IC since it can be placed into a socket and removed if it develops any problem. This type of package is standardized as to size. It can be placed into circuit boards by machines, which increases its usefulness in electronics equipment. Many thousands of ICs can be made at a time. This means the cost of manufacturing

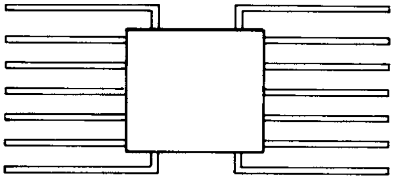

Figure 11-14 Flat pack IC.

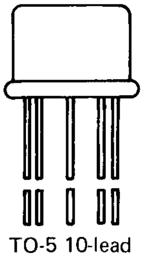

Figure 11-15 TO-5 case used for IC.

is very low. DIPs are used in computers, calculators, and control devices for air-conditioning and heating equipment. Amplifiers are fabricated as complete units. Everything seems to use ICs today. Toys, calculators, computers, and automobiles all use ICs or chips in one form or another. The possibilities are unlimited. ICs will play a more important role in air-conditioning, refrigeration, and heating devices in the future.

Solid-state demand defrost control

An excellent example of a refrigeration control using semiconductor technology is the demand defrost control. The idea of defrosting only when needed saves money and energy and protects the quality of the refrigerated product, since extremes in temperature swings are minimized.

Thermistor Sensing

A temperature difference concept can be used to automatically initiate the defrost cycle on vertical open frozen food display cases that use electric defrost (see Fig. 11-17). If the cover is lifted, you can see the electronic package. There are a few transistors and the usual capacitors, resistors, and a transformer. The sensor that feeds in the information needed to operate properly as a control is shown in Fig. 11-18. These two sensors are simple in construction. They are simple thermistors that change resistance when temperature changes (see Fig. 11-19). Their operation is not affected by dirt, moisture, lint, food particles, or ice. They can sense the least temperature change precisely.

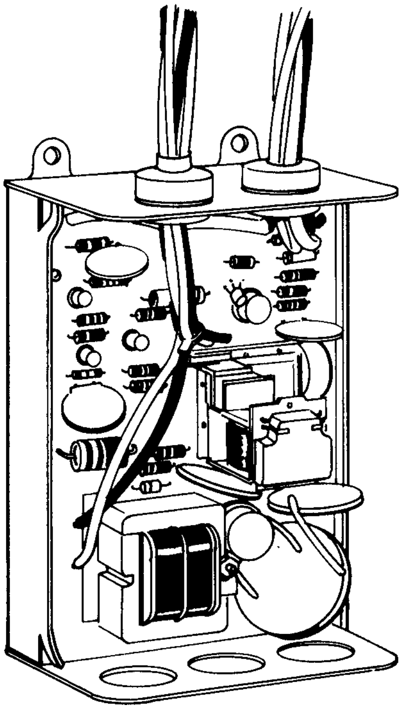

Figure 11-18 Cover removed from the DF-1 defrost control. (Courtesy of Tyler)

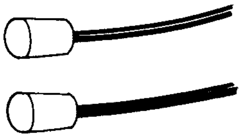

Figure 11-19 Thermistors used to sense temperature differences. (Courtesy of Tyler)

Figure 11-20 shows how frost buildup is sensed to cause the circuit to know what is happening. This tells when defrost should be started and terminated. The ever widening temperature difference is a sure sign of frost buildup. The temperature difference of air flowing over a coil increases in direct proportion to frost buildup. This is what the thermistor monitors to trigger defrost only when needed. Refrigeration fixtures run at peak efficiency all the time. They use less energy and keep the product at a lower, steadier temperature.

Humidity Sensing

Figure 11-21 shows how defrost frequency and humidity are related. Improvements in the design of humidity-sensing elements and the materials used in their construction have minimized many past limitations of humidity sensors. One type of humidity sensor used with electronic controls is a resistance CAB (cellulose acetate butyrate) element (see Fig. 11-22). This resistance element is an improvement over other resistance elements. It has greater contamination resistance, stability, and durability. The humidity CAB element is a multilayered, humidity-sensitive, polymeric film. It consists of an electrically conductive core and insulating outer layers. These layers are partially

hydrolyzed. The element has a nominal resistance of 2500 ohms. It has a sensitivity of 2 ohms per 1% relative humidity (rh) at 50% rh. Its humidity sensing range is rated at 0% to 100% rh.

The CAB element consists of conductive humidity-sensitive film, mounting components, and a protective cover (see Fig. 11-23). The principal component of this humidity sensor is the film. The film has five layers of CAB in the form of a ribbon strip. The CAB material is used because of its good chemical and mechanical stability and high sensitivity to humidity. It also has excellent film-forming characteristics.

The CAB resistance element is a carbon element having a resistance/humidity tolerance favorable to inclusion in a control circuit. With an increase in relative humidity, water is absorbed by the CAB, causing it to swell. This swelling of the polymer matrix causes the suspended carbon particles to move farther apart from each other. This results in an increased element resistance.

When relative humidity decreases, water is given up by the CAB. The contraction of the polymer causes the carbon particles to come closer together. This, in turn, makes the element more conductive or less resistive.

Bridge Circuit

A bridge circuit is a network of resistances and capacitive or inductive impedances. The bridge circuit is usually used to make precise measurements. The most common bridge circuit is the Wheatstone bridge. This consists of variable and fixed resistances. Simply, it is a series-parallel circuit (see Fig. 11-24). The branches of the circuit forming the diamond shape are called legs.

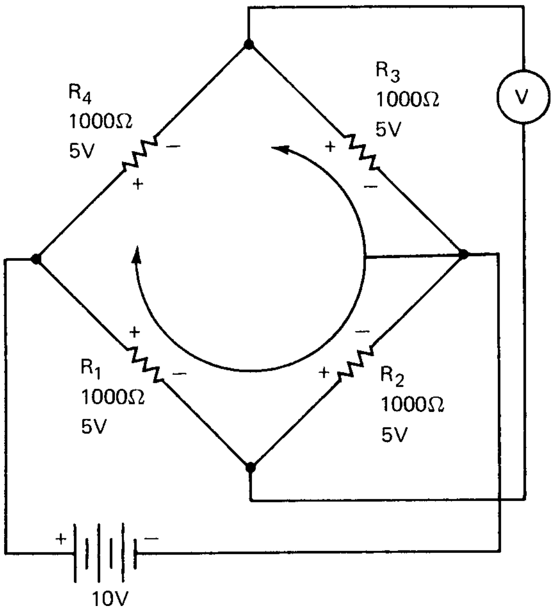

Figure 11-25 Current in a balanced bridge circuit.

If 10 volts dc is applied to the bridge circuit shown in Fig. 11-25, one current will flow through R_1 and R_2, and another through R_3 and R_4. Since R_1 and R_2 are both fixed 1000-ohm resistors, the current through them is constant. Each resistor will drop one-half of the battery voltage, or 5 volts. Thus, 5 volts is dropped across each resistor. The meter senses the sum of the voltage drops across R_2 and R_3. Both are 5 volts. However, the R_2 voltage drop is a positive (+) to negative (−) drop. The R_3 drop is a negative to positive drop. They are opposite in polarity and cancel each other. This is called a *balanced bridge*. The actual resistance values are not important. What is important is that this ratio be maintained and the bridge be balanced.

Unbalanced bridge

In Fig. 11-26, the value of the variable resistor R_4 is 950 ohms. The other resistors have the same value. Using Ohm's law, the voltage drop across R_4 is found to be 4.9 volts. The remaining voltage, 5.1 volts, is dropped across R_3 (see Fig. 11-26). The voltmeter measures the sum of the voltage drops across R_2 and R_3 as 5.0 volts (+ to −) and 5.1 volts (− to +). It registers a total of −0.1 volt.

In Fig. 11-27, the converse is true. The value of R_4 is 1050 ohms. The voltage drop across R_3 is 4.9 volts. The voltmeter senses the sum of 5 volts (+ to −) and 4.9 volts (− to +), or +0.1 volt.

When R_4 changes the same amount above or below the balanced-bridge resistance, the magnitude of the dc output measured by the voltmeter is the same. However, the polarity is reversed.

Sensors

The *sensor* in a control system is a resistance element that varies in resistance value with charges in the variable it is measuring. This may be humidity or temperature. These resistance changes are converted into proportional amounts of voltage by a bridge circuit. The voltage is amplified and used to position actuators that regulate the controlled variable.

Controllers

The sensing bridge is the section of the controller circuit that contains the temperature-sensitive element or elements. The potentiometer for establishing the set point is also part of the control system. The bridges are energized with a dc voltage. This permits long wire runs in sensing circuits without the need for compensating wires or for other capacitive compensating arrangements.

Both integral (room) and remote-sensing element controllers produce a proportional 0- to 16-volt dc output signal in response to a measured temperature change. Controllers can be wired to provide direct or reverse action. Direct-acting operation provides an increasing output signal in response to an increase in temperature. Reverse-acting operation provides an increasing output signal in response to a decrease in temperature.

Electronic Controllers

Electronic controllers have three basic elements: the bridge, the amplifier, and the output circuit. Two legs of the bridge are variable resistances in Fig. 11-28. The sensor and the set-point potentiometer are shown in the bridge configuration. If temperature changes or if the set point is changed, the bridge is in an unbalanced state. This gives a corresponding output result. The output signal, however, lacks power to position actuators. Therefore, this signal has to be amplified to become useful in the control of devices associated with making sure the right amount of heat of cooled air gets to the room intended.

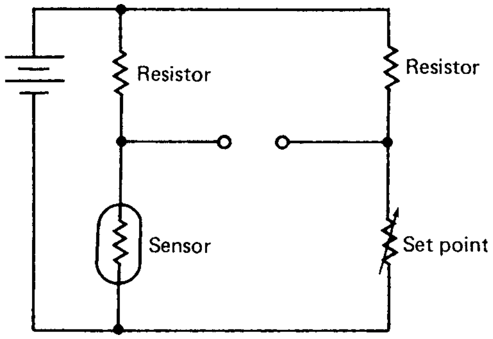

Figure 11-28 Bridge circuit with a sensor and a set point.

Differential Amplifiers

Controllers utilize direct-coupled dc differential amplifiers to increase the millivolt signal from the bridge to the necessary 0- to 16-volt level for the actuators. There are two amplifiers, one for direct reading and the other for reversing signals. Each amplifier has two stages of amplification. This arrangement is shown in block form in Fig. 11-29.

The differential transistor circuit provides gain and good temperature stability. Figure 11-30 compares a single transistor amplifier stage with a differential amplifier. Transistors are temperature sensitive. That is, the currents they allow to pass depend on the voltage at the transistor and its ambient temperature. An increase in the ambient temperature in the circuit shown in Fig. 11-30a causes the current through the transistor to increase. The output voltage decreases. The emitter resistor, R_E, reduces this temperature effect. It also reduces the available voltage gain in the circuit because the signal voltage across the resistor amounts to a negative feedback voltage. That is, it causes a decrease in the voltage difference that was originally produced by the change in temperature at the sensing element.

Since it is desirable for the output voltage of the controller to correspond only to the temperature of the sensing elements and not to the ambient temperature of the amplifier, the circuit shown in Fig. 11-30b is used. Here any ambient temperature changes affect both transistors at the same time. The useful output is taken as the difference in output levels of each transistor, and the effects of temperature changes are canceled. The voltage gain of the circuit shown in Fig. 11-30b is much higher than that shown in Fig. 11-30a. This is

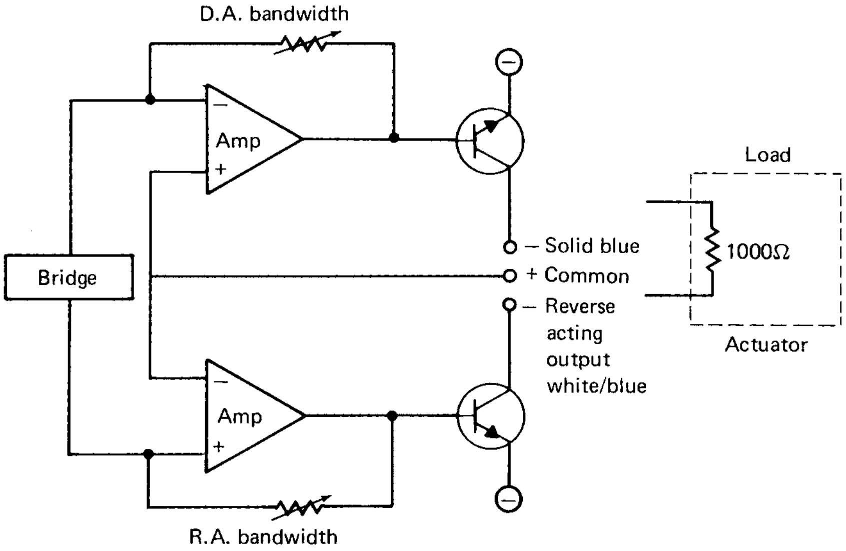

Figure 11-29 DC differential amplifier for use in a controller circuit.

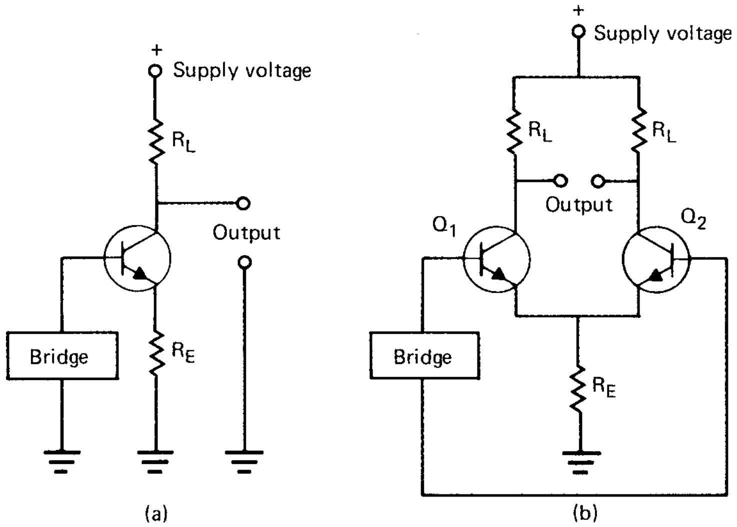

Figure 11-30 (a) Single transistor amplifier stage. (b) Two-transistor amplifier stage.

because the current variations in the two transistors produced by the bridge signal are equal and opposite. An increase in current through Q_1 is accompanied by a decrease in current through Q_2. The sum of these currents through R_E is constant. No signal voltage appears at the emitters to cause negative feedback as in Fig. 11-30a.

The result of sequentially varying dc signals in response to temperature change at the sensing element is shown in Fig. 11-31.

Actuators

Cybertronic actuators perform the work in an electronic system. They accept a control signal and translate that signal into mechanical movement. This is used to position valves and dampers. The electrohydraulic actuators are so called

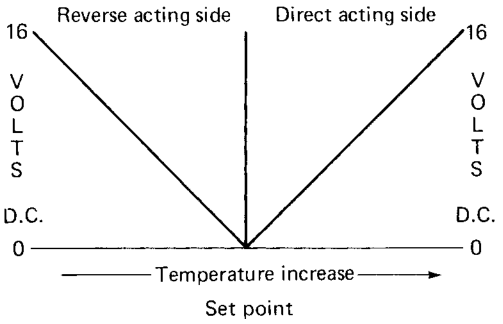

Figure 11-31 Result of sequentially varying dc signals in response to temperature change at the sensing element.

because they convert electrical signals into a fluid movement or force. Damper actuators, equipped with linkage for connection to dampers, and value actuators, having a yoke and linkage to facilitate mounting on a valve body, are also available.

Other Devices

Low- and high-signal selectors accept several control signals. Such selectors then compare the signals and pass the lowest or highest. For example, a high-signal selector can be used on a multi-zone unit to control the cooling coil. The zone requiring the most cooling transmits the highest control signal. This, in turn, will be passed by the high-signal selector to energize the cooling.

The future of electronics in the control of heating, cooling, and refrigeration is unlimited. Only a few examples have been given. More and more mechanically operated thermostats and valves will be replaced and become electronically controlled. A computer has already been utilized in making a programmable controller that can process the information fed to it by many inputs. This will improve process control in industry and increase the comfort of large buildings by more accurately controlling the flow of heat or cooled air. The computer also aids in locating the source of trouble in a system, thereby eliminating a lot of troubleshooting.

Solid-State Compressor Motor Protection

Solid-state circuitry for air-conditioning units has been in use for some time. The following is an illustration of how some of the circuitry has been incorporated into the protection of compressor motors. This module is manufactured by Robertshaw Controls Company.

Solid-state motor protection prevents motor damage caused by excessive temperature in the stator windings. These solid-state devices provide excellent phase-leg protection by means of separate sensors for each phase winding. The principal advantage of this solid-state system is its speed and sensitivity to motor temperature and its automatic reset provision.

There are two major components to the protection system:

1. The protector sensors are embedded in the motor windings at the time the motor is manufactured.
2. The control module is a sealed enclosure containing a transformer and a switch. Figure 11-32 shows two models.

Operation of the module

Leads from the internal motor sensors are connected to the compressor terminals as shown in Fig. 11-33. Leads from the compressor terminals to the control

module are connected as shown in Fig. 11-34. Figure 11-34a shows the older model and Fig. 11-34b the newer model. While the exact internal circuitry is quite complicated, basically the modules sense resistance change through the sensors as the result of motor temperature changes in the motor windings. This resistance change triggers the action of the control circuit relay at predetermined opening and closing settings, which causes the line voltage circuit to the compressor to be broken and completed, respectively.

The modules are available for either 208/240- or 120-volt circuits. The module is plainly marked as to the input voltage. The sensors operate at any of the stated voltages because an internal transformer provides the proper power for the solid-state components.

The two terminals on the module marked Power Supply (T_1 and T_2) are connected to a power source of the proper voltage; normally the line terminals on the compressor motor contactor or the control circuit transformer as required.

Troubleshooting the control

The solid-state module cannot be repaired in the field, and if the cover is opened or the module physically damaged, the warranty on the module is voided. No attempt should be made to adjust or repair this module, and if it becomes defective, it must be returned intact for replacement. This is the usual procedure

for most solid-state units. However, if the unit becomes defective, you should be able to recognize that fact and replace it.

If the compressor motor is inoperable or is not operating properly, the solid-state control circuit may be checked as follows:

1. If the compressor has been operating and has tripped on the protector, allow the compressor to cool for at least 1 hour before checking to allow time for the motor to cool and the control circuit to reset.
2. Connect a jumper wire across the control circuit terminals on the terminal board (see Fig. 11-34). This will bypass the relay in the module. If the compressor will not operate with the jumper installed, then the problem is external to the

solid-state protection system. If the compressor operates with the module bypassed, but will not operate when the jumper wire is removed, then the control circuit relay is open.

3. If, after allowing time for motor cooling, the protector still remains open, the motor sensors may be checked as follows:
    a. Remove the wiring connections from the sensor and common terminals on the compressor board (see Figs. 11-33 and 11-34).

WARNING: *Use an ohmmeter with a 3-volt maximum battery power supply. The sensors are sensitive and easily damaged, and no attempt should be made to check continuity through them. Any external voltage or current applied to the sensors may cause damage, necessitating compressor replacement.*

b. Measure the resistance from each sensor terminal to the common terminal. The resistance should be in the following range: 75 ohms (cold) to 125 ohms (hot). Resistance readings in this range indicate the sensors are good. A resistance approaching zero indicates a short. A resistance approaching infinity indicates an open connection. If the sensors are damaged, they cannot be repaired or replaced in the field, and the compressor must be replaced to restore motor protection.

4. If the sensors have proper resistance and the compressor will run with the control circuit bypassed but will not run when connected properly, the solid-state module is defective and must be replaced. The replacement module must have the same voltage specification and made by the same manufacturer as the original module on the compressor.

Restoring service

In the unlikely event that one sensor is damaged and has an open circuit, the control module will prevent compressor operation even though the motor may be in perfect condition. If such a situation should be encountered in the field, as an emergency means of operating the compressor until such time as a replacement can be made, a properly sized resistor can be added between the terminal of the open sensor and the common sensor terminal in the compressor terminal box (see Figs. 11-33 and 11-35). This then indicates to the control module an acceptable resistance in the damaged sensor circuit, and compressor operation can be restored. The emergency resistor should be a 2 watt, 82 ohm, wire wound with a tolerance of ±5%.

In effect, the compressor will continue operation with two-leg protection rather than three-leg protection. While this obviously does not provide the same high degree of protection, it does provide a means of continuing compressor operation with a reasonable degree of safety.

- Know how a three-phase motor is electrically connected and properly maintained.

Motors

Most ac motors are of the induction type. They are, in general, simpler and cheaper to build than equivalent dc machines. They have no commutator, slip rings, or brushes, and there is no electrical connection to the rotors. Only the stator winding is connected to the ac source, and, then, as their name implies, induction produces the currents in the rotor. A common and particularly simple form of rotor for this type of motor is the squirrel-cage rotor (see Fig. 12-1). It is so named because of its resemblance to a treadmill-type squirrel cage. The induction motor is based on a rotating magnetic field. This is achieved by using multiple stator field windings (poles), each pair of which is excited by an ac voltage of the same amplitude and frequency as, but phase-displaced from, the voltage supplying the neighboring pair. Figure 12-2 shows how the magnetic field rotates in a four-pole induction motor, where the voltages to the two pairs of poles are 90° out of phase with each other. When the rotor is placed in the stator's rotating field, the induced currents set up their own fields, which react with the stator's field and push the rotor around.

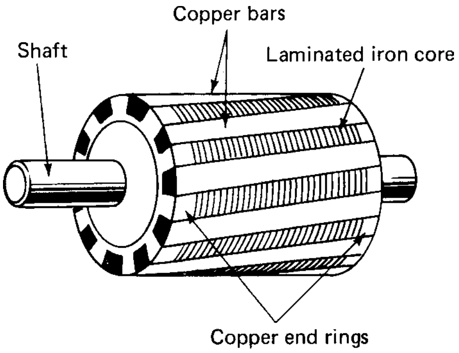

Figure 12-1 Squirrel-cage rotor.

Note that some motors are skewed. The skew of a rotor refers to the amount of angle between the conductor slots and the end face of the rotor laminations. Normally, the conductors are in a nearly straight line, but for high torque applications the rotor is skewed, which increases the angle of the conductors. The term full skew refers to the maximum practical amount (see Fig. 12-3). Figure 12-4 shows how the rotor is located in reference to the stator and the end bells that hold it in place.

A number of types of ac motors are available. The types presented here are those most often encountered when working with heating, air-conditioning, and refrigeration equipment.

The shaded-pole induction motor is a single-phase motor. It uses a unique method to start the rotor turning. The effect of a moving magnetic field is produced by constructing the stator in a special way (see Fig. 12-5).

Portions of the pole piece surfaces are surrounded by a copper strap called a shading coil. The strap causes the field to move back and forth across the face of the pole piece. In Fig. 12-6, a numbered sequence and points on the magnetization curve are shown. As the alternating stator field starts increasing from zero (1), the lines of force expand across the face of the pole piece and cut through the strap. A voltage is induced in the strap. The current that results generates a field that opposes the cutting action (and decreases the strength) of the main field. This action causes certain actions: As the field increases from zero to a maximum of 90°, a large portion of the magnetic lines of force is concentrated in the unshaded portion of the pole (1). At 90° the field reaches its maximum value. Since the lines of force have stopped expanding, no emf is induced in the strap, and no opposite

magnetic field is generated. As a result, the main field is uniformly distributed across the poles as shown in (2).

From 90° to 180°, the main field starts decreasing or collapsing inward. The field generated in the strap opposes the collapsing field. The effect is to concentrate the lines of force in the shaded portion of the poles, as shown in (3).

Note that from 0° to 180°, the main field has shifted across the pole face from the unshaded to the shaded portion. From 180° to 360°, the main field goes through the same change as it did from 0° to 180°. However, it is now in the opposite direction (4). The direction of the field does not affect the way the shaded pole works. The motion of the field is the same during the second half-hertz as it was during the first half-hertz.

The motion of the field back and forth between shaded and unshaded portions produces a weak torque. This torque is used to start the motor. Because of the weak starting torque, shaded-pole motors are built in only small sizes. They drive such devices as fans, timers, and blowers.

Reversibility. Shaded-pole motors can be reversed mechanically. Turn the stator housing and shaded poles end for end. These motors are available from $^{1}/_{25}$ to $^{1}/_{2}$ horsepower.

Uses. As previously mentioned, this type of motor is used as a fan motor in refrigerators and freezers and in some types of air-conditioning equipment where the demand is not too great. It can also be used as part of a timing device for defrost timers and other sequenced operations.

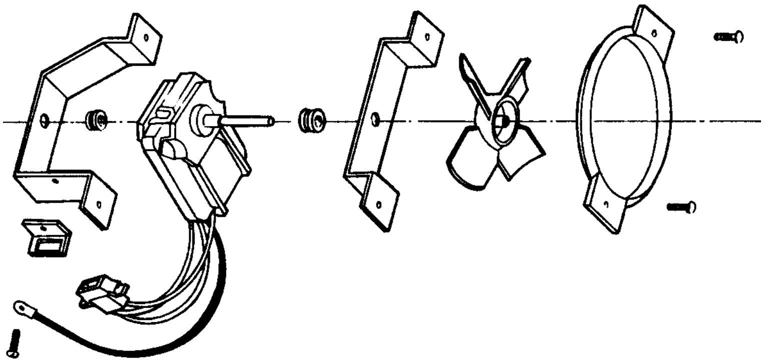

Figure 12-7 Fan, motor, and bracket assembly. (Courtesy of Kelvinator)

The fan and motor assembly are located behind the provisions compartment in the refrigerator, directly above the evaporator in the freezer compartment. The suction-type fan pulls air through the evaporator and blows it through the provisions compartment air dot and freezer compartment fan grille. Figure 12-7 shows a shaded-pole motor with a molded plastic fan blade. For maximum air circulation, the location of the fan on the motor shaft is most important. Mounting the fan blade too far back or too far forward on the motor shaft, in relation to the evaporator cover, will result in improper air circulation. The freezer compartment fan must be positioned with the lead edge of the fan $^1/_4$ inch in front of the evaporator cover. The fan assembly shown in Fig. 12-8 is used on top freezer, no-frost, fiberglass-insulated model refrigerators. Split-Phase Motor

The field of a single-phase motor, instead of rotating, merely pulsates. No rotation of the rotor takes place. A single-phase pulsating field may be visualized as two rotating fields revolving at the same speed, but in opposite directions. It follows, therefore, that the rotor will revolve in either direction at nearly synchronous speed, if it is given an initial impetus in either one direction or the other. The exact value of this initial rotational velocity varies widely with different machines. A velocity higher than 15% of the synchronous speed is usually sufficient to cause the rotor to accelerate to the rated or running speed. A single-phase motor can be made self-starting if means can be provided to give the effect of a rotating field.

To get the split-phase motor running, a run winding and a start winding are incorporated into the stator of the motor. Figure 12-9 shows the split-phase motor with the end cap removed so you can see the starting switch and governor mechanism.

This type of motor is difficult to use with air-conditioning and refrigeration equipment inasmuch as it has very little starting torque and will not be able to start a compressor since it presents a load to the motor immediately upon starting. This type of motor, however, is very useful in heating equipment (see Fig. 12-10).

Getting the motor started

One of the most important parts of the single-phase electric motor is the start mechanism. A special type is needed for use with single-phase motors. A centrifugal switch is used to take a start winding out of the circuit once the motor

has come up to within 75% of its run speed. The split-phase, capacitor-start, and other variations of these types all need the start mechanism to get them running.

The stator of a split-phase motor has two types of coils; one is called the run winding and the other the start winding. The run winding is made by winding the enamel-coated copper wire through the slots in the stator punchings.

The start winding is made in the same way except that the wire is smaller. Coils that form the start windings are positioned in pairs in the stator directly opposite each other and between the run windings. When you look at the end of the stator, you see alternating run windings and start windings (see Fig. 12-9).

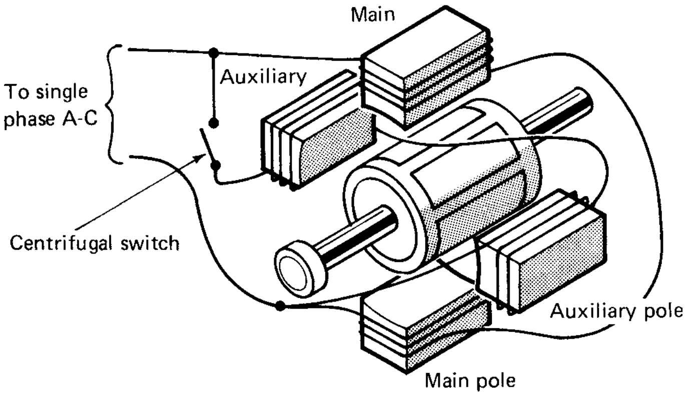

Figure 12-11 Single-phase induction motor.

The run windings are all connected together, so the electrical current must pass through one coil completely before it enters the next coil, and so on through all the run windings in the stator. The start windings are connected together in the same way, and the current must pass through each in turn (see Fig. 12-11).

The two wires from the run windings in the stator are connected to terminals on an insulated terminal block in one end bell where the power cord is attached to the same terminals. One wire from the start winding is tied to one of these terminals also. However, the other wire from the start winding is connected to the stationary switch mounted in the end bell. Another wire then connects this switch to the opposite terminal on the insulated block. The stationary switch does not revolve, but is placed so the weights in the rotating portion of the switch, located on the rotor, will move outward when the motor is up to speed and open the switch to stop electrical current from passing through the start winding.

The motor then runs only on the main winding until such time as it is shut off. Then, as the rotor decreases in speed, the weights on the rotating switch again move inward to close the stationary switch and engage the start winding for the next time it is started.

Reversibility. The direction of rotation of the split-phase motor can be changed by reversing the start winding leads.

Uses. This type of motor is used for fans, furnace blowers, oil burners, office appliances, and unit heaters.

Repulsion Start, Induction Run Motor

The repulsion-induction motor starts on one principle of operation and, when almost up to speed, changes over to another type of operation. Very high twisting forces are produced during starting by the repulsion between the magnetic pole in the armature and the same kind of pole in the adjacent stator field winding. The repulsing force is controlled and changed so that the armature rotational speed increases rapidly, and, if not stopped, would continue to increase beyond a practical operating speed. It is prevented by a speed-actuated mechanical switch that causes the armature to act as a rotor that is electrically the same as the rotor in single-phase induction motors. That is why the motor is called a *repulsion-induction motor*.

The stator of this motor is constructed very much like that of a split-phase or capacitor-start motor, but only run or field windings are mounted inside. End bells keep the armature and shaft in position and hold the shaft bearings.

The armature consists of many separate coils of wire connected to segments of the commutator. Mounted on the other end of the armature are governor weights that move push rods that pass through the armature core. These rods push against a short-circuiting ring mounted on the shaft on the commutator end of the armature. Brush holders and brushes are mounted in the commutator end bell, and the brushes, connected by a heavy wire, press against segments on opposite sides of the commutator (see Fig. 12-12).

When the motor is stopped, the action of the governor weights keeps the short-circuiting ring from touching the commutator. When the power is turned on and current flows through the stator field windings, a current is induced in the armature coils. The two brushes connected together form an electromagnetic coil that

produces a north and south pole in the armature, positioned so that the north pole in the armature is next to a north pole in the stator field windings. Since like poles try to move apart, the repulsion produced in this case can be satisfied in only one way: the armature turns and moves the armature coil away from the field windings.

The armature turns faster and faster, accelerating until it reaches what is approximately 80% of the run speed. At this speed, the governor weights fly outward and allow the push rods to move. These push rods, which are parallel to the armature shaft, have been holding the short-circuiting ring away from the commutator. Now that the governor has reached its designed speed, the rods can move together electrically in the same manner that the cast aluminum discs did in the cage of the induction motor rotor. This means that the motor runs as an induction motor.

The repulsion-induction type of motor can start very heavy, hard-to-turn loads without drawing too much current. They are made from $^1/_2$ to 20 horsepower. This type of motor is used for such applications as large air compressors, refrigeration equipment, and large hoists and is particularly useful in locations where low line voltage is a problem.

This type of motor is no longer used in the refrigeration industry. Some older operating units may be found with this type of motor still in use.

Capacitor-Start Motor

The capacitor motor is slightly different from a split-phase motor. A capacitor is placed in the path of the electrical current in the start winding (see Fig. 12-13). Except for the capacitor, which is an electrical component that slows any rapid change in current, the two motors are the same electrically. A capacitor motor can usually be recognized by the capacitor can or housing that is mounted on the stator (see Fig. 12-14).

Adding the capacitor to the start winding increases the effect of the two-phase field described in connection with the split-phase motor. The capacitor means that the motor can produce a much greater twisting force when it is started. It also reduces the amount of electrical current required during starting to about 1.5 times the current required after the motor is up to speed. Split-phase motors require three or four times the current in starting that they do in running.

Reversibility. An induction motor will not always reverse while running. It may continue to run in the same direction, but at a reduced efficiency. An inertia-type load is difficult to reverse. Most motors that are classified as reversible while running will reverse with a non-inertial-type load. They may not reverse if they are under no-load conditions or have a light lead or an inertial load.

One problem related to the reversing of a motor while it is still running is the damage done to the transmission system connected to the load. In some cases, it is possible to damage a load. One way to avoid this is to make sure the right motor is connected to a load.

Reversing (while standing still) the capacitor-start motor can be done by reversing its start winding connections. This is usually the only time that a field technician will work on a motor. The available replacement motor may not be rotating in the direction desired, so the technician will have to locate the start winding terminals and reverse them in order to have the motor start in the desired direction.

Uses. Capacitor motors are available in sizes from $^1/_6$ to 20 horsepower. They are used for fairly hard starting loads that can be brought up to run speed in under 3 seconds. They may be used in industrial machine tools, pumps, air conditioners, air compressors, conveyors, and hoists.

Figure 12-15 shows a capacitor-start, induction-run motor used in a compressor. This type uses a relay to place the capacitor in and out of the circuit. More about this type of relay will be discussed later. Figure 12-16 shows how the capacitor is located outside the compressor.

Permanent Split-Capacitor Motor

The permanent split-capacitor (PSC) motor is used in compressors for air-conditioning and refrigeration units. It has an advantage over the capacitor-start motor inasmuch as it does not need a centrifugal switch with its associated problems.

The PSC motor has a run capacitor in series with the start winding. Both run capacitor and start winding remain in the circuit during start and after the motor is up to speed. Motor torque is sufficient for capillary and other self-equalizing systems. No start capacitor or relay is necessary. The PSC motor is basically an air-conditioner compressor motor. It is also used in refrigerator compressors. It is very common through 3 horsepower. It is also available in the 4- and 5-horsepower sizes (see Fig. 12-17).

Theory of operation

The capacitor is inserted in series with the start winding (see Fig. 12-18). The phase shift produced by the capacitor is similar to that produced by the capacitor-start, induction-run motor. The run capacitor is usually between 5 and 50 μF. Thus, it is smaller than the start capacitor used in the capacitor-start motor. This also means it will have less starting torque than the capacitor-start motor. However, the torque is enough to start the motor running even with a small load. The capacitor is in the circuit all the time. It is not removed by a relay or any other type of device. It is a permanent part of the circuit.

After the compressor or fan is started and begins to run at speed, the motor produces a counter electromotive force. The cemf builds up to within a few volts of the applied voltage when the motor has reached full speed. As long as the difference between the applied voltage and the cemf is small, very little current flows in the start winding. This is because the capacitor will allow more current to pass as the difference in applied voltage and cemf gets larger, and less current to flow when the voltage difference is small. There is a small difference in voltage at full rpm, so the current in the start winding will be small. The 2 to 4 amperes does not constitute enough to cause damage to the compressor start winding (see Fig. 12-19).

The run capacitor left in the circuit aids in speed regulation. One thing to remember on this type of motor is to make sure the capacitor is placed in the circuit properly. The run capacitor has a red dot or some other marking on or

near one of the two terminals. This is the outside foil of the capacitor. The run capacitor used here is in a grounded steel case that aids in the dissipation of heat (see Fig. 12-19b). The outside foil is near the capacitor case. If the insulation breaks down or shorts to the outside foil, it will make contact with the case. Excessive current will flow in the circuit when the short occurs. The main objective here is to keep the current as low as possible and have it do the least

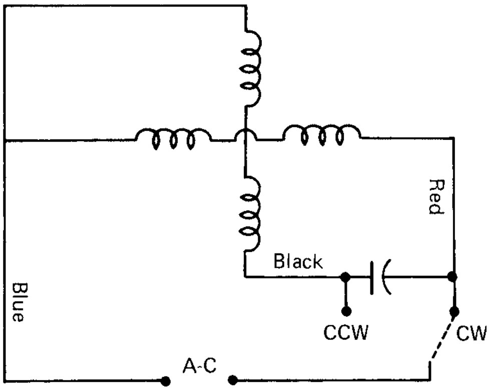

Figure 12-20 Permanent split-capacitor three-lead schematic.

damage possible. That is why the red dot or mark is always placed where it is supposed to be. In Fig. 12-19, the red dot terminal should be connected to L_2. Then, if it shorts, the foil touches the case, shorts to ground, causes excess current to flow, and trips the circuit breaker or blows the fuse.

However, if the red dot is connected incorrectly, the short will burn out the compressor start winding since it puts the winding directly across the power source by grounding one end of the winding. Make sure the capacitor's red dot is connected to the line side and not to the compressor start winding (see Fig. 12-19a).

Reversibility. The PSC motor can be reversed if it has three wires leading from the case (see Fig. 12-20). To reverse, simply connect either side of the capacitor to the line. However, with compressors it is best to leave them as is. They have been designed without the possibility of reversing in most cases. To reverse the four-wire type motor, transpose the black leads as shown in Fig. 12-21.

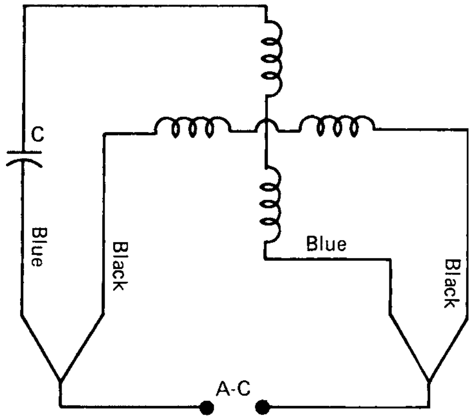

Figure 12-21 Permanent split-capacitor four-lead schematic.

Uses. Permanent split-capacitor motors may also be used for the fans that are mounted behind the condensers on air-conditioning units. They move the air past the condenser and thus remove the heat from the building being air conditioned. This type of motor can also be varied in speed by changing its windings. A number of color-coded windings are brought out so they may be connected to a switching arrangement for low, medium, and high speeds.

Capacitor-Start, Capacitor-Run Motor

The capacitor start and run (CSR or CSCR) motor arrangement uses a start capacitor and a run capacitor in parallel with each other and in series with the motor start windings. This motor has high starting torque and runs efficiently. It is used in many refrigeration and air-conditioning applications up to 5 horsepower. A potential relay removes the start capacitor from the circuit after the motor is up to speed. Potential relays must be as accurately matched to the compressor (see Fig. 12-22). Efficient operation depends on this.

Theory of operation

The CSCR motor is used on air-conditioning and refrigeration units that need large starting torque. You will find the CSCR motor used on equipment that has an expansion valve and on air-conditioning systems when the permanent-split compressor has trouble starting. In some cases, the technician adds a capacitor in the field to make the PSC motor start more easily. This produces the same electrical characteristics as a CSCR type when the additional capacitor is hooked up

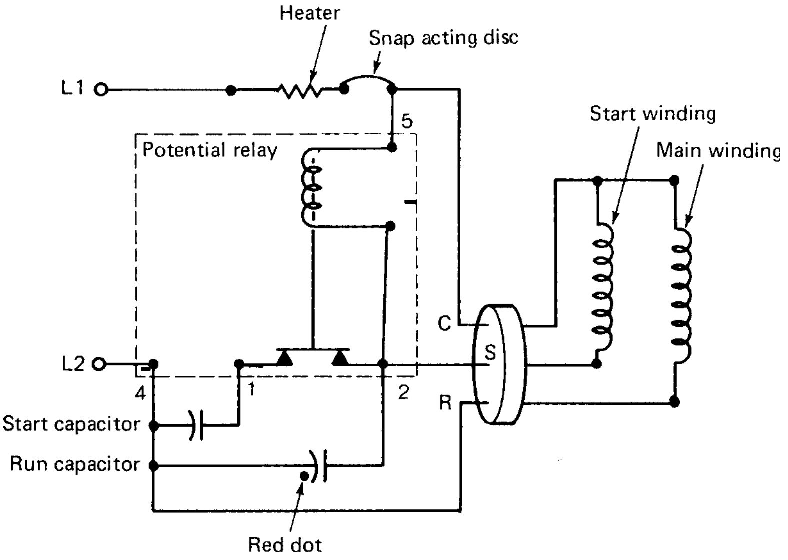

Figure 12-22 Capacitor start and run motor schematic. (Courtesy of Tecumseh)

to the existing arrangement. When the capacitor is added by the technician in the field, it is referred to as a hard-start kit.

Since the CSCR motor has the additional capacitor added during starting time, some way must be provided to move it once its purpose has been served. The potential relay is called upon to do the job. This type of relay will be discussed later in this chapter.

The start capacitor is available in sizes up to 600 μF. This is a large capacitor when compared to the run capacitor of up to 75 μF (see Fig. 12-22). The large capacitance value causes a larger phase shift between the start and run winding voltages. As the compressor motor starts to turn, the cemf begins to build. The cemf is present between the S and C terminals of the compressor. The potential relay coil is connected at terminals 2 and 5 in Fig. 12-22. Note the symbol used for the coil of the potential relay. A PE (for potential relay) and a small resistor-like symbol show the coil part of the relay.

When the compressor reaches approximately 75% of its full rpm, the cemf is strong enough to energize the potential relay coil. This pulls the contacts open. Contactors are shown as two parallel lines with a slant line through them with PR underneath. When the potential relay contacts open, the start capacitor is removed from the circuit. This leaves the run capacitor still in the circuit and in series with the start winding. The result is good starting torque and good running efficiency. The efficiency is increased inasmuch as the power factor is brought closer to unity or 1.00.

Reversibility. This type of motor can be reversed by changing the leads from the start winding. It is, however, difficult to do if the compressor is sealed. In open-type motors, it is possible to reverse the direction of rotation by simply reversing the connections of the start windings.

Uses. This type of motor is used on equipment with a need for good starting torque. This includes some types of refrigeration equipment and some hard to start air-conditioning systems.

Three-Phase Motor

The three-phase motor does not need centrifugal switches or capacitors. The three phases of this type of power generate their own rotating magnetic field when applied to a stator with three sets of windings (see Fig. 12-23). The stator windings are placed 120° apart. The rotor is a form-wound type or a cage type. The squirrel-cage rotor is standard for motors smaller than 1 hp (see Fig. 12-24).

Theory of operation

For the purpose of identification of phases, note that the three phases are labeled A, B, and C in Fig. 12-25. Phase B is displaced in time from A by $^1/_3$ hertz, and phase C is displaced from phase B by $^1/_3$ hertz. In the stator, the different phase windings are plated adjacent to each other so that a B winding is next to an A, a

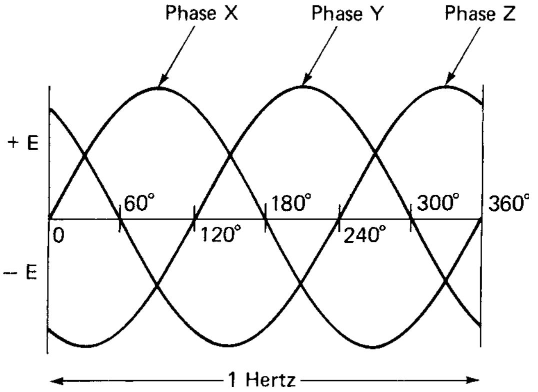

Figure 12-23 Three-phase ac waveform.

C is next to a B, and then an A is next to a C, and so on around the stator (see Fig. 12-25).

The next step is to picture the magnetic fields produced by the three phases in just one group of A, B, and C windings for 1 hertz. Start with the A phase at its maximum positive peak current value. This A winding is a north pole at its maximum strength. As the cycle progresses, the magnetic pole at A will decrease to zero as the current changes direction. It will become a south pole. The strength of the field will increase until the current reaches its greatest negative value. This produces a maximum-strength south pole, and then a decrease. It then passes through zero or neutral and becomes a maximum north pole at the end of the cycle.

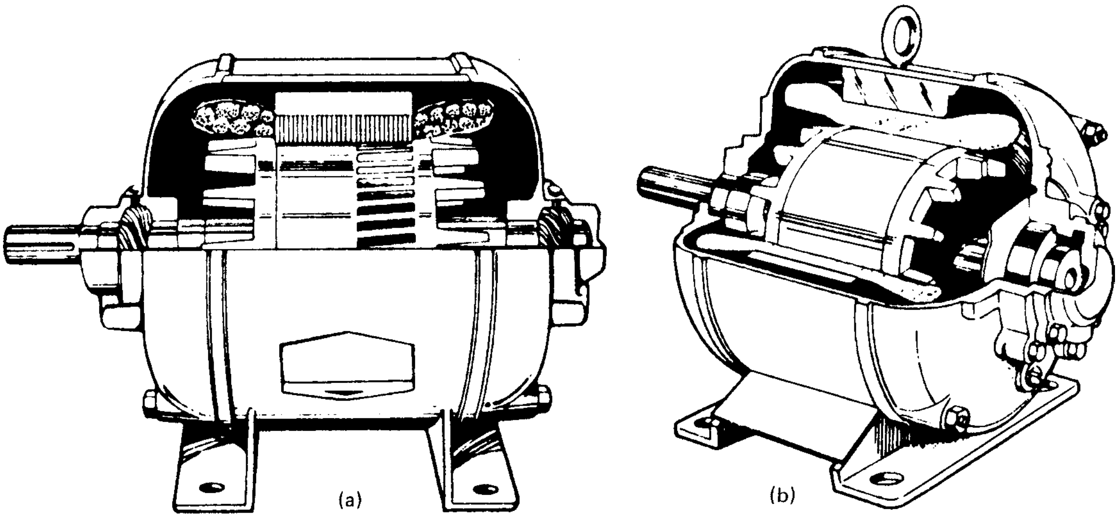

Figure 12-24 Cutaway view of a three-phase motor with (a) a half-etched squirrel-cage rotor and (b) a three-phase motor with a cast rotor.

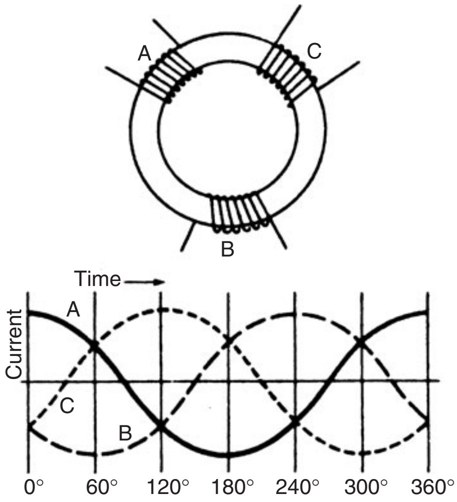

Figure 12-25 Three-phase current and coil placement in a motor.

The B phase winding does exactly the same thing, except that the rise and fall of the magnetic fields follow behind the A phase by $^{1}/_{3}$ hertz, and the C phase winding magnetic field follows behind B by $^{1}/_{3}$ hertz and the A phase by $^{2}/_{3}$ hertz.

Assume that you can see only the maximum north poles produced by each phase. Your view of the motor is from the end of a complete stator connected to a three-phase power source. The north poles will move around the stator and appear to be revolving because of the current relationship of the A, B, and C phases.

The three-phase motor has a rotor that consists of steel discs pressed onto the motor shaft. The slots or grooves are filled with aluminum and connected on the ends to form a cage for the electrical current (see Fig. 12-26). The rotating magnetic field in the stator induces current into this electrical cage, and thereby sets up north and south poles in the rotor. These north and south poles then follow their opposite members in the stator and the shaft rotates. Polyphase induction motors are often called squirrel-cage motors because of this rotor construction. This rotating field makes it possible for the motor to start without capacitors or switches. Thus, it is a simpler motor to maintain and operate.

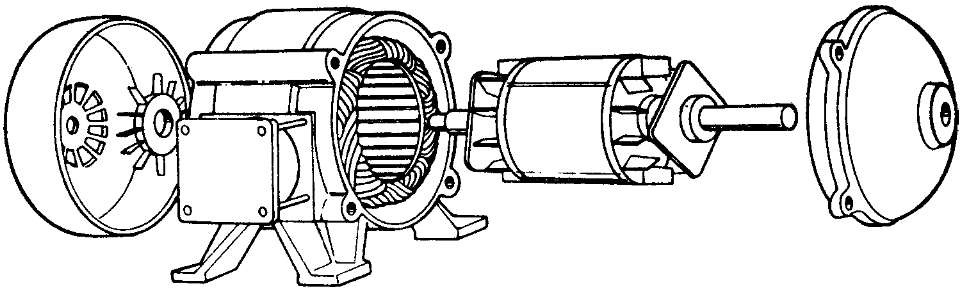

Figure 12-26 Three-phase motor with explosion-proof construction.

Reversibility. Three-phase motors can be reversed while running. It is very hard on the bearings and the driven machine, but it can be done by reversing any two of the three connections. This is usually done by a switch specially designed for the purpose.

Open phase. If a three-phase motor develops an open “leg” or one phase (two instead of three wires are coming into the motor terminal with power), it will slow down and hum noticeably. It will, however, continue to run in the same direction. If you try to start it with only two legs (or phases), it will not start but will rotate if started by hand (in fact, it will start in either direction). Once the other phase is connected, it will quickly come up to speed. The loss of one leg is usually due to a fuse in that leg blowing (that is, if there are three individual fuses in the three-phase circuit, as is normally the case).

Uses. Three-phase motors are used for machine tools, industrial pumps and fans, air compressors, and air-conditioning equipment. They are recommended wherever a polyphase power supply is available. They provide high starting and breakdown torque with smooth pull-up torque. They are efficient to operate and are designed for 208 to 220/460-volt operation with horsepower ratings from one-fourth to the hundreds.

Capacitor Ratings

You have already been introduced to capacitors that are used for starting a motor and for improving the power factor and torque characteristics of the motor. Here we would like to take a look at the ratings and the proper care of capacitors for long-time operation.

Never use a capacitor with a lower rating than specified on the original equipment. The voltage rating and the microfarad rating are important. A higher voltage rating than that specified is always usable. However, a voltage rating lower than that specified can cause damage. Make sure the capacitance marked on the capacitor in microfarads is as specified. Replace with a capacitor of the same size rated in μF, MF, UF, or MFD. All these abbreviations are used to indicate microfarads. See Table 12-1 for a listing of the start capacitors and their ratings for different voltages. Note that the capacitors are not exactly what they are rated for in microfarads. They have a tolerance and the limits are shown.

Start Capacitors and Bleeder Resistors

The development of high-power-factor, low-current, single-phase compressor motors that require start and run capacitors used with potential-type relays has created electrical peculiarities that did not exist in previous designs. In some situations, relay contacts may weld together, causing compressor motor failure. This phenomenon occurs due to the high voltage in the start capacitor discharging

Figure 12-27 Bleeder resistor across the capacitor terminals.

(arcing) across the potential relay contacts. To eliminate this, start capacitors are equipped with bleeder resistors across the capacitor terminals (see Fig. 12-27).

Bleeder resistor-equipped capacitors may not be available. Then a 2-watt, 1500-ohm resistor can be soldered across the capacitor terminals. This does not interfere with the operation of the circuit, but does allow the capacitor to discharge across the resistor instead of across the relay switch points. This resistor is called a *bleeder* because it bleeds off the capacitor charge.

Run capacitors

The marked terminal of run capacitors should be connected to the R terminal of the compressor and thus to L_2. Check the wiring diagram for the correct terminal. The run capacitor is in the circuit whenever the compressor is running. It is an oil-filled electrolytic capacitor that can take continuous use.

If the start capacitor is left in the circuit too long, in some cases the coil of the potential relay will open from vibration or use and cause the start capacitor to stay in the circuit longer than 10 to 15 seconds. This causes the electrolytic capacitor to explode or spew out its contents.

Motor Protectors

In most compressors, there is a motor protector (see Fig. 12-28). The overload protector is inserted into the motor windings so that if they overheat, the device will open the contacts of the switch. The bimetal element expands to cause the contacts to remove the power to the windings. These protectors are in addition to any circuit breakers that may be mounted outside the compressor.

Compressor Motor Relays

A hermetic compressor motor relay is an automatic switching device designed to disconnect the motor start winding after the motor has come up to running speed (see Fig. 12-29). The two types of motor relays used in refrigeration and air-conditioning compressors are the current and the potential type.

Current-type relay

The current-type relay is most often used with small refrigeration compressors up to a horsepower. Where power is applied to the compressor motor, the relay solenoid coil attracts the relay armature upward. This causes bridging contact and stationary contact to engage (see Fig. 12-30). This energizes the motor start winding. When the compressor motor comes up to running speed, the motor's main winding current is such that the relay solenoid coil de-energizes. This allows the relay contacts to drop open, which disconnects the motor start winding.

One thing to remember about this type of relay is its mounting. It should be mounted in a true vertical position so that the armature and bridging contact will drop free when the relay solenoid is de-energized.

Potential-type relay

This relay is generally used with large commercial and air-conditioning compressors (see Fig. 12-31). The motors may be capacitor-start, capacitor-run types up to 5 horsepower. Relay contacts are normally closed. The relay coil is wired across the start winding. It senses voltage change. Start winding voltages increase with motor speed. As the voltage increases to the specific pickup value, the armature pulls up, opening the relay contacts and de-energizing the start windings. After switching, there is still sufficient voltage induced in the start winding to keep the relay coil energized and the relay starting contacts open. When the

power is shut off to the motor, the voltage drops to zero. The coil is de-energized and the start contact is reset for the next start.

Many of these relays are extremely position sensitive. When changing a compressor relay, care should be taken to install the replacement in the same position as the original. Never select a replacement relay solely by horsepower or other generalized rating. Select the correct relay from the parts guide book furnished by the manufacturer.

Visual inspection can distinguish the two relays. The current relay has heavy wire for the coil and the potential relay has fine wire for the coil.

- Know how the ground-fault circuit interrupter works.
- Know where the GFCI is used.
- Know the color-coding of wiring systems.

Safety Devices

Air-conditioning, refrigeration, and heating systems all utilize the convenience of electrical controls. These devices are made with a particular application in mind. Each is designed for a specific purpose. By using low voltage in most instances to control higher voltages, the devices are suited for remote operation since the size of the wire is rather small and inexpensive to install.

Some control devices are designed to protect the technician while repairing or maintaining equipment. Certain safety procedures are necessary to make sure you do not receive a fatal electric shock. The following should be helpful in making it safe to work on electrically controlled and operated equipment.

Safety Precautions

It takes very little current to cause physical damage to the human body. In some cases, death may result from as little as one-tenth (0.1) of an ampere (see Table 13-1). You may react to a slight shock and then move quickly and come in contact with operating machinery. Involuntary actions caused by electric shock are more harmful in most instances than the actual mild shock. It is very easy to become careless. Just keep in mind that the human body has a skin

resistance of between 400,000 and 800,000 ohms. This can be used in an Ohm's law formula to determine the current

$$I = E/R$$

$$I = 120/400{,}000 = 0.3 \text{ milliamperes}$$

This is not enough to cause you to feel it. However, if you have wet hands or make contact with part of the body that is not dry, you may have a body resistance as low as 50,000 ohms and receive a current of 2.4 milliamperes. That is enough to cause you to jump back from a slight tingle. The backward movement on a roof may be enough to cause you to fall a great distance. You may also drop the equipment or tools you are working with and cause further damage. If you are working around 240 volts, the danger is greater. At 240 volts, a contact resistance of 50,000 ohms produces 4.8 milliamperes or enough to cause a heavy shock with tightening of the muscles. A low body resistance of say 200 ohms can be fatal. This can happen whenever the skin is wet or you are standing on a wet surface. With 200 ohms resistance and 120 volts current, you will receive 600 milliamperes, enough to cause death.

Main Switches

If you are working on equipment with the power on, be sure you are standing on a dry surface and your hands do not make contact with anything other than the probes being used to make measurements. It is always a good practice when working around live circuits to keep one hand in your pocket so that you will not complete the path across your chest. It is, of course, always better to have the power off when working on equipment. A good procedure is to turn off the main circuit breakers and put a sign on them so that no one turns them on without your knowledge. If there is a control box or distribution panel with a lock on it, make sure the lock is in place and locked with the lever in the down or off position (see Figs. 13-1 and 13-6). Fusing of the circuits is shown in Fig. 13-1.

Portable Electrical Tools

Grounding portable tools aids in preventing shocks and damage to equipment under certain conditions. A grounding conductor has a white-colored jacket in a two- or three-wire cable (neutral wire). It is terminated to the white- or silver-colored terminal in a plug cap or connector. And it is terminated at the neutral bar in the distribution box. Keep in mind that gray is also used to color code wires in industrial and commercial installations. Gray wires are also used for grounding.

When there is an electrical fault that allows the hot line to contact the metal housing of electrical equipment, in a typical two-wire system, or some other ungrounded conductors, any person who touches that equipment or conductor will receive a shock. The person completes the circuit from the hot line to the ground and current passes through the body. Because a body is not a good conductor, the current is not high enough to blow the fuse. Thus, the current continues to pass through the body as long as the body remains in contact with the equipment (see Fig. 13-2).

A grounding conductor, or equipment ground, is a wire attached to the housing or other conductive parts of electrical equipment that are not normally energized to carry current from them to the ground. Thus, if a person touches a part that is accidentally energized, there will be no shock, because the grounding line furnishes a much lower resistance path to the ground (see Fig. 13-3). The high current passes through the wire conductor and blows the fuses and stops the current. In normal operation, a grounding conductor does not carry current.

The grounding conductor in a three-wire conductor cable has a green jacket. The grounding conductor is always terminated at the green-colored hexhead screw on the cap or connector. It utilizes either a green-colored conductor or a metallic conductor as its path to ground. In Canada, and England, this conductor is referred to as the earthing conductor, which is somewhat more descriptive and helpful in distinguishing between grounding conductors and neutral wires, or grounded conductors.

Ground-Fault Circuit Interrupters (GFCI)

A safety device that should be used by all technicians in the field who do not have time to test out each circuit before it is used is the ground-fault circuit interrupter (GFCI). It is designed to protect you from shock.

The differential ground-fault interrupter, available in various modifications, has current-carrying conductors passing through the circular iron core of a doughnut-shaped differential transformer. As long as all the electricity passes through the transformer, the differential transformer is not affected and will not trigger the sensing circuit. If a portion of the current flows to ground and through the fault-detector line, however, the flow of electricity through the sensing windings of the differential transformer causes the sensing circuit to open the circuit breaker. These devices can be arranged to interrupt a circuit for currents of as little as 5 milliamperes flowing to ground (see Fig. 13-4).

Another design is the isolation-type ground-fault interrupter. This unit combines the safety of an isolation system with the response of an electronic sensing circuit. In this setup, an isolating transformer provides an inductive coupling between load and line. Both the hot and neutral wires are connected to the isolating transformer. There is no continuous wire connected in between.

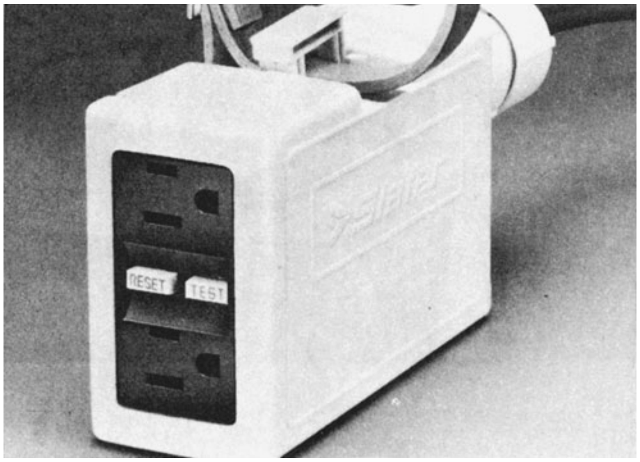

Figure 13-4 Ground-fault circuit interrupter (GFCI) used for portable tools.

In the latter type of interrupter, a ground fault must pass through the electronic sensing circuit, which has sufficient resistance to limit current flow to as low as 2 milliamperes, well below the level of human perception.

Types of Circuit Protectors

There are two types of circuit protectors made in the circuit breaker configuration. They are circuit breakers that work on the heating principle. A bimetallic strip is heated by having circuit current pass through it. When too much current flows, the strip is overheated. The expansion of the strip causes the breaker to trip, thereby causing the circuit to be opened (see Fig. 13-5). This type is slower to cool down than the magnetic type. It takes a little longer for it to cool to a point where it can be reset. If the overload still exists, the breaker will trip again.

The magnetic type uses a coil to operate. The circuit current is drawn through the coil. If too much current flows, the magnetic properties of the coil cause the circuit breaker to trip and open the circuit. This type is quicker in terms of being able to reset it. The overload must, of course, be removed before it will remain in the reset position.

To restore service when fault is cleared you simply move operating handle to "Off" position and then to "On."

Figure 13-5 Cutaway view of a circuit breaker in various positions. (Courtesy of Wadsworth)

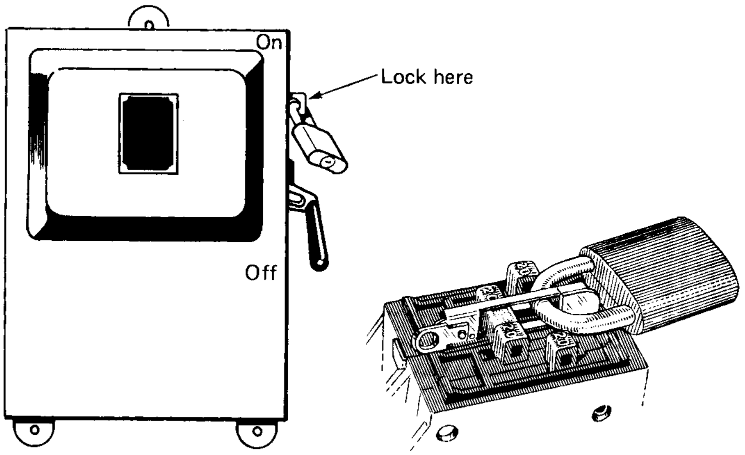

Figure 13-6 Lock the box by using a lock and keep the key until you need to unlock it.

In most cases where the power is 240 volts single-phase, the circuit breakers will be locked together with a pin. If one side of the power circuit is opened, the other circuit is also tripped since they are tied together physically.

In three-phase circuits, the three circuit breakers are tied together so that when one trips, all three circuits are disconnected from the power line.

If air-conditioning or refrigeration equipment is served by a separate box, make sure the lock is in place and the handle is in the down or off position before making an inspection or working on the equipment (see Fig. 13-6).

Many types of controls are available for use on air-conditioning, refrigeration, and heating equipment. They come in many sizes and shapes and do the job well for a period of time, but they all require periodic inspections, repairs, and replacement.

Power Relays

One of these controls is the power relay. It is one of the most often used controls for controlling compressors in refrigeration and air conditioning. The power relay is also referred to as the *main conductor*. It is used to apply the main line voltage to the motor circuit. The coil of the relay is usually operated by voltages lower than the line provides. This means that it uses a transformer for the lower control voltages. The symbols used for this type of relay are shown in Fig. 14-1.

Magnetic contactors are normally used for starting polyphase motors, either squirrel cage or single phase. Contactors may be connected at any convenient point in the main circuit between the fuses and the motor. Small control wires (using low voltage) may be run between the contactor and the point of control.

Motor start relays

Relays are a necessary part of many control and pilot-light circuits. They are similar in design to contactors, but are generally lighter in construction so they carry smaller currents.

Compressors used for household refrigerators, freezers, dehumidifiers, vending machines, and water coolers have the capacitor-start, induction-run type of motor. This type of compressor may have a circuit that resembles Fig. 14-2. When the compressor is turned on by the thermostat demanding action, the relay is closed and the start winding is in the circuit. Once the motor comes up to about 75% of rated speed, there is enough current flow through the relay coil to cause it to energize, and it pulls the contacts of the relay open, thereby taking the start capacitor and start winding out of the circuit. This allows the motor to run with one winding as designed.

Figure 14-3 shows the current type of relay. This is generally used with small refrigeration compressors up to $^3/_4$ horsepower. Figure 14-4 shows the potential

type of relay. This is generally used with large commercial and air-conditioning compressors up to 5 horsepower.

Protection of the motor against prolonged overload is accomplished by time limit overload relays. They are operative during the starting period and running period. Relay action is delayed long enough to take care of the heavy starting currents and momentary overloads without tripping.

Relays with more than one contact

Some power relays are made with more than one set of contacts. They are used to cause a sequence of events to take place. The contacts can be wired into a

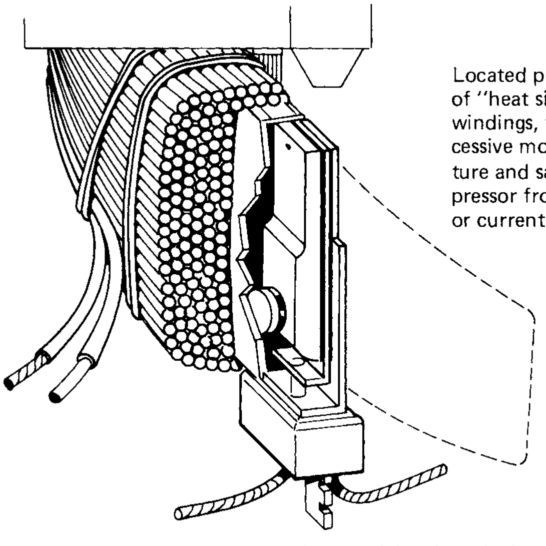
circuit that controls functions other than the on-off operation of the compressor motor (see Fig. 14-5).

Thermal overload protectors

Motors for commercial units are protected by a bimetallic switch. The switch is operated on the heat principle. This is a built-in motor overload protector (see Fig. 14-6). It limits the motor winding temperature to a safe value. In its simplest form, the switch or motor protector consists essentially of a bimetal switch mechanism that is permanently mounted and connected in series with the motor circuit (see Fig. 14-7). Figure 14-8 shows how the external line-break overload operates.



Located precisely in the center of "heat sink" portion of motor windings, this device detects excessive motor winding temperature and safely protects compressor from excessive heat and/or current draw.

Time-delay relays

In time-delay relays, bimetallic strips are heated with an electrical resistance mounted near or around them. The strips expand when heated. When they expand, they make contact and complete the circuit with their contacts closed (see Fig. 14-9). The time delay can be adjusted by the resistance of the heater unit. This type of unit is different from that shown as a protector in Fig. 14-7.

The heating element in Fig. 14-7 causes the circuit to open and protect the motor. The time-delay relay is used to make sure that certain things take place within the refrigeration cycle before another is commenced.

Solenoids

Solenoid valves are used in many heating and cooling applications. They are electrically operated. A solenoid valve, when connected as in Fig. 14-10, remains open when current is supplied to it. It closes when the current is turned off. In general, solenoid valves are used to control the liquid refrigerant flow into the expansion valve or the refrigerant gas flow from the evaporator when it or the fixture it is controlling reaches the desired temperature. The most common application of the solenoid valve is in the liquid line, and it operates with a thermostat (see Fig. 14-11).

The solenoid shown in Fig. 14-12 controls the flow of natural gas in a hot-air furnace. Note how the coil is wound around the plunger. The plunger is the core of the solenoid. It has a tendency to be sucked into the coil whenever the coil is

energized by current flowing through it. The electromagnetic effect causes the plunger to be attracted upward into the coil area. When the plunger is moved upward by the pull of the electromagnet, the soft disc is pulled upward, allowing gas to flow through the valve. This basic technique is used to control water, gasoline, oil, or any other liquid or gas.

Thermostats

Temperature control by using thermostats is common to both heating and cooling equipment. Thermostats are used to control heating circuits that cause furnaces and boilers to operate and provide heat. Thermostats are also used to control cooling equipment and refrigeration units. Each of these purposes may have its own specially designed thermostat or may use the same one. For instance, in the home you use the same thermostat to control the furnace and the air-conditioning unit.

Bellows-type thermostats

On modern condensing units, low-pressure control switches are largely superseded by thermostatic control switches. A thermostatic control consists of three main parts: a bulb, a capillary tube, and a power element or switch. The bulb is attached to the evaporator in a manner that assures contact with the evaporator. It may contain a volatile liquid, such as a refrigerant. The bulb is connected to the power element by means of a small capillary tube (see Fig. 14-13).

Operation of the bellows is provided by a change in temperature. Or the operation of the thermostatic control switch is such that, as the evaporator temperature increases, the bulb temperature also increases. This raises the pressure of the thermostatic liquid vapor. This, in turn, causes the bellows to expand and actuate an electrical contact. The contact closes the motor circuit, and the motor and compressor start operating. As the evaporator temperature decreases, the bulb becomes colder and the pressure decreases to the point where the bellows contracts sufficiently to open the electrical contacts, thus turning off the motor circuits. In this manner, the condensing unit is entirely automatic. Thus, it is

able to produce exactly the amount of refrigeration needed to meet any normal operating condition.

Bimetallic-type thermostats

Temperature changes can cause a bimetallic strip to expand or contract in step with changes in temperature. These thermostats are designed for the control of heating and cooling in air-conditioning units, refrigeration storage rooms, greenhouses, fan coils, blast coils, and similar units. This is the type used in most homes for control of the central air-conditioning and central heating system.

Figure 14-14 shows how the bimetallic strip thermostat works. Two metals, each having a different coefficient of expansion, are welded together to form a bimetallic unit or blade. With the blade securely anchored at one end, a circuit is formed and the contact points are closed. This allows the passage of an electric current through the closed points. Because an electric current provides heat in its passage through the bimetallic blade, the metals in the blade begin to expand. However, they expand at a different rate. The metals in the blade are so arranged that the one with a greater coefficient of expansion is placed at the bottom of the unit. After a certain time, the operating temperature is reached and the contact points become separated. This disconnects the device from its power source.

After a short period, the contact blade will again become sufficiently cooled to cause the contact point to join, thus reestablishing the circuit and permitting the current again to actuate the circuit. The cycle is repeated over and over again. In this way, the bimetallic thermostat prevents the temperature from rising too high or dropping too low.

Heating and cooling thermostats

Some thermostats can be used for both heating and cooling. The thermostat shown in Fig. 14-15 is such a device. The basic thermostat element has a permanently sealed, magnetic SPDT switch. The thermostat element plugs into the subbase and contains the heat anticipation, the magnetic switching, and a room

temperature thermometer. The subbase unit contains fixed cool anticipation and circuitry. This thermostat is used with 24 volts ac. In this case, the thermostatic element (bimetal) does not make direct contact with the electric circuit. Instead, the expansion of the bimetal causes a magnet to move. This, in turn, causes the switch to close or open. Figure 14-16 shows that the bimetal is not in the electric circuit.

Mercury contacts. Some thermostats use the expanding bimetal arrangement to cause a tube of mercury to move. As the mercury moves in the tube, it comes in contact with two wires inserted into the glass tube. When the mercury comes in contact with the two wires, it completes the electric circuit. This type of

thermostat needs to be so arranged that the tube of mercury is pivoted and can be moved by the expanding or contracting bimetal strip, which exerts or releases pressure on the tube of mercury.

Thermostats used in home air-conditioning and heating systems are now equipped with mercury contacts (see Fig. 14-17). They are made so that the mercury contacts two wires that control the air conditioning in one position and two wires that control the heating system in the other position (see Fig. 14-18).

The advantage of the mercury bulb type of switch is the elimination of switch contact points. Contact points are in need of constant attention. In most cases,

the dust from the air will eventually cause them to function improperly. It is necessary to clean the points by running a piece of clean paper through them to remove the dust particles and arcing residue. Since the mercury type is sealed and the arcing created on make and break of the circuit simply causes the mercury to vaporize slightly and then return to a liquid state, it provides a trouble-free switching operation.

Microprocessor thermostats

Semiconductor technology has produced another means of more accurately controlling air-conditioning and heating systems to provide better regulated temperatures in the home, office, and business. The microprocessor makes use of the semiconductor chip or integrated circuit discussed earlier in Chapter 11. All the external connections are the same as for any other type of thermostat. Only the internal circuitry has changed to provide a better regulated temperature and a variety of operations that allow you to set it for any energy-saving program desired (see Fig. 14-19). Unless a battery is included, it does not retain the program in most instances, and the clock, if there is one on the unit, has to be reset each time the power goes off.

Thermostat Adjustments

In Fig. 14-16, a cold anticipation and a heat anticipation adjustment are placed in the thermostat circuit. The heat anticipation control is placed in series with the switch. The cold anticipation resistor is placed in shunt or parallel with the switch. Thus, when the switch is closed the shunt is shorted out.

Heat anticipators

The reason for the heat anticipator is to limit the degree of swing between turning on the furnace and the temperature of the room. It is a resistance heater element that is inserted in series with the thermostat line that runs to the heat contactor coil. Once the thermostat contacts are closed, current flows through the resistor. This causes it to heat up. The heat generated by the resistor causes the thermostat to open slightly before the desired room temperature is reached by the heating system. This allows the heat in the plenum of the furnace to continue to heat the room. Thus, the resistor aids the thermostat in anticipating the amount of heat that will be provided to the room by using the heat already produced in the plenum.

Cold anticipators

The cold anticipator is a fixed resistor and is not adjustable. It heats the bimetallic coil that operates the points whenever the air-conditioner compressor is not on. When the compressor is on, the resistor is shorted out by the thermostat points being closed. The heating of the coil while the points are open causes it to close a little earlier than if it waited for the room to heat up sufficiently to cause it to turn on. This way the heat produced by the anticipator resistor causes the compressor to turn on a little before the thermostat would have normally told it to do so. By turning it on before the room has reached the selected temperature, the anticipator causes the temperature swing in the room to be reduced and makes it more comfortable.

Switches of Many Types

Many types of switches are used to limit the amount of heat produced in a furnace. The upper limit has to be controlled so that the furnace does not cause fires by overheating. Limit switches take various forms depending on the manufacturer. However, Fig. 14-20 shows a typical switch and how it works. This is a combination of fan and limit controller that combines the functions of a fan controller and a limit controller in a single unit. One sensing element is used for both controls.

Combination controllers are wired in much the same way as individual controls. These combined controls can be used on line voltage, low voltage, or self-energizing millivolt systems.

Figure 14-21 shows the fluid-filled type of capillary tube used in a limit switch. The one shown in Fig. 14-20 is the bimetal type that twists as it heats up, causing the control unit to move. These limit switches are placed in the plenum of the furnace to control when the fan goes on and off; when the plenum has reached the desired temperature, it turns off the solenoid and shuts off the flow of natural gas to the burner. Limit switches of a slightly different configuration are also used for electrical strip heaters. They may also be of the low voltage (24 volts) or line voltage type.

Pressure Control Switches

One safety feature for air-conditioning units with a compressor and condenser is a pressure-controlled switch. This switch is wired into the circuit to protect the system in case the system develops a leak. If a leak develops, it is possible to draw in moisture and air and damage the whole system. If the pressure

builds too high, it can cause a rupture of any of the joints or weaker points in the system.

A low-voltage (24-volt) relay is wired into the 240-volt line that supplies the compressor motor. The relay contacts are wired into the supply line for the motor (see Fig. 14-22). The solenoid of the relay is wired in series with two pressure-operated switches. If the pressure builds too high, the high switch will open and cause the solenoid to de-energize. If this happens, it causes the contacts of the relay to open. This removes power from the compressor motor. If the low-pressure switch opens, it will do the same thing. This way the compressor is protected from both high and low pressure, causing damage to the system.

Both manual and automatic controls are available. Automatic controls reset when the pressure is stabilized in the system. If it is not stabilized, it will again turn the system off and keep recycling until it reaches the design pressure.

Water Tower Controls

Temperature controls for refrigerating service are designed to maintain adequate head pressure with evaporative condensers and cooling towers. Low refrigerant head pressure, caused by abnormally low cooling water temperature, reduces the capacity of the refrigeration system.

Two systems of control for mechanical and atmospheric draft towers and evaporative condensers are shown in Figs. 14-23 and 14-24. The control opens the contacts when the temperature drops. These contacts are wired in series with the fan motor. Or they can be wired to the pilot of a fan-motor controller. Opening the contacts stops the fan when the cooling water temperature falls to a predetermined minimum value. This value corresponds to the minimum head pressure for proper operation. In the control system shown in Fig. 14-24, the contacts close on a temperature drop and are wired in series with a normally closed motorized valve or a solenoid valve. The contacts open the valve when low cooling temperature occurs. The cooling water then flows through a low header in the atmospheric tower. This reduces its cooling effect and the head pressure increases.

Float switches are used to control the level of water in the cooling tower. Automatic float switches provide automatic control for motors operating tank or sump pumps. They are built in several styles and can be supplied with several types of accessories that provide rod or chain operation and either wall or floor mounting. A sensor system may also be used. There are hundreds of sensor types. They usually sense the level of water by using two probes. When the water contacts the probes, it causes a small electric current (at low voltages) to flow and energize a solenoid or relay that in turn causes the water to be turned off. When the level of water is below the two probes and a complete circuit is not available, the normally closed relay contacts are closed by de-energizing the relay. This causes the water solenoid to be energized. This allows makeup water to flow into the cooling tower until it reaches the point where the probes are immersed in water and the cycle is repeated.

- Know how to troubleshoot the Pulse furnace using the flowchart provided by the manufacturer.

Hot-air furnaces are self-contained and self-enclosed units. They are usually centrally located within a building or house. Their purpose is to make sure the temperature of the interior of the structure is maintained at a comfortable level throughout. The design of the furnace is determined by the type of fuel used to fire it. Cool air enters the furnace and is heated as it comes in contact with the hot-metal heating surfaces. As the air becomes warmer, it also becomes lighter, which causes it to rise. The warmer, lighter air continues to rise until it is either discharged directly into a room, as in the pipeless gravity system, or is carried through a duct system to warm-air outlets located at some distance from the furnace.

After the hot air loses its heat, it becomes cooler and heavier. Its increased weight causes it to fall back to the furnace, where it is reheated and repeats the

cycle. This is a very simplified description of the operating principles involved in hot-air heating and it is especially typical of those involved in gravity heating systems. The forced-air system relies on a blower to make sure the air is delivered to its intended location. The blower also causes the return air to move back to the furnace faster than with the gravity system.

With the addition of a blower to the system, there must be some way of turning the blower on when needed to move the air and to turn it off when the room has reached the desired temperature. Thus, electrical controls are needed to control the blower action.

Basic Gas Furnace Operation

The gas furnace is the simplest to operate and understand. Therefore, we will use it here to look at a typical heating system. This type of natural-gas furnace is used to heat millions of homes in the United States.

Figure 15-1 is a simple circuit needed to control the furnace with a blower. Note the location of the blower switch and the limit switch. The transformer provides low voltage for control of the gas solenoid. If the limit switch opens (it is shown in a closed position), there is no power to the transformer and the gas solenoid cannot energize. This is a safety precaution because the limit switch will open if the furnace gets too hot. When the thermostat closes, it provides 24 volts to the gas solenoid, which energizes and turns on the gas. The gas is ignited by the pilot light and provides heat to the plenum of the furnace. When the air in the plenum reaches 120°F, the fan switch closes and the fan starts. The fan switch provides the necessary 120 volts to the fan motor for it to operate.

After the room has heated up to the desired thermostat setting, the thermostat opens. When it opens, the gas solenoid is de-energized, and the spring

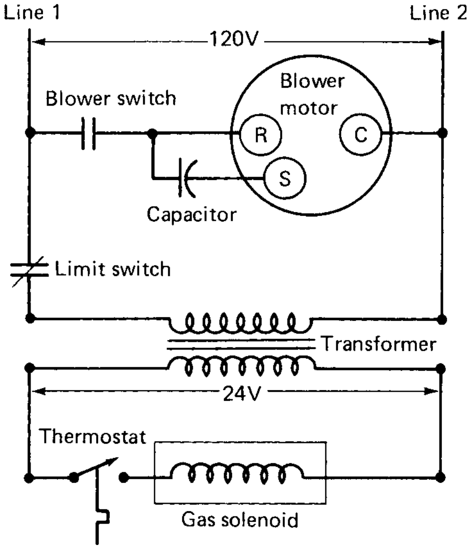

Figure 15-1 Simple one-stage furnace control system.

action of the solenoid causes it to close off the gas supply, thereby turning off the source of heat. When the plenum on top of the furnace reaches 90°F, the blower switch opens and turns off the blower. As the room cools down, causing the thermostat to once again close, the cycle starts over again. The gas solenoid opens to let in the gas and the pilot light ignites it. The heat causes the temperature to rise in the plenum above the limit switch's setting and the switch closes to start the blower. Once the thermostat has been satisfied, it opens, and causes the gas solenoid to turn off the gas supply. The blower continues to run until the temperature in the plenum reaches 90°F and it turns off the blower by opening. This cycle is repeated over and over again to keep the room or house at a desired temperature.

Basic Electric Heating System

Electric-fired heat is the only heat produced almost as fast as the thermostat calls for it. It is almost instantaneous. There are no heat exchangers to warm up. The heating elements start producing heat the moment the thermostat calls for it. A number of types of electric-fired furnaces are available. They can be bought in 5- to 35-kilowatt sizes. The outside looks almost the same as the gas-fired furnace. The heating elements are located where the heat exchangers would normally be located. Since they draw high amperage, they need electrical controls that can take the high currents.

The operating principle is simple. The temperature selector on the thermostat is set for the desired temperature. When the temperature in the room falls below this setting, the thermostat calls for heat and causes the first heating circuit in the furnace to be turned on. There is generally a delay of about 15 seconds before the furnace blower starts. This prevents the blower from circulating cool air in the winter. After about 30 seconds, the second heating circuit is turned on. The other circuits are turned on one by one in a timed sequence.

Once the temperature reaches the desired level, the thermostat opens. After a short time, the first heating circuit is shut off. The others are shut off one by one in a timed sequence. The blower continues to operate until the air temperature in the furnace drops below a specified temperature.

Basic operation

In Fig. 15-2, the electrical heating system has a few more controls than the basic gas-fired furnace. The low-resistance element used for heating draws a lot of current, so the main contacts have to be of sufficient size to handle the current.

The thermostat closes and completes the circuit to the heating sequencer coil. The sequencer coil heats the bimetal strip that causes the main contacts to close. Once the main contacts are closed, the heating element is in the circuit and across the 240-volt line. The auxiliary contacts will also close at the same time as the main contacts. When the auxiliary contacts close, they complete the low-voltage circuit to the fan relay. The furnace fan will be turned on at this time.

Once the thermostat has been satisfied, it opens. This allows the heating sequencer coil to cool down slowly. Thus, the main contacts do not open immediately to remove the heating element from the line. So the furnace continues to produce heat after the thermostat has been satisfied. The bimetal cools down in about 2 minutes. Once it cools, it opens the main and auxiliary contacts, which removes the heating element from the line and also stops the fan motor. After the room cools down below the thermostat setting, the thermostat closes and starts the sequence all over again.

Ladder Diagrams

Electrical schematics are used to make it simple to trace the circuits of various devices. Some of these can appear complicated, but they are usually very simple when you start at the beginning and wind up at the end. The beginning is one side of the power line and the end is the other side of the line. What happens in between is that a number of switches are used to make sure the device turns on or off when it is supposed to cool, freeze, or heat.

The ladder diagram makes it easier to see how these devices are wired. It consists of two wires drawn parallel and representing the main power source. Along each side you find connections. By simply looking from left to right, you are able to trace the required power for the device. Symbols are used to represent the devices. There is usually a legend on the side of the diagram to tell you, for example, that CC means compressor contactor, EFR means evaporator fan relay, and HR means heating relay (see Fig. 15-3).

Take a look at the thermostat in Fig. 15-3. The location of the switch determines whether the evaporator fan relay coil, the compressor contactor coil, or the heating relay coil is energized. Once the coil of the EFR is energized by having the thermostat turned to make contact with the desired point (G), it closes the points in the relay and the evaporator fan motor starts to move. This means that the low voltage (24 volts) has energized the relay. The relay energizes and closes the EFR contacts located in the high-voltage (240 volts) circuit. If the thermostat is turned to W or the heating position, it will cause the heating relay coil to be energized when the thermostat switch closes and demands

heat. The energized heating relay coil causes the HR contacts to close, which in turn places the heating element across the 240-volt line and it begins to heat up. Note that the HR contacts are in parallel with the evaporator fan relay contacts. Thus, the evaporator fan will operate when either the heating relay or the evaporator fan relay is energized.

Manufacturer's Diagrams

Figure 15-4 shows how the manufacturer represents the location of the various furnace devices. The solid lines indicate the line voltage to be installed. The dotted lines are the low voltage to be installed when the furnace is put into service.

The motor is four speed. It has various colored leads to represent the speeds. You may have to change the speed of the motor to move the air to a given location. Most motors come from the factory with a medium-high speed selected. The speed is usually easily changed by removing a lead from one point and placing it on another where the proper color is located. In the schematic of Fig. 15-5, the fan motor has white connected to one side of the 120-volt line (neutral), and the red and black are switched by the indoor blower relay to black for the cooling speed and red for the heating speed. It takes a faster fan motor to push cold air than that required for hot air because cold air is heavier than hot air.

In Fig. 15-5, the contacts on the thermostat are labeled R, W, Y, G, R, and W are used to place the thermostat in the circuit. It can be switched from W to Y manually by moving the Heat-Cool switch on the thermostat to Cool position.

Notice in Fig. 15-5 that the indoor blower relay coil is in the circuit all the time when the "auto on" switch on the thermostat is located at the "on" position. The schematic also shows the cool position has been selected manually, and the thermostat contacts will complete the circuit when it moves from W1 to Y1.

Figure 15-5 Schematic for a hot-air installation.

In Fig. 15-4, note that the low-voltage terminal strip has a T on it. This is the common side of the low voltage from the transformer. In Fig. 15-5, the T is the common side of the low-voltage transformer secondary. In Fig. 15-4, the T terminal is connected to the compressor contactor by a wire run from the terminal to the contactor. Note that the other wire to the contactor runs from Y on the terminal strip. Now go back to Fig. 15-5, where the Y and T terminals are shown as connection points for the compressor contactor. Are you able to relate the schematic to the actual device? The gas valve is wired by having wire T of the terminal strip attached to one side of the solenoid and a wire run from the limit switch to the other side of the solenoid.

Figure 15-6 shows how the wiring diagram comes from the factory. It is usually located inside the cover for the cold-air return. In most instances, it is glued to the cover so that it is handy for the person working on the furnace whenever there is a problem after installation.

Field Wiring

The installation of a new furnace requires you to follow a factory diagram furnished in a booklet that accompanies the unit. The wiring to be done in the field is represented by the dotted lines in Fig. 15-7. All electrical connections should be made in accordance with the National Electrical Code and any local codes or ordinances that might apply.

WARNING: *The unit cabinet must have an uninterrupted or unbroken electrical ground to minimize personal injury if an electrical fault should occur. This may consist of electrical wire or approved conduit when installed in accordance with existing electrical codes.*

Low-Voltage Wiring

Make the field low-voltage connections at the low-voltage terminal strip shown in Fig. 15-7. Set the thermostat heat anticipator at 0.60 ampere (or whatever is called for by the manufacturer). If additional controls are connected in the thermostat circuit, their amperage draw must be added to this setting. Failure to make the setting will result in improper operation of the thermostat.

With the addition of an automatic vent damper, the anticipator setting would then be 0.12 ampere. As you can see from this and the schematic (see Fig. 14-16), the anticipator resistor is in series with whatever is in the circuit and is to be controlled by the thermostat. The more devices controlled by the thermostat, the more current will be drawn from the transformer to energize them. As the current demand increases, the current through the anticipator is also increased. As you remember from previous chapters, a series circuit has the same current through each component in the circuit.

Thermostat location. The room thermostat should be located where it will be in the natural circulating path of room air. Avoid locations where the thermostat

is exposed to cold-air infiltration, drafts from windows, doors, or other openings leading to the outside, or air currents from warm- or cold-air registers, or to exposure where the natural circulation of the air is cut off, such as behind doors and above or below mantels or shelves. Also keep the thermostat out of direct sunlight.

The thermostat should not be exposed to heat from nearby fireplaces, radios, televisions, lamps, or rays from the sun. Nor should the thermostat be mounted on a wall containing pipes or warm-air ducts or a flue or vent that could affect its operation and prevent it from properly controlling the room temperature. Any hole in the plaster or panel through which the wires pass from the thermostat should be adequately sealed with suitable material to prevent drafts from affecting the thermostat.

Printed circuit board control center. Newer hot-air furnaces feature printed circuit control. The board shown in Fig. 15-8 is such that it is easy for the technician installing the furnace to hook it up properly the first time. The markings are designed for making it easy to connect the furnace for accessories, if needed. Figures 15-9 and 15-10 show the factory-furnished schematic. See if you can trace the schematic and locate the various points on the printed circuit boards.

Heat Pumps

The heat pump is a heat multiplier. It takes warm air and makes it hot air. This is done by compressing the air and increasing its temperature. Heat pumps received more attention during the fuel embargo of 1974 with some emphasis being placed on them now. Energy conservation has become a more important concern for everyone. If a device can be made to take heat from the air and heat a home or commercial building, it is very useful.

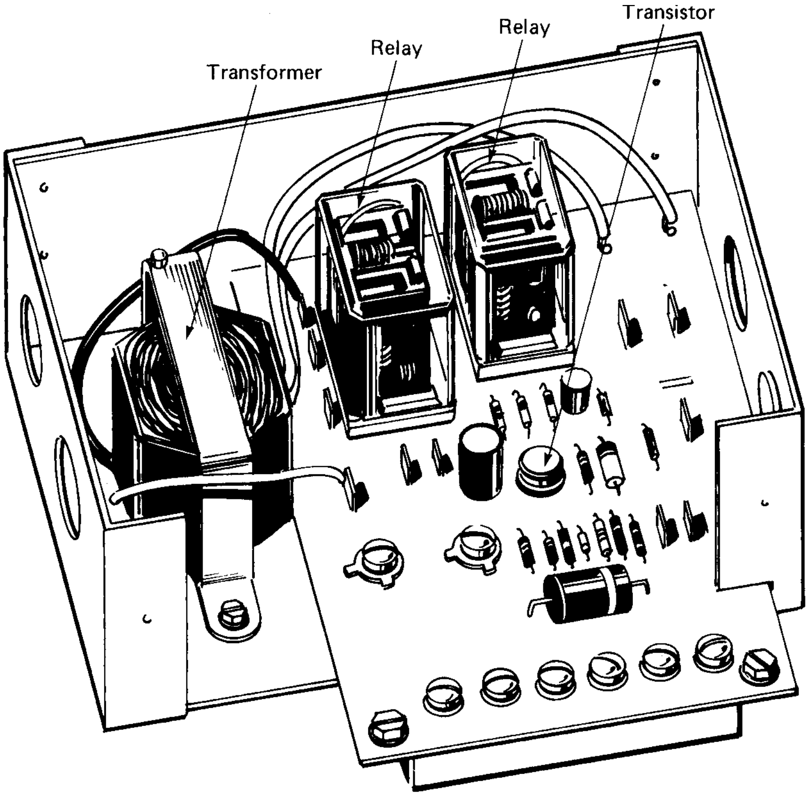

Figure 15-8 Printed circuit control center: heat and cool models. (Courtesy of Carrier)

The heat pump can take the heat generated by a refrigeration unit and use it to heat a house or room. Most of them take the heat from outside the home and move it indoors (see Fig. 15-11). This unit can be used to air condition the house in the summer and heat it in the winter by taking the heat from the outside air and moving it inside.

Operation

On mild temperature heating days, the heat pump handles all heating needs. When the outdoor temperature reaches the balance point of the home, that is, when the heat loss is equal to the heat-pump heating capacity, the two-stage indoor thermostat activates the furnace (a secondary heat source, in most cases electric heating elements). As soon as the furnace is turned on, a heat relay de-energizes the heat pump. When the second-stage (furnace) need is satisfied and the plenum temperature has cooled to below 90 and 100°F, the heat-pump relay turns the heat pump back on and controls the conditioned space until the

second-stage operation is required again. Figure 15-12 shows the heat-pump unit. The optional electric heat unit shown in Fig. 15-13 is added in geographic locations where needed. This particular unit can provide 23,000 to 56,000 Btus per hour (Btuh) and up to 112,700 Btuh with the addition of electric heat.

If the outdoor temperature drops below the setting of the low-temperature compressor monitor, the control shuts off the heat pump completely and the furnace handles all the heating needs.

During the defrost cycle, the heat pump switches from heating to cooling. To prevent cool air from being circulated in the house when heating is needed, the

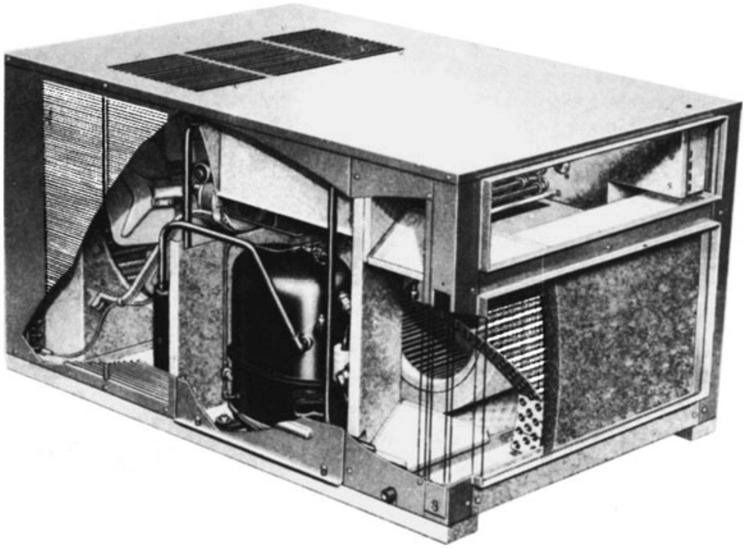

Figure 15-12 Single package heat pump.

control will automatically turn on the furnace to compensate for the heat-pump defrost cycle (see Fig. 15-14). When supply air temperature climbs above 110 to 120°F, the defrost limit control turns off the furnace and keeps indoor air from getting too warm.

If, after a defrost cycle, the air downstream of the coil gets above 115°F, the closing point of the heat-pump relay, the compressor will stop until the heat exchanger has cooled down to 90° to 100° as it does during normal cycling operation between furnace and heat pump.

During summer cooling, the heat pump works as a normal split system, using the furnace blower as the primary air mover (see Fig. 15-15).

In a straight heat pump/supplementary electric heater application, at least one outdoor thermostat is required to cycle the heaters as the outdoor temperature drops. In the system shown here, the indoor thermostat controls the supplemental heat source (furnace). The outdoor thermostat is not required.

Figure 15-13 Optional electric heat for a heat pump.

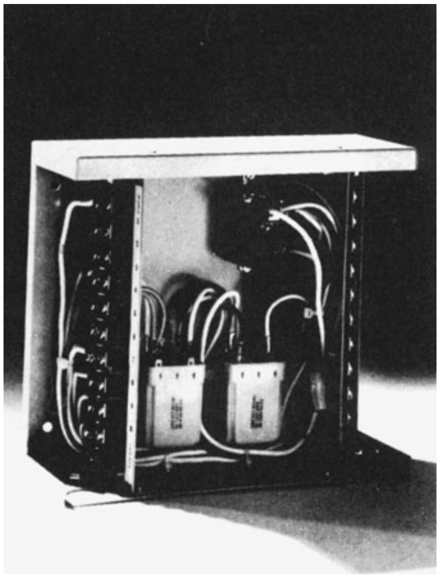

Figure 15-14 Control box for an add-on type heat pump.

Since the furnace is serving as the secondary heat source, the system does not require the home rewiring usually associated with supplemental electric strip heating.

Special requirements of heat-pump systems

The installation, maintenance, and operating efficiency of the heat-pump system are like those of no other comfort system. A heat-pump system requires the same air quantity for heating and cooling. Because of this, the air-moving capability of an existing furnace is extremely important. It should be carefully

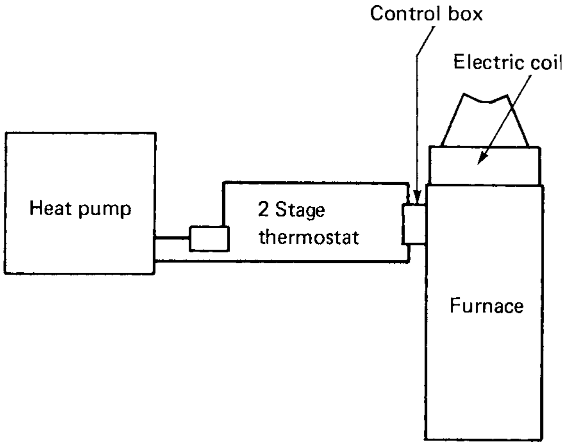

Figure 15-15 Heat pump with a two-stage thermostat and control box mounted on the furnace.

checked before a heat pump is added. Heating and load calculations must be accurate. System design and installation must be precise and according to the manufacturer's suggestions.

The air-distribution system and diffuser location are equally important. Supply ducts must be properly sized and insulated. Adequate return air is also required. Heating supply air is cooler than with other systems. This is quite noticeable to homeowners accustomed to gas or oil heat. This makes diffuser location and system balancing critical.

Heat-pump combinations

There are four ways to describe the heat-pump methods of transporting heat into the house:

1. *Air-to-air:* This is the most common method. It is the type of system previously described.
2. *Air-to-water:* This type uses two different types of heat exchangers. Warmed refrigerant flows through pipes to a heat exchanger in the boiler. Heated water flows into radiators located within the heated space.
3. *Water-to-water:* This type uses two water-to-refrigerant heat exchangers. Heat is taken from the water source (well water, lakes, or the sea) and is passed on by the refrigerant to the water used for heating. The reverse takes place in the cooling system.
4. *Water-to-air:* Well water furnishes the heat. This warms the refrigerant in the heat-exchanger coil. The refrigerant, compressed, flows to the top of the unit, where a fan blows air past the heat exchanger.

Each type of heat pump has its advantages and disadvantages. Each needs to be properly controlled. This is where the electrical connections and controls are used to do the job properly. Before attempting to work on this type of equipment, make sure you have a complete schematic of the electrical wiring and know all the component parts of the system.

High-Efficiency Furnaces

Furnaces have been designed (since 1981) with efficiencies of up to 97%, as compared to older types with efficiencies in the 60% range. The Lennox Pulse is one example of the types available. The G14 series pulse combustion up-flow gas furnace provides efficiency of up to 97%. Eight models for natural gas and LPG are available with input capacities of 40,000, 60,000, 80,000, and 100,000 Btuh. The units operate on the pulse-combustion principle and do not require a pilot burner, main burners, conventional flue, or chimney. Compact, standard-sized cabinet design, with side or bottom return air entry, permits installation in a basement, utility room, or closet. Evaporator coils may be added, as well as electronic air cleaners and power humidifiers (see Fig. 15-16).

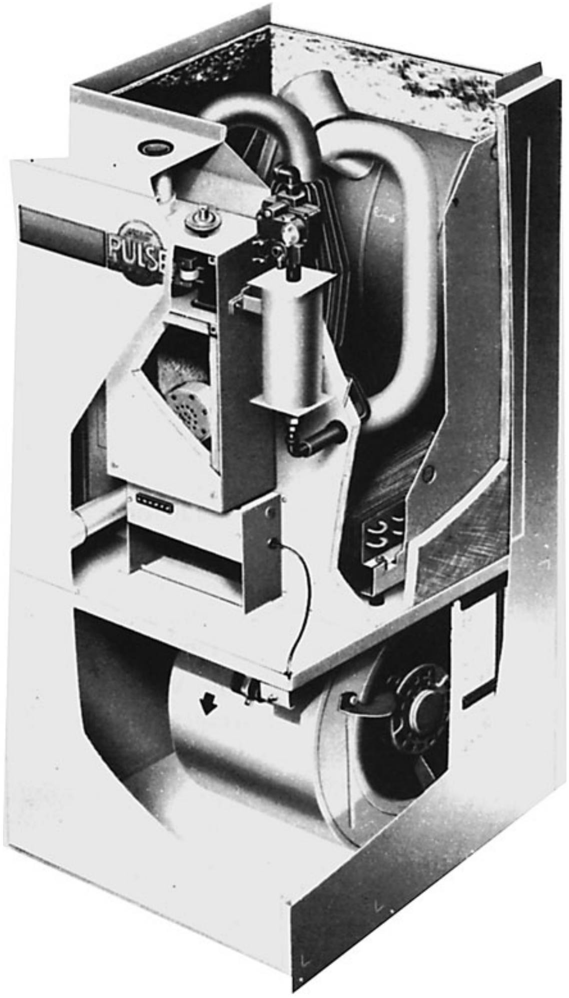

Figure 15-16 Lennox Pulse furnace. (Courtesy of Lennox)

Operation

The high-efficiency furnaces achieve a high level of fuel conversion by using a unique heat-exchanger design. It features a finned cast-iron combustion chamber, temperature-resistant steel tailpipe, aluminized steel exhaust de-coupler section, and a finned stainless-steel tube condenser coil similar to an air-conditioner coil. Moisture, in the products of combustion, is condensed in the coil, thus wringing almost every usable Btu out of the gas. Since most of the combustion heat is utilized in the heat transfer from the coil, flue vent temperatures are as low as 100 to 130°F, allowing for the use of 2-inch diameter polyvinyl chloride (PVC) pipe. The furnace is vented through a sidewall or roof or to the top of an existing chimney with up to 25 feet of PVC pipe and four 90° elbows. Condensate created in the coil

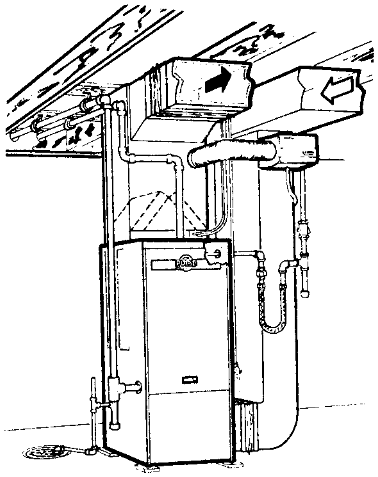

Figure 15-17 Basement installation of the Pulse with cooling coil and automatic humidifier. Note the floor drain for condensate. (Courtesy of Lennox)

may be disposed of in an indoor drain (see Fig. 15-17). The condensate is not harmful to standard household plumbing and can be drained into city sewers and septic tanks without damage.

The furnace has no pilot light or burners. An automotive-type spark plug is used for ignition on the initial cycle only, saving gas and electrical energy. Due to the pulse-combustion principle, the use of atmospheric gas burners is eliminated, with the combustion process confined to the heat-exchanger combustion chamber. The sealed combustion system virtually eliminates the loss of conditioned air due to combustion and stack dilution. Combustion air from the outside is piped to the furnace with the same type of PVC pipe used for exhaust gases.

Electrical controls

The furnace is equipped with a standard-type redundant gas valve in series with a gas expansion tank, gas intake flapper valve, and air intake flapper valve. Also factory installed are a purge blower, spark plug igniter, and flame sensor with solid-state control circuit board. The standard equipment includes a fan and limit control, a 30-VA transformer, blower cooling relay, flexible gas line connector, and four isolation mounting pads, as well as a base insulation pad, condensate drip leg, and cleanable air filter. Flue vent/air intake line, roof or wall termination installation kits, LPG conversion kits, and thermostat are available as accessories and must be ordered extra, or you can use the existing one when replacing a unit.

The printed circuit board is replaceable as a unit when there is a malfunction of one of the components. It uses a multivibrator transistorized circuit to generate the high voltages needed for the spark plug. The spark plug gets very little use except to start the combustion process. It has a long life expectancy. Spark gap is 0.115 inch and the ground electrode is adjusted to 45° (see Fig. 15-20).

Sequence of operation

On a demand for heat, the room thermostat initiates the purge blower operation for a prepurge cycle of 34 seconds, followed by energizing of the ignition and opening of the gas valve. As ignition occurs, the flame sensor senses proof of ignition and de-energizes the spark igniter and purge blower (see Fig. 15-18). The furnace blower operation is initiated 30 to 45 seconds after combustion ignition. When the thermostat is satisfied, the gas valve closes and the purge blower is re-energized for a postpurge cycle of 34 seconds. The furnace blower remains in operation until the preset temperature setting (90°F) of the fan control is reached. Should the loss of flame occur before the thermostat is satisfied, flame sensor controls will initiate three to five attempts at reignition before locking out the unit operation. In addition,

loss of either combustion intake air or flue exhaust will automatically shut down the system.

Combustion process

The process of pulse combustion begins as gas and air are introduced into the sealed combustion chamber with the spark plug igniter. Spark from the plug ignites the gas/air mixture, which in turn causes a positive pressure buildup that closes the gas and air inlets. This pressure relieves itself by forcing the products of combustion out of the combustion chamber through the tailpipe into the heat-exchanger exhaust de-coupler and on into the heat-exchanger coil. As the combustion chamber empties, its pressure becomes negative, drawing in air and gas for ignition of the next pulse. At the same instant, part of the pressure pulse is reflected back from the tailpipe at the top of the combustion chamber. The flame remnants of the previous pulse of combustion ignite the new gas/air mixture in the chamber, continuing the cycle.

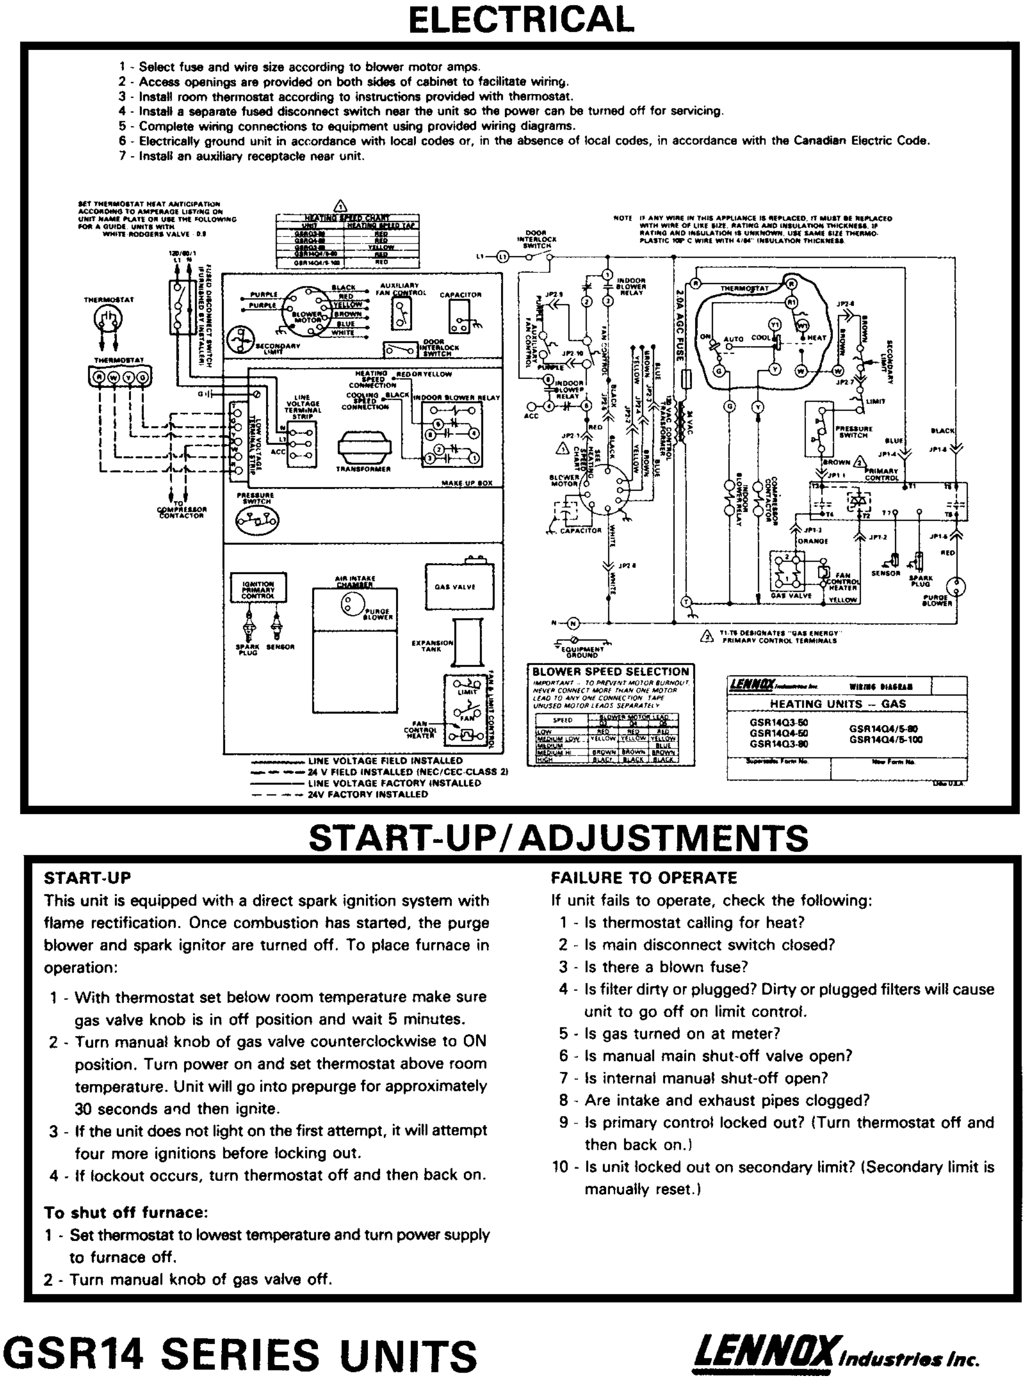
Once combustion is started, it feeds on itself, allowing the purge blower and spark igniter to be turned off. Each pulse of gas/air mixture is ignited at the rate of 60 to 70 times per second, producing one-fourth to one-half Btu per pulse of combustion. Almost complete combustion occurs with each pulse. The force of these series of ignitions creates great turbulence, which forces the products of combustion through the entire heat-exchanger assembly, resulting in maximum heat transfer (see Fig. 15-18).

Start-up procedures for the GSR-14Q series of Pulse furnaces, as well as maintenance and repair parts, are shown in Fig. 15-19.

Troubleshooting the Pulse Furnace

Troubleshooting procedures for the Pulse furnaces are shown in Fig. 15-20. Figure 15-21 shows the circuitry for the G-14Q series of furnaces. Note the difference in the electrical circuitry for the G-14 and GSR-14. Blower speed color-coded wires are also indicated for the different units. The 40, 60, 80, and 100 after the G-14Q indicates whether it is a 40,000, 60,000, 80,000, or 100,000 Btuh unit. Thermostat heat anticipation is also given for the Robertshaw valve and the Rodgers valve. This type of electrical diagram is usually glued to the cabinet so that it is with the unit whenever there is need for troubleshooting.

The troubleshooting flowchart is typical of those furnished with newer equipment in the technical manuals furnished the dealers who provide the service. After locating the exact symptoms, check with the other part of Fig. 15-20 to find how to use the multimeter to check out all the circuitry to see if the exact cause of the problem can be determined.



ELECTRICAL

1 - Select fuse and wire size according to blower motor amps.
2 - Access openings are provided on both sides of cabinet to facilitate wiring.
3 - Install room thermostat according to instructions provided with thermostat.
4 - Install a separate fused disconnect switch near the unit so the power can be turned off for servicing.
5 - Complete wiring connections to equipment using provided wiring diagrams.
6 - Electrically ground unit in accordance with local codes or, in the absence of local codes, in accordance with the Canadian Electric Code.
7 - Install an auxiliary receptacle near unit.

START-UP/ADJUSTMENTS

START-UP

This unit is equipped with a direct spark ignition system with flame rectification. Once combustion has started, the purge blower and spark ignitor are turned off. To place furnace in operation:

1 - With thermostat set below room temperature make sure gas valve knob is in off position and wait 5 minutes.
2 - Turn manual knob of gas valve counterclockwise to ON position. Turn power on and set thermostat above room temperature. Unit will go into prepurge for approximately 30 seconds and then ignite.
3 - If the unit does not light on the first attempt, it will attempt four more ignitions before locking out.
4 - If lockout occurs, turn thermostat off and then back on.

To shut off furnace:

1 - Set thermostat to lowest temperature and turn power supply to furnace off.
2 - Turn manual knob of gas valve off.

FAILURE TO OPERATE

If unit fails to operate, check the following:

1 - Is thermostat calling for heat?
2 - Is main disconnect switch closed?
3 - Is there a blown fuse?
4 - Is filter dirty or plugged? Dirty or plugged filters will cause unit to go off on limit control.
5 - Is gas turned on at meter?
6 - Is manual main shut-off valve open?
7 - Is internal manual shut-off open?
8 - Are intake and exhaust pipes clogged?
9 - Is primary control locked out? (Turn thermostat off and then back on.)
10 - Is unit locked out on secondary limit? (Secondary limit is manually reset.)

ADJUSTMENTS (CONT.)

GAS FLOW

To check proper gas flow to combustion chamber, determine BTU input from the appliance rating plate. Divide this input rating by the BTU per cubic foot of available gas. Result is the number of cubic feet per hour required. Determine the flow of gas through gas meter for 2 minutes and multiply by 30 to get the hourly flow of gas to burner.

GAS PRESSURE

1 - Check gas line pressure with unit firing at maximum rate. Normal natural gas inlet line pressure should be 7.0 in. (178 mm) w.c. Normal line pressure for LP gas is 11 in. (280 mm) w.c.
IMPORTANT - Minimum gas supply pressure is listed on unit rating plate for normal input. Operation below minimum pressure may cause nuisance lockouts.

2 - After line pressure is checked and adjusted, check regulator pressure. Correct manifold pressure (unit running) is specified on nameplate. To measure, connect gauge to pressure tap in elbow below expansion tank.

TEMPERATURE RISE AND EXTERNAL STATIC PRESSURE

Check temperature rise and external static pressure. If necessary, adjust blower speed to maintain temperature rise and external static pressure within range shown on unit rating plate.

ELECTRICAL

1 - Check all wiring for loose connections.
2 - Check for correct voltage at unit (unit operating).
3 - Check amp-draw on blower motor.
Motor Nameplate__________Actual__________

NOTE - Do not secure electrical conduit directly to duct work or structure.

BLOWER SPEEDS

Multi-tap drive motors are wired for different heating and cooling speeds. Speed may be changed by simply interchanging motor connections at indoor blower relay and fan control. Refer to speed selection chart on unit wiring diagram.

CAUTION - To prevent motor burnout, never connect more than one (1) motor lead to any one connection. Tape unused motor leads separately.

MAINTENANCE

NOTE - Disconnect power before servicing.

ANNUAL MAINTENANCE

At the beginning of each heating season, system should be checked by qualified serviceman as follows:

A - Blower
1 - Check and clean blower wheel.
2 - Check motor lubrication.
Always relubricate motor according to manufacturer's lubrication instructions on each motor. If no instructions are provided, use the following as a guide:
  a - Motors Without Oiling Ports — Prelubricated and sealed. No further lubrication required.
  b - Direct Drive Motors with Oiling Ports — Prelubricated for an extended period of operation. For extended bearing life, relubricate with a few drops of SAE No. 10 non-detergent oil once every two years. It may be necessary to remove blower assembly for access to oiling ports.

B - Electrical
1 - Check all wiring for loose connections.
2 - check for correct voltage at unit (unit operating).
3 - Check amp-draw on blower motor.
Motor nameplate ________ Actual ________
4 - Check to see that heat tape (if applicable) is operating.

C - Filters
1 - Filters must be cleaned or replaced when dirty to assure proper furnace operation.
2 - Reusable foam filters supplied with GSR14 can be washed with water and mild detergent. They should be sprayed with filter handicoater when dry prior to reinstallation. Filter handicoater is RP products coating No. 481 and is available as Lennox part No. P-8-5069.
3 - If replacement is necessary, order Lennox part No. P-8-7831 for 20 X 25 inch (508 X 635 mm) filter.

D - Intake and Exhaust Lines

Check intake and exhaust PVC lines and all connections for tightness and make sure there is no blockage. Also check condensate line for free flow during operation.

E - Insulation

Outdoor piping insulation should be inspected yearly for deterioration. If necessary, replace with same materials.

Air-Conditioning Circuits

Performance Objectives

- Know what is meant by modes of cooling.
- Know where the temperature sensor is located on an air conditioner.
- Know how to adjust the fan speed on an air conditioner.
- Know what an auxiliary winding does.
- Know the purpose of a run capacitor in the compressor circuit.
- Know how to read a ladder diagram.
- Know the function of the AUTO and ON positions of a thermostat.
- Know how the overload protector works in an air conditioner compressor motor.
- Know how to troubleshoot an air conditioner using a troubleshooting chart.

Circuits for air-conditioning units vary slightly with the manufacturer. The best source for schematics of the electrical system is the manufacturer's service manuals and bulletins. In this chapter we will be concerned primarily with the circuits of domestic (home) air-conditioning equipment.

Basic Air-Conditioning Unit

The basic or simple air-conditioning unit consists of a plug, a thermostat, overload protector, compressor, condenser, evaporator, capacitors for the motors, and some kind of switching for control of the fan motor.

The shaft on the fan motor usually extends from both ends of the motor. A fan blade is attached to one end to cool the condenser, and another fan blade is attached to the other end of the motor to cause air to flow over the evaporator

and cool the room. This way only one motor is used. This is the type of arrangement most often encountered in the window air conditioner.

The air-conditioning unit that fits into the window (see Fig. 16-1) usually has at least two speeds. The fan is used in some cases without the compressor running. Thus, there are three modes of cooling: (1) fan only, (2) fan at high speed and cooling furnished by the compressor, and (3) fan at low speed and cooling furnished by the compressor. This basic window unit consists of the compressor, the fan motor, the thermostat, and push buttons for the selection of the type of cooling desired (see Fig. 16-2).

Push-button switches

The push-button switches that operate the window unit usually resemble those in Fig. 16-3. If the unit has a two-speed fan and a compressor that operates in conjunction with the high- and low-speed fan positions, it will have an OFF button that disengages the push buttons that are depressed, and thereby opens the circuit and turns off the power to both compressor and fan.

The thermostat is variable by twisting a knob. This moves the bimetallic strips closer together to provide the proper operation of the thermostat in relation to the room temperature. Thermostats can have a number of design configurations, depending on the manufacturer. The knobs differ slightly, but basically the thermostat is the same for all window units. The temperature sensor located on the inlet side of the evaporator senses the air returned to the air conditioner from the room being conditioned.

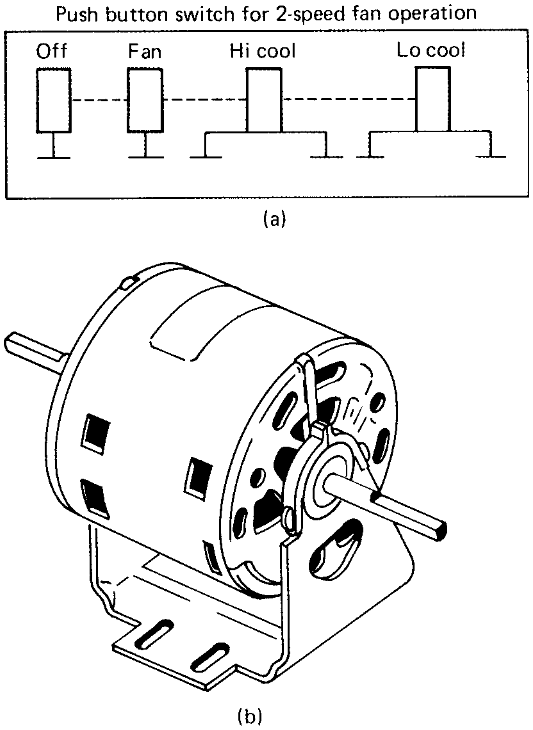

Figure 16-3 (a) Push-button switches used in a window unit for fan and compressor control. (b) Fan with double shaft. Used in window units with a blade on each end.

Fans

The fan is two speed. It has an auxiliary winding with a capacitor in series with it. The run windings are arranged so that when one of them is in the circuit it runs at high speed. When the two run windings are placed in series, it slows down and the fan speed is LO. This permanent split-capacitor (PSC) motor is commonly used in two- or three-speed configurations for fans.

Schematics

To be able to troubleshoot this type of window unit, it is necessary to know how each control functions and what will happen when each malfunctions. The best way to understand the unit is to look at the schematic in Fig. 16-2, and trace it out.

Tracing it out will result in Fig. 16-4. In Fig. 16-4a, you can see how one side of the power source is connected to the fan motor C and run capacitor. Then it goes to the run capacitor on the compressor and the R connection of the compressor. This completes the line for one side of the power. But, for anything to work electrically, two sides of the power line must be taken into consideration.

Figure 16-4 (*Continued*)

It takes both sides to cause the circuit to be complete. Now let's look at the other line as seen in Fig. 16-4b.

All the controls are in this other line. The push-button switch has an "off" button, a "fan only" button, a "hi cool" button, and a "lo cool" button. Each of these has a definite circuit that must be traced out to aid in troubleshooting later when possible switching problems develop.

Figure 16-4c shows the "fan only" circuit. Push-button B is depressed. It makes contact with 1 and 2 on the switch block. This completes the other side of the power line through the switch to the high connection of the fan motor. Thus, power is now available to cause the "hi winding" of the fan motor to be energized. The "aux winding" is also completed to the power line at this time, and the fan motor runs. However, this is the only thing operational in the window unit at this time. The fan is sometimes needed to circulate air in the room when a number of people are assembled. The fan only is often all that is needed to keep the room cool. Keep in mind that the thermostat is not in the circuit, so the fan will run until it is turned off by depressing the "off button."

Figure 16-4d shows how the compressor is operated with a demand for "hi cool." The hi cool push button is depressed and it completes the circuit from 3 and 4 to the hi side of the fan motor. The fan runs. Hi cool also is so arranged that the push button will complete the circuit from 5 to 6. The 5 and 6 combination completes the circuit to the thermostat and, if it is closed, on to the overload and to the compressor motor. The compressor will now run while the fan is also running. Once the thermostat opens (the room has cooled down to where the thermostat has been adjusted), the compressor is turned off. However, as long as the hi cool button is depressed, the fan motor will continue to operate. The compressor is cycled on and off by the demands of the thermostat. The fan will continue to run until the off button is depressed to mechanically push up the hi cool switch.

Figure 16-4e shows the completed circuit for the “lo cool” position of the push buttons. Note how terminals 7 and 8 are connected to complete the circuit to the lo position of the fan motor. This means that the two main run windings of the fan motor are now in series. This causes the fan motor to run at a slower speed than when only one winding is in the circuit.

Terminals 9 and 10 are used to complete the circuit to cause the compressor to operate. Here, again, the fan runs at lo speed all the time, whether the compressor operates or not. The compressor operates at the command of the thermostat.

To troubleshoot the unit, you should understand how it operates when all systems are functional. Then the symptoms can be traced to either the refrigerant system or electrical system.

Here we are primarily interested in the problems associated with the electrical system. Problems are shown in Table 16-1, which covers both systems. Note how many of the problems are electrical.

Window units with three-speed fans are also available. All you do is place windings in series with one another to reduce the fan speed. The push buttons do the same things as just explained for the two-speed unit. In larger compressors for 18,000 Btu units, a start potential relay is used to switch on the start winding. A start capacitor is placed in and out of the circuit as required, and the run capacitor stays in the circuit. This type of arrangement is discussed in detail in Chapter 17 for refrigerators.

Ladder Diagrams

Ladder diagrams make it easier to visualize the circuitry. The two power lines are drawn parallel with one another and the components are connected between the two lines to complete the various system circuits (see Fig. 16-5).

Another air-conditioning unit is shown in Fig. 16-5. It utilizes 220 to 240 volts and is wired into the line permanently. This type of unit usually becomes part of a hot-air type of furnace and provides cooling in the summer and heating in the winter. The evaporator is located in the plenum of the furnace, and the blower motor is used to move air over the evaporator during the air-conditioning season and move the hot air in the plenum from the furnace during the winter.

Thermostats

The thermostat is in the cool position. This means that when the room reaches a high temperature, the thermostat closes. Once the thermostat closes, the circuit to the compressor contactor (CC) relay is completed. The CC contacts are closed

Problem	Probable cause	Remedy
Compressor won't start.	1. Open line circuit.	1. Check the wiring, fuses, and receptacle.
There is no hum.	2. Protector open.	2. Check current drawn from the line after waiting for the reset to cool down.
	3. Contacts open on control relay.	3. Check the control and check the pressure readings.
	4. Open circuit in the motor stator.	4. Replace the stator or the whole compressor.
Compressor hums intermittently but will not start. However, it will cycle with the protector.	1. Incorrectly wired.	1. Check the wiring diagram and the actual wiring.
	2. Low line voltage.	2. Check the line voltage; find the cause of the dropping voltage and correct.
	3. Start capacitor could be open.	3. Replace with one known to be good.
	4. Contacts on relay do not close.	4. Check by manually operating the relay; replace if defective.
	5. Start winding could be open.	5. Check the stator leads; replace the compressor if the leads check out and are all right.
	6. Stator winding could be grounded. (This usually blows the fuse.)	6. Check stator leads; replace compressor if the leads are OK.
	7. Discharge pressure could be too high.	7. Remove the cause of excessive pressure; discharge shutoff and receiver valves should be open.
	8. Discharge pressure too high.	8. Compressor too tight.
	9. Start capacitor weak.	9. Replace the start capacitor.
Compressor starts, but the motor will not speed up enough to have start winding drop out of the circuit.	1. Low line voltage.	1. Increase the voltage.
	2. Compressor incorrectly wired.	2. Rewire according to wiring diagram.
	3. Defective relay.	3. Check operation; if defective, replace.
	4. Run capacitor shorted.	4. Disconnect the run capacitor and check for short.
	5. Start and run windings shorted.	5. Check winding resistance; if incorrect, replace the compressor.
	6. Start capacitor weak.	6. Check the capacitors; replace those found to be defective.
	7. Discharge pressure too high.	7. Check the discharge shutoff valves; check the pressure.
	8. Tight compressor.	8. Check the compressor oil level; check for binding; replace if necessary.
Compressor starts and runs, but it cycles on the protector.	1. Low line voltage.	1. Increase the voltage.
	2. Too much current being drawn through the protector.	2. Check to see if the fans or pumps are wired to the wrong connector.
	3. Suction pressure is too high.	3. Check the compressor; see if it is the right size for the job.

Problem	Probable cause	Remedy
	4. Discharge pressure is too high.	4. Check the ventilation of the compressor; check for overcharge; also check for obstructions to airflow or refrigerant flow.
	5. Protector is weak.	5. Check the current; replace the protector if it is not clicking out at the right point.
	6. Defective run capacitor.	6. Check the capacitance; replace if found to be defective.
	7. Stator partially shorted or grounded.	7. Check the resistance for a short to the frame; replace if found shorted to the frame.
	8. Insufficient motor cooling.	8. Correct airflow.
	9. Compressor tight.	9. Check oil level; check the cause of the binding.
	10. Three-phase line unbalanced.	10. Check each leg or phase; correct if the voltages are not the same between legs.
	11. Discharge valve leaks or is damaged.	11. Replace the valve plate.
Start capacitors burn out.	1. Short cycling.	1. Reduce the number of starts; they should not exceed 20 per hour.
	2. Start winding left in circuit too long.	2. Reduce the starting load; install a crankcase pressure-limit valve; increase the low voltage if this is found to be the condition; replace the relay if it is found to be defective.
	3. Relay contacts are sticking.	3. Clean the relay contacts; or replace the relay.
	4. Wrong relay or wrong relay setting.	4. Replace the relay.
	5. Wrong capacitor.	5. Check the specs for correct-sized capacitor; be sure the MFD and the WVDC are correct for this compressor.
correct	6. Working voltage of the capacitor is too low.	6. Replace with a capacitor of voltage rating.
	7. Water shorts out the terminals of the capacitor.	7. Place the capacitor so the terminals will not get wet.
Run capacitors burn out. They spew their contents over the surfaces of anything nearby. This problem can usually be identified with a visual inspection.	1. Line voltage too high.	1. Reduce the line voltage; should not be over 10% of motor rating.
	2. Light load with a high line voltage.	2. Reduce voltage if not within the 10% overage limit.
	3. Voltage rating of the capacitor too low.	3. Replace with capacitors of the correct WVDC.
	4. Capacitor terminals shorted by water.	4. Place the capacitor so the terminals will not get wet.
Relays burn out.	1. Low line voltage causes high current drain.	1. Increase the voltage to within the 10% limit.
	2. High line voltage.	2. Reduce voltage to within 10% of the motor rating.
	3. Wrong-sized capacitor.	3. Use the correct-sized capacitor; the proper MFD rating should be

and complete the circuit to the compressor and condenser. The compressor begins to pump the refrigerant, and the fan starts to cool the condenser. Note how the condenser fan motor is connected in parallel with the compressor. The condenser is on when the compressor is on and off when the compressor is off. Both are controlled by the CC contacts. Opening of the thermostat causes the compressor to stop running, and the fan motor for the condenser also stops until needed again when the thermostat switch closes.

Fan switches

The fan switch has two positions: “auto” and “on”. When it is in the on position, it means the fan relay solenoid is energized and the fan runs continually until the switch is returned to auto. When the fan switch is in the auto position, it works in conjunction with the thermostat. When the thermostat closes, the fan switch closes. Thus, it starts the fan only when the compressor is operating. However, if you wish to move the air in the room without the benefit of the cooling action of the compressor, you may do so by manually moving the switch to the on position.

Note that the fan relay contacts have to be closed in order for the evaporator fan motor to operate. These relay contacts close when the fan relay solenoid energizes. This solenoid and the compressor contactor solenoid are both powered from a 24-volt transformer that provides the low voltage necessary for their operation. This low-voltage control also removes the possibility of shock for persons operating the controls.

Troubleshooting

Problems in air conditioners can be caused by a number of malfunctioning parts. We have already mentioned how the thermostat, overload protector, start relay on larger units, and fan motor work. Knowing how they work means a lot in troubleshooting. If you know how they work, you can more easily identify why they are not working.

Throughout the industry, you will find Problem-Probable Cause-Remedy charts made available by manufacturers of equipment. These are an aid to troubleshooting. They help in locating the possible trouble component or system. Then you need to identify the schematic and read it properly to be able to identify the problems associated with the electrical system.

Table 16-1 is a Problem-Probable Cause-Remedy listing of possible troubles with the hermetic compressors used in air-conditioning units. Take a close look at it and determine which are the troubles caused by electrical failure and those caused by the refrigerant system.

Circuits for refrigerators vary slightly according to the manufacturer. The best source for these schematics is the manufacturer's service manuals and bulletins. In this chapter we will be concerned primarily with the circuits of domestic (home) refrigerators with freezers as part of the unit.

Basic Refrigerator

The basic or simple refrigerator has an electric circuit that consists of a plug, terminal board or plug-in connector, a start relay with overload protector, and a thermostat or temperature control. A light switch and lamp are usually included in the basic type of circuit (see Fig. 17-1).

Thermostats

Thermostats can have a number of design configurations, depending on the manufacturer. Figure 17-2 shows three different types of thermostats. Each has a knob on the end of the shaft when installed in a refrigerator.

Start relays

The design of a start relay varies with the manufacturer of the device. Figures 17-3 and 17-4 show two types used for refrigerators. They are usually located on the compressor. S stands for start winding connection, C for the common line, and R for the run winding connection to the compressor motor.

Refrigerator-Freezer Combination

Manual defrost

The refrigerator-freezer combination exists in a manual defrost model for those interested in the most inexpensive device available. It has only the addition of a fan in the freezer compartment and may or may not have a light in the freezer section (see Fig. 17-5).

Automatic defrost

Frost-free refrigerators and freezers call for some means of timing the defrost cycle. As the frost accumulates in the freezer and refrigerator sections, it must be removed. It is easily removed if done often enough to avoid a buildup.

The defrost timer is used to control how often the defrost cycle takes place (see Fig. 17-6). Contacts 1 and 3 are used for the defrost-motor coils. Contacts 2 and 4 are used to make contact with the proper circuit components to provide energy to the defrost heater or compressor (see Fig. 17-7).

The termination thermostat shown in the circuit is located near or on the evaporator to sense its temperature and indicate that the defrost cycle is complete and has done its job of removing the frost from the evaporator. The defrost timer can be located in any number of places. Figure 17-8 illustrates how it may be placed on the back of the refrigerator.

A wiring diagram of a frost-free refrigerator is shown in Fig. 17-9. Note the addition of other features, such as a drip catcher heater, mullion heater, and door heater. These heaters serve different purposes. The drip catcher heater allows the water that forms during defrost to drain out of the freezer unit to a pan underneath to be evaporated by the heat of the compressor nearby. The mullion heater and door heater are used to prevent a frost buildup on and around the doors of the freezer and refrigerator compartments when the outside air is very humid.

Defrosting

The timing of defrost operations is very important. Too long and you waste energy. Too short a time will result in a job half done, with the resulting decrease in efficiency of the unit since the evaporator is loaded with frost and its ability to cool the compartment is diminished. A number of methods are utilized to defrost. They are all electrically controlled and therefore part of the circuits associated with refrigerator-freezers.

Defrost thermostats

Defrost thermostats are precision built and tested to within ±6°F of the specified limit. A unique characteristic of a bimetal disc is that its calibration is fixed and does not change (see Fig. 17-10). This provides for reliability in excess of the life expectancy of the refrigerator or freezer.

Continual life tests at the factory of 100,000 cycles, corresponding to 100 years, reveal that the calibration of a defrost thermostat does not drift out of tolerance. A slight creep of about 2°F occurs at about 28,000 cycles during the life of all defrost thermostats as the components wear out. A defrost thermostat can, however, be incorrectly calibrated from the beginning. But defrost thermostats never get weak during the life of the refrigerator or freezer. Therefore, if the defrost system has functioned properly for several months before failure, disregard the possibility of an incorrectly calibrated defrost thermostat. Do not suspect that the defrost thermostat has the wrong calibration unless residual ice is found in the evaporator.

The only method for checking the defrost thermostat in the field is to test it for continuity. The contacts should be closed at all times except during the later part of the defrost cycle and for the first 10 minutes thereafter, when the compressor resumes operation.

You can determine that the defrost thermostat contacts are closed on side-by-side models by feeling the mullion for heat. On side-by-side models, the mullion heater is in series with the defrost thermostat. Thus, if the mullion heater is warm, the thermostat contacts must be closed (see Fig. 17-11).

Defrost cycle

Resistance heat is used in automatic defrosting. A radiant heater is attached to the bottom of the evaporator with two aluminum straps. A defrost heater and defrost termination thermostat are wired in series with the defrost heater. The defrost timer initiates and terminates a 21-minute defrost cycle every 6 hours. A termination thermostat cycles the defrost heater off at a predetermined temperature, prior to termination of the 21-minute defrost cycle. The aluminum drain positioned below the evaporator is defrosted by the defrost heater. Some refrigerators have a 25-minute defrost cycle. Another manufacturer makes models with a 17-minute cycle every 8 hours. As you can see, the timer is important in

making sure the defrost takes place when needed to keep the evaporator free of frost.

Another method used is the accumulated compressor time. In this case, the defrost operates whether there is any frost on the evaporator or not. The amount of frost buildup is a function of the amount of time the compressor operates. Therefore, it is only reasonable that the accumulated time for which the compressor operates is proportional to the frost buildup. This means defrost timing is typical in some manufacturers' models.

The defrost timer motor in Fig. 17-12 is controlled by the refrigerator thermostat. The defrost timer motor operates only when the refrigerator thermostat calls for compressor operation. After about 6 hours of accumulated compressor operation, the defrost timer switch cam has rotated sufficiently to open the connection between terminals 1 and 4 of the timer. The compressor stops while the refrigerator thermostat continues to call for compressor operation. The circuit through the defrost timer now uses terminals 1 and 2. Power is fed to the defrost heater instead of the compressor. The switch remains in this position (causing the heater to warm up) for approximately 25 minutes. During this time period, the cam on the timer motor has been rotating. This rotation causes the switch to flip from terminal 2 to terminal 4. This action allows power to be restored from terminal 1 to terminal 4. The compressor can now operate and cool until the refrigerator thermostat switch opens.

One other method used to defrost is the accumulated compressor time hot-gas defrost. This type of defrosting uses hot gas from the compressor to melt the frost accumulation on the evaporator. The defrost solenoid is important in this operation (see Fig. 17-13). The solenoid is used to open the line from the compressor

to the piping alongside the evaporator, allowing hot gas to flow in the line. This piping is placed there originally by the manufacturer of the refrigerator. As the hot gas circulates through the piping, it causes the frost on the evaporator to melt. The compressor and evaporator are still in the refrigeration mode, and the cooling process continues while defrosting takes place. Timing is a function of the defrost timer motor and its cams.

Other Devices

As the refrigerator progressed from an "ice-box" replacement to one with a number of conveniences, other circuit changes were necessitated. In most instances they were add-ons. Some of the add-ons were the ice maker, juice dispenser, soft drink dispenser, and cold water faucets. Each refrigerator manufacturer has its own way of designing these devices. You should refer to the manufacturer's manuals and bulletins to be sure of the particular model's electric circuits. See Fig. 17-11 for an illustration of where the ice maker is placed in the circuit.

Operation of the ice maker can be seen in Fig. 17-14. In Fig. 17-14a, note that near the completion of the first revolution the timing cam closes the water valve

switch. However, since the thermostat is still closed, the mold heater circuit is energized. Current will not pass through the water valve solenoid and its switch since electric current follows the path of least resistance.

At the end of the first revolution (Fig. 17-14b), the timing cam opens the holding switch. However, since the thermostat is still closed, a second revolution begins.

Troubleshooting

To see the importance of the electric circuits used in refrigerators and freezers, study Table 17-1. It shows some of the troubles that occur in a simple domestic freezer. The electrical problems have been emphasized. Compare these with what happens with the mechanics of refrigerant part of the freezer.

TABLE 17-1 Troubleshooting Freezers: Upright Models

Trouble	Probable cause	Remedy or repair
Product too cold.	1. Temperature selector knob set too cold.	1. Set warmer.
	2. Thermostat bulb contact bad.	2. If the bulb contact is bad, the bulb temperature will lag behind the cooling coil temperature. The unit will run longer and make the freezer too cold. See that the bulb makes good contact with the bulb well.
	3. Thermostat is out of adjustment.	3. Readjust or change the thermostat.
Product too warm.	1. Thermostat selector knob set too warm.	1. Set cooler.
	2. Thermostat contact points dirty or burned.	2. Replace thermostat.
	3. Thermostat out of adjustment.	3. Readjust or change the thermostat.
	4. Loose electrical connection.	4. This may break the circuit periodically and cause the freezer to become warm because of irregular or erratic operation; check the circuit and repair or replace parts.
	5. Excessive service load or abnormally high room temperature.	5. Unload part of the contents; move unit to a room with lower temperature or exhaust excess room heat.
	6. Restricted air circulation over wrapped condenser.	6. Allow 6-inch clearance above the top and $3^1/_2$-inch clearance at the sides and between the back of the cabinet and the wall.
	7. Excessive frost accumulation on the refrigerated shelves (manual defrost models).	7. Remove the frost.
	8. Compressor cycling on overload protector.	8. Check the protector and line voltage at the compressor.
Unit will not operate.	1. Service cord out of wall receptacle.	1. Plug in the service cord.
	2. Blown fuse in the feed circuit.	2. Check the wall receptacle with a test lamp for a live circuit; if the receptacle is dead but the building has current, replace the fuse; determine the cause of the overload or short circuit.
	3. Bad service cord plug, loose connection, or broken wire.	3. If the wall receptacle is live, check the circuit and make necessary repairs.
	4. Inoperative thermostat.	4. Power element may have lost charge or points may be dirty; check the points; short out the thermostat; repair or replace the thermostat.

TABLE 17-1 Troubleshooting Freezers: Upright Models (*Continued*)

Trouble	Probable cause	Remedy of repair
	5. Inoperative relay.	5. Replace.
	6. Stuck or burned-out compressor.	6. Replace the compressor.
	7. Low voltage. Cycling on overload.	7. Call utility company, asking them to increase voltage to the house; or move unit to a separate household circuit.
	8. Inoperative overload protector.	8. Replace.
Unit runs all the time.	1. Thermostat out of adjustment.	1. Readjust or change the thermostat.
	2. Short refrigerant charge (up to 4 oz). Cabinet temperatures abnormally low in lower section.	2. Not enough refrigerant to flood the evaporator coil at the outlet to cause the thermostat to cut out; recharge and test for leaks.
	3. Restricted airflow over the wrapper condenser.	3. Provide proper clearances around the cabinet.
	4. Inefficient compressor.	4. Replace.
Unit short cycles.	1. Thermostat erratic or out of adjustment.	1. Readjust or change the thermostat.
	2. Cycling on the relay.	2. This may be caused by low or high line voltage that varies more than 10% from the 115 volts; it may also be caused by high discharge pressures caused by air or noncondensable gases in the system; correct either condition.
Unit runs too much.	1. Abnormal use of the cabinet.	1. Heavy usage requires more operation; check the usage and correct or explain.
	2. Shortage of refrigerant.	2. Unit will run longer to remove the necessary amount of heat and it will operate at a lower than normal suction pressure; put in the normal charge and check for leaks.
	3. Overcharge of refrigerant.	3. Excessively cold or frosted suction line results in lost refrigeration effort; unit must run longer to compensate for the loss; purge off excessive charge.
	4. Restricted airflow over the condenser.	4. This can result if the cabinet is enclosed; this will obstruct the airflow around the cabinet shell; restricted airflow can also be caused by air or noncondensable gases in the system; this results in a higher head pressure; the higher head pressure produces more re-expansion during the suction stroke of the compressor; consequently, less suction vapor is taken; increased running time must compensate for loss of efficiency; correct the condition.
	5. High room or ambient temperature.	5. Any increase in temperature around the cabinet will increase the refrigeration load; this will result in longer running time to maintain cabinet temperature.
Too much frost on refrigerated surfaces—lowside.	1. Abnormally heavy usage in humid weather.	1. Do not leave the freezer door open any longer than necessary to load or remove products.
	2. Poor door gasket seals.	2. This permits the entrance of moisture by migration, which freezes out of the air as frost on the refrigerated surfaces.

Rapid Electrical Diagnosis

General Electric and Hotpoint have a quick and accurate device for diagnosing electrical faults in a refrigerator. The handheld dc device is a result of downsizing a computer used in the factory to check production models of refrigerators. The device is called "Big Red" for Rapid Electrical Diagnosis unit (see Fig. 17-15). It allows the technician to check almost every electrical component in the refrigerator within 6 minutes. It is not necessary to unplug the refrigerator, unload any food, move the refrigerator from the wall, or, usually, open the door.

Multi-connectors are designed into the refrigerator wiring harness. They are located behind the front grill. A mini-manual contains information that makes the device useful for a particular refrigerator model. All the latest models with the RED feature have a packet or envelope containing the necessary information. The packet contains the pictorial and schematic wirings, RED component circuits, machine wiring diagram, and components energized through the RED system (see Figs. 17-16 and 17-17).

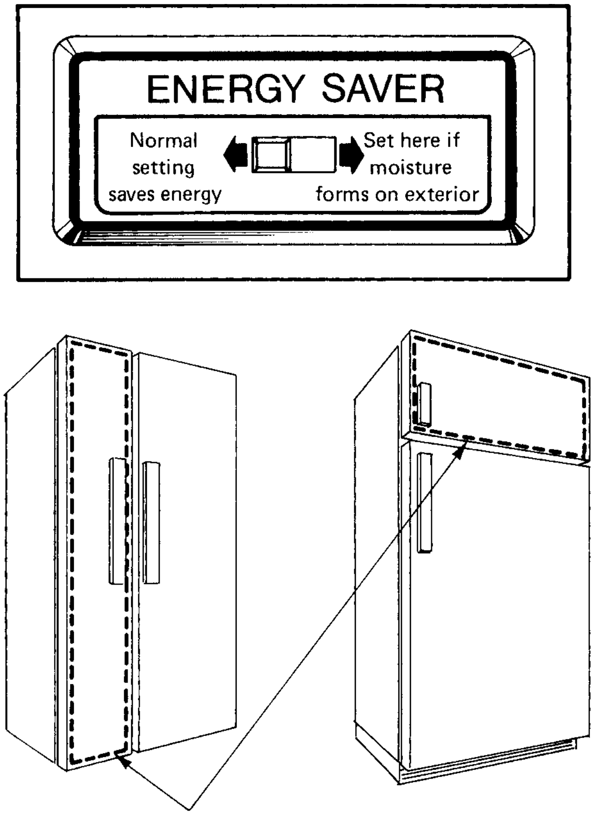
Figure 17-17 Ladder diagram of a GE 20-cubic-feet refrigerator that uses the RED system.

Figure 17-16 shows the pictorial of the wiring harness and color code for the RED connector. Figure 17-17 gives the electrical schematic and beside it is the same diagram, but with the < and > connections indicating whether it is a female- or male-type connection for that point.

Use of RED may reduce the technician's service time by 20%. It reduces the additional service callbacks for the same problem by 50%. All "no-frost" GE models 16 cubic feet and larger have this feature. Hotpoint uses the same system. Newer refrigerators have more advanced electronics units and testing devices. This explanation provides you with some of the early progress in the refrigerator field.

Energy-Saver Switches

An energy-saver switch is the latest development in refrigerator design (see Fig. 17-18). The energy-saver switch can reduce operating costs by taking some of the heaters out of the circuit.



ENERGY SAVER
Normal setting saves energy
Set here if moisture forms on exterior
Antisweat heaters for humid conditions only

Figure 17-18 Energy-saver switches save electricity and one used in conjunction with the antisweat heaters located around the freezer section doors.

Controls for the case and mullion antisweat heaters are incorporated into the energy-saver switch. The heaters prevent moisture formation on the outside of the case in humid conditions. The normal setting may be used about 80% of the time due to low humidity in the winter and air conditioning in the summer. The switch can also be set to an alternate setting only if moisture forms on the outside of the refrigerator.

Chapter 18

Troubleshooting

Performance Objectives

- Know some of the common sense rules for safely working around air-conditioning and refrigeration equipment.
- Know how often filters on air conditioners have to be cleaned.
- Know how the low supply voltage affects the operation of electrical equipment.
- Know the source of most trouble in air-conditioning systems.
- Know the source of most trouble in heating systems.
- Know how to test motor capacitors.
- Know how to use a clamp-on meter to troubleshoot.
- Know how to test the centrifugal switch in a single-phase motor.
- Know how to measure the capacitance of a capacitor in a piece of heating and cooling equipment.
- Know good troubleshooting procedures.

From time to time, air-conditioning and refrigeration units experience problems with the electrical and the mechanical aspects of their operation. They have in some cases been moved and damaged, and in other cases they have been repaired with components that are incorrect or wired into the circuits incorrectly.

The service technician must be aware of the problems that may develop in a period of time so that they may be located quickly, easily, and without undue expense to the owner of the unit. In this chapter, we will attempt to show how troubleshooting procedures can aid in making the job faster and easier.

Safety

Safety first has its direct and implied meaning. You can work with air-conditioning and refrigeration equipment safely if a few common sense rules are followed.

Copyright © 2007 by The McGraw-Hill Companies, Inc. Click here for terms of use.

Handling refrigerants

The proper use of gloves, eye protection, and clothing to protect the body is necessary. Freon or any refrigerant escaping from a refrigeration unit can cause permanent damage to the skin. It can also cause blindness if you are hit in the face with the gases under pressure. Make sure you wear the proper clothing at all times when troubleshooting or recharging a unit.

Testing precaution

Pressure testing or cleaning refrigeration and air-conditioning systems can be dangerous. Be careful not to exceed 150 psig when pressure testing a complete system.

Electrical safety

The main rule for electrical safety is to see to it that the main circuit breaker is in the off position and locked before starting to remove or check (with an ohmmeter) any refrigeration, air-conditioning, or heating equipment. Keep in mind that some compressors have power applied at all times to the off-cycle crankcase heater. Even if the compressor is not running, the power is applied to the crankcase heater. Some run capacitors are connected to the compressor motor windings even when the compressor is not running. Other devices are energized when the compressor is not running. Thus, electrical power is applied to the unit even when the compressor is not running.

Compressor Problems

A number of compressor problems can be quickly identified from a table of problems, possible causes, and suggested repair (see Table 18-1). The compressor is the heart of the refrigeration system whether it is the air conditioner, refrigerator, or freezer. That makes it of primary concern in any troubleshooting procedure.

PSC compressors

The permanent split-capacitor (PSC) compressor has some problems that should be uppermost in your mind so that you are aware of them (see Table 18-2). The low-voltage problems are listed and possible corrections given. The branch-circuit fuse or circuit breaker trips and causes the unit to become disabled. The possible cause could be that the rating of the protection device is not high enough to handle the current. Some problems are within the scope of the work the technician can handle. Others like low line voltage caused by factors beyond the control of the homeowner call for the utility company to correct them.

A lot of troubleshooting is common sense. If the fuse is blown and you put in another and it blows, it tells you that there is something drawing too much current. Simply check for cause.

Air-conditioner compressors

Home air conditioners, those that fit into a window or those that are part of a central air-conditioning system, are subject to problems with their compressors

Compressor starts, but does not switch off of start winding.	1. Improperly wired.	1. Check wiring against diagram.
	2. Low voltage to unit.	2. Determine reason and correct.
	3. Relay failing to open.	3. Determine reason and replace if necessary.
	4. Run capacitor defective.	4. Determine reason and replace.
	5. Excessively high discharge pressure.	5. Check discharge shutoff valve, possible overcharge, or insufficient cooling of condenser.
	6. Compressor motor has a winding open or shorted.	6. Replace compressor.
	7. Internal mechanical trouble in compressor (tight).	7. Replace compressor.
Compressor starts and runs, but short cycles on overload protector.	1. Additional current passing through the overload protector.	1. Check wiring against diagram; check added fan motors, pumps, etc., connected to wrong side of protector.
	2. Low voltage to unit (or unbalanced if three phase).	2. Determine reason and correct.
	3. Overload protector defective.	3. Check current, replace protector.
	4. Run capacitor defective.	4. Determine reason and replace.
	5. Excessive discharge pressure.	5. Check ventilation, restrictions in cooling medium, restrictions in refrigeration system.
	6. Suction pressure too high.	6. Check for possibility of misapplication; use stronger unit.
	7. Compressor too hot—return gas is hot.	7. Check refrigerant charge. (Repair leak.) Add refrigerant if necessary.
	8. Compressor motor has a winding shorted.	8. Replace compressor.
Unit runs, but short cycles on.	1. Overload protector.	1. Check current; replace protector.
	2. Thermostat.	2. Differential set too close; widen.
	3. High-pressure cutout due to insufficient air or water supply, overcharge, or air in system.	3. Check air or water supply to condenser; reduce refrigerant charge, or purge.

Causes	Corrections
Low Voltage	
1. Inadequate wire size.	1. Increase wire size.
2. Watt-hour meter too small.	2. Call utility company.
3. Power transformer too small or feeding too many homes.	3. Call utility company.
4. Input voltage too low.	4. Call utility company.
Note: Starting torque varies as the square of the input voltage.	
Branch Circuit Fuse or Circuit Breaker Tripping	
1. Rating too low.	1. Increase size to a minimum or 175% of unit FLA (full load amperes) to a maximum of 225% of FLA.
System Pressure High or Not Equalized	
1. Pressures not equalizing within 3 minutes.	1. a. Check metering device (capillary tube or expansion valve). b. Check room thermostat for cycling rate; off cycle should be at least 5 minutes; also check for "chattering." c. Has some refrigerant dryer or some other possible restriction been added?
2. System pressure too high.	2. Make sure refrigerant charge is correct.
3. Excessive liquid in crankcase (split-system applications).	3. Add crankcase heater and suction line accumulator.

and electrical controls. Most of those that operate in the window are designed for 120- or 240-volt operation. In some cases, during the summer when line voltage is low, they may experience some low-voltage problems.

The units are equipped with some kind of filter to make sure the air is cleaned before it is forced into the room being cooled. These filters usually require a change or cleaning at least once a year. Where dust is a problem, such maintenance should be more frequent. At this time, the condenser coil should be brushed with a soft brush and flushed with water. The filters should be vacuumed and then washed to remove dust. The outside of the case should be wiped clean with a soapy cloth. The cleaner the filter, the more efficient the unit. In some cases a clogged filter can cause compressor problems. Table 16-1 shows some of the problems associated with the compressor in these units. Note how most of the problems associated with air conditioners are electrical.

Low-Voltage Operation

Electrical apparatus designed to produce at full capacity at the voltage indicated on the rating plate can malfunction at lower than designated voltages. Motors operated at lower than rated voltage cannot provide full horsepower without shortening their service life. Relays and solenoids can also fail to operate if low voltage is present.

The Air Conditioning and Refrigeration Institute (ARI) certifies the cooling units after testing them. The units are tested to make sure they will operate with ±10% above or below rated voltage. This does not mean they will operate continuously without damage to the motor. Most air-conditioning compressor burnouts are caused by low-voltage operation. A hermetic compressor is entirely enclosed within the refrigerant cycle; it is very important that it not be abused by overloading or low voltage. Both conditions can occur during peak load periods. A national survey has shown that the most common cause of compressor low voltage is the use of undersized conductors between the utility lines and the condensing unit.

Using a System to Troubleshoot (Electrical)

Refrigeration, air-conditioning, and heating units all have various systems that cause them to operate and do the job they were designed for. First, you have to identify the system and the problems most commonly associated with the particular system. Then you have to be able to determine exactly what caused the symptom you are witnessing. Next, you have to be able to correct the problem and put the unit back into operation.

Electrical tests are the most common because the electrical problems are the most frequently encountered in all three types of equipment. A systematic procedure is necessary to obtain the needed results.

Motor testing

Testing a motor in a sealed condensing unit to determine why it does not operate becomes a very simple process if the correct procedure is followed. Each test made should be one of a series of eliminations to determine what part of the system is defective. By checking other parts of the wiring system before checking the unit itself, a great deal of time can be saved since, in most cases, the trouble will be in the wiring or controls rather than in the unit.

To make a complete electrical test on electrical outlets and on the unit itself, it is advisable to make a test cord (see Fig. 18-1). By connecting the black and white terminals together and placing a light bulb in the socket, the cord may be used to check the wall outlet into which the unit is connected. By connecting the

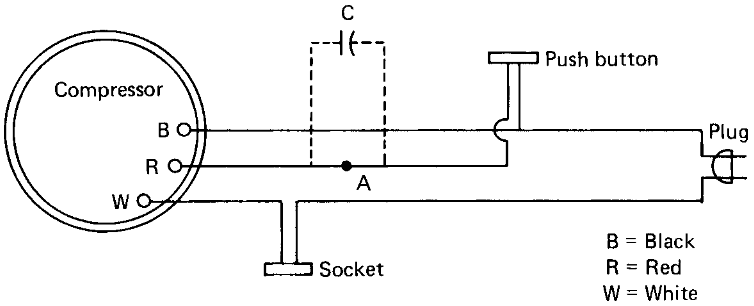

Figure 18-1 Test lamp for troubleshooting.

white and red terminal clips, this same test may be made by depressing the push button. This will serve as a test to make certain the push button is in working order. This test cord should have a capacitor installed in the red lead to the push button if the compressor is a capacitor-start type.

Once these tests have been completed and it is known that current is being supplied to the unit, the next step is to check the three wires on the base of the compressor unit. Pull the plug from the wall receptacle and carefully examine the nuts that hold the wires in position. Then try each wire to be sure it is held firmly in place, as a loose wire may keep the unit from operating. Test the thermostatic switch to determine whether or not contact is being made at that point. Turn the cold-control knob several times. If this fails to start the unit, then short across the thermostatic switch terminals on the switch. To do this, it will be necessary to remove the switch cover from the top of the switch. If the unit starts, it is an indication that the thermostatic switch is not operating properly and must be repaired or replaced. After the thermostatic switch has been checked and if the trouble is not located, it will be necessary to determine whether the trouble is in the motor, motor-protector relay, or capacitor.

Capacitor testing

The capacitor must be checked before testing the unit itself. This is done in the following manner:

1. Disconnect the capacitor wires from the motor-protector relay.
2. Connect these two wires to the black and white terminals of the test cord.
3. Put a 150-watt light bulb in the receptacle on the test cord, and plug it into an outlet.

If the 150-watt bulb does not light up, it is an indication that the capacitor has an open circuit and must be replaced. However, if the bulb does light up, it is not an indication that the capacitor is perfect. This must be checked further by shorting across the two terminals of the capacitor with a screwdriver with an insulated handle. If the brilliance of the light changes, that is, if the light bulb burns brighter when the terminals of the capacitor are shorted, it indicates that the capacitor is in proper operating condition. A decided sparking of the terminals will also be noticed when the terminals are shorted. If the brilliance of the bulb does not change, it is an indication that the capacitor has an internal short and must be replaced.

Motor-protector relay testing

If the overload protector is found defective during the preceding test, replace it (see Fig. 18-2). The motor overload protector is usually accessible for replacement and is located near the compressor (see Fig. 18-3). Remove the clips holding the overload in position, and remove the wire from the terminal by pulling it outward. Notice the position of the electrical lead before replacing it (see Fig. 18-4). Place the electrical leads on the replacement overload and check for correct connections against the wiring diagram. Close up the unit (see Fig. 18-5). Test for proper operation.

Using Meters to Check for Problems

The voltmeter and the ohmmeter can be used to isolate various problems. You should be able to read the schematic and make the proper voltage or resistance measurements. An incorrect reading will indicate the possibility of a problem.

Troubleshooting charts will aid in isolating the problem to a given system. Once you have arrived at the proper system that may be causing the symptoms noticed, you will then need to use the ohmmeter with the power off to isolate a section of the system. Once you have zeroed in on the problem, you can locate it by knowing what the proper reading should be. Deviation from a stated reading of over 10% is usually indicative of a malfunction, and in most cases the component part must be replaced to assure proper operation and no callbacks.

Using a Volt-Ammeter for Troubleshooting Electric Motors

Most electrical equipment will work satisfactorily if the line voltage differs ±10% from the actual nameplate rating. In a few cases, however, a 10% voltage drop may result in a breakdown. Such may be the case with an induction motor that is being loaded to its fullest capacity both on start and run. A 10% loss in the line voltage will result in a 20% loss in torque.

The full-load current rating on the nameplate is an approximate value based on the average unit coming off the manufacturer's production line. The actual current for any one unit may vary as much as ±10% at rated output. However, a load current that exceeds the rated value by 20% or more will reduce the life of the motor due to higher operating temperatures, and the reason for excessive current should be determined. In many cases it may simply be an overloaded motor. The percentage of increase in load will not correspond with percentage of increase in load current. For example, in the case of a single-phase induction motor, a 35% increase in current may correspond to an 80% increase in torque output.

The operating conditions and behavior of electrical equipment can be analyzed only by actual measurement. A comparison of the measured terminal voltage and current will check whether the equipment is operating within electrical specifications.

A voltmeter and an ammeter are needed for the two basic measurements. To measure voltage, the test leads of the voltmeter are in contact with the terminals of the line under test. To measure current, the conventional ammeter must be connected in series with the line so that the current will flow through the ammeter.

To insert the ammeter, you must shut down the equipment, break open the line, connect the ammeter, and then start up the equipment to read the meter. And you have to do the same to remove the meter once it has been used. Other time-consuming tests may have to be made to locate the problem. However, all this can be eliminated by the use of a clamp-on volt-ammeter.

Clamp-on volt-ammeters

The pocket size volt-ammeter shown in Fig. 18-6 is the answer to most troubleshooting problems on the job. The line does not have to be disconnected to obtain a current reading. The meter works on the transformer principle; it picks up the magnetic lines surrounding a current-carrying conductor and presents this as a function of the entire amount flowing through the line. Remember, in transformers we discussed how the magnetic field strength in the core of the transformer determines the amount of current in the secondary. The same principle is used here to detect the flow of current and how much.

To get transformer action, the line to be tested is encircled with the split-type core by simply pressing the trigger button. Aside from measuring terminal voltages and load currents, the split-core ammeter-voltmeter can be used to track down electrical difficulties in electric motor repair.

Looking for grounds

To determine whether a winding is grounded or has a very low value of insulation resistance, connect the unit and test leads as shown in Fig. 18-7. Assuming the available line voltage is approximately 120 volts, use the unit's lowest voltage range. If the winding is grounded to the frame, the test will indicate full line voltage.

A high-resistance ground is simply a case of low insulation resistance. The indicated reading for a high-resistance ground will be a little less than line voltage. A winding that is not grounded will be evidenced by a small or negligible

reading. This is due mainly to the capacitive effect between the windings and the steel lamination.

To locate the grounded portion of the windings, disconnect the necessary connection jumpers and test. Grounded sections will be detected by a full line voltage indication.

Looking for opens

To determine whether a winding is open, connect test leads as shown in Figs. 18-8 and 18-9. If the winding is open, there will be no voltage indication. If the circuit is not open, the voltmeter indication will read full line voltage.

Looking for shorts

Shorted turns in the winding of a motor behave like a shorted secondary of a transformer. A motor with a shorted winding will draw excessive current while running at no load. Measurement of the current can be made without disconnecting lines.

You engage one of the lines with the split-core transformer of the tester. If the ammeter reading is much higher than the full-load ampere rating on the nameplate, the motor is probably shorted.

In a two- or three-phase motor, a partially shorted winding produces a higher current reading in the shorted phase. This becomes evident when the current in each phase is measured.

Motors with Squirrel-Cage Rotors

Loss in output torque at rated speed in an induction motor may be due to opens in the squirrel-cage rotor. To test the rotor and determine which rotor bars are loose or open, place the rotor in a growler. Engage the split-core ammeter around the lines going to the growler, as shown in Fig. 18-10. Set the switch to the highest current range. Switch on the growler and then set the test unit to the approximate current range. Rotate the rotor in the growler and take note of the current indication whenever the growler is energized. The bars and end rings in the rotor behave similarly to a shorted secondary of a transformer. The growler windings act as the primary. A good rotor will produce approximately the same current indications for all positions of the rotor. A defective rotor will exhibit a drop in the current reading when the open bars move into the growler field.

Testing the Centrifugal Switch in a Single-Phase Motor

A defective centrifugal switch may not disconnect the start winding at the proper time. To determine conclusively that the start winding remains in the circuit, place the split-core ammeter around one of the start-winding leads. Set the instrument to the highest current range. Turn on the motor switch. Select the appropriate current range. Observe if there is any current in the start-winding circuit. A current indication signifies that the centrifugal switch did not open when the motor came up to speed (see Fig. 18-11).

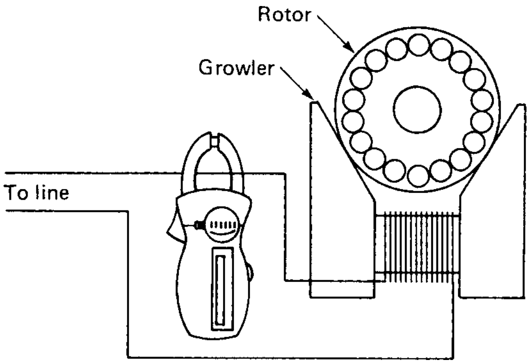

Figure 18-10 Using a growler to test a motor. (Courtesy of Amprobe)

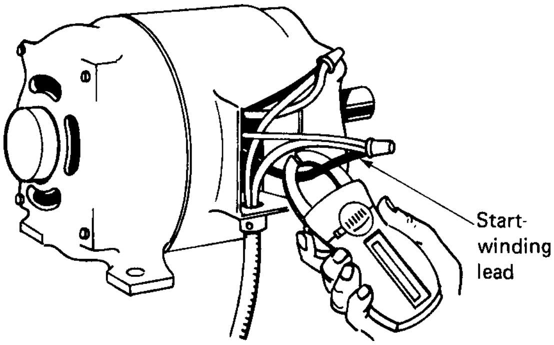

Figure 18-11 Checking the centrifugal switch with a clamp-on meter. (Courtesy of Amprobe)

Testing for a Short Circuit Between Run and Start Windings

A short between run and start windings may be determined by using the ammeter and line voltage to check for continuity between the two separate circuits. Disconnect the run- and start-winding leads and connect the instrument as shown in Fig. 18-12. Set the meter on voltage. A full-line voltage reading will be obtained if the windings are shorted to one another.

Capacitor testing

Defective capacitors are very often the cause of trouble in capacitor-type motors. Shorts, opens, grounds, and insufficient capacity in microfarads are conditions for which capacitors should be tested to determine whether they are good.

You can determine a grounded capacitor by setting the instrument on the proper voltage range and connecting it and the capacitor to the line as shown in Fig. 18-13. A full-line voltage indication on the meter signifies that the capacitor is grounded to the can. A high-resistance ground is evident from a voltage

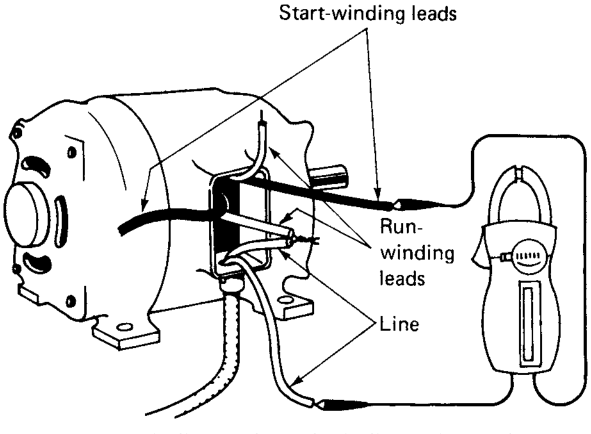

Figure 18-12 Finding a shorted winding using a clamp-on meter. (Courtesy of Amprobe)

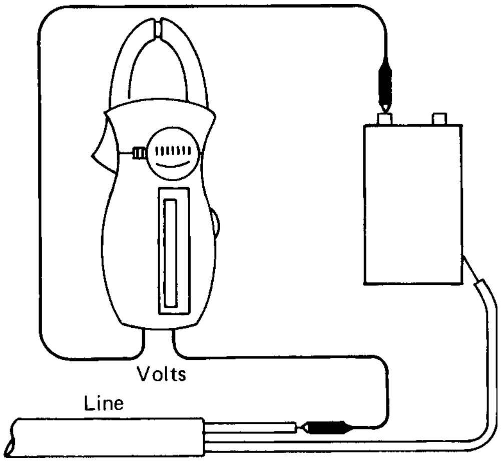

Figure 18-13 Finding a grounded capacitor with a clamp-on meter. (Courtesy of Amprobe)

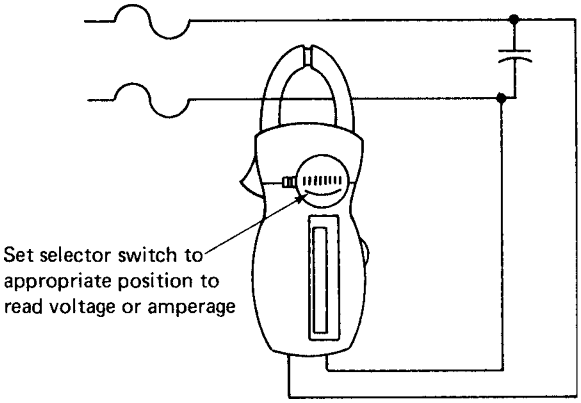
reading that is somewhat below the line voltage. A negligible reading or a reading of no voltage indicates that the capacitor is not grounded.

Measuring the capacity of a capacitor

To measure the capacity of the capacitor, set the test unit's switch to the proper voltage range and read the line voltage indication. Then set to the appropriate current range and read the capacitor current indication. During the test, keep the capacitor on the line for a very short period of time, because motor-starting electrolytic capacitors are rated for intermittent duty (see Fig. 18-14). The capacity in microfarads is then computed by substituting the voltage and current readings in the following formula, assuming that a full 60-hertz line is used:

$$\text{Microfarads} = \frac{2650 \times \text{amperes}}{\text{volts}}$$



Set selector switch to appropriate position to read voltage or amperage

Figure 18-14 Finding the size of a capacitor with a clamp-on meter. (Courtesy of Amprobe)

An open capacitor will be evident if there is no current indication in the test. A shorted capacitor is easily detected. It will blow the fuse when the line switch is turned on to measure the line voltage. Troubleshooting can be broken down into a simple procedure. Logical thinking is what it takes to be able to accurately diagnose a problem and then correct it. For instance, you can isolate a particular system since you know how the system is supposed to operate. If it is not operating according to expectations, then you know something is causing the problem. By concentrating on a particular system that has been located, it is possible to concentrate your thinking on things that would cause the malfunction.

Once you have determined which components in the system can cause the symptoms being experienced, it is possible to find the faulty component.

After the problem has been located and the component identified, it is then necessary to take the component out and repair it or replace it.

Once the problem has been located, the part removed and a new one inserted or the old one repaired is necessary to check the operation of the system to make sure it is performing according to its design characteristics.

All this can be broken down into key words that will aid you in any troubleshooting situation.

Troubleshooting Procedure

A stepwise set of actions to be taken to troubleshoot has been described next.

Isolate. Isolate the system giving the trouble. The system may be:

- the evaporator
- the condenser
- the compressor
- the controls

Use the Problem-Probable Cause-Remedy charts to aid in isolating the problem.

Concentrate. Concentrate on the isolated system. Concentrate on how it works and why it would malfunction.

Differentiate. Determine which components could cause the identified symptoms; then locate each possible troublemaking part.

Eliminate. Eliminate the possible troublemakers one by one. Use the proper test instrument to do so.

Repair or replace. Either repair or replace the identified troublemaker.

Check. Check to see if the unit operates properly with the repaired or replaced parts.

Controlling Electrical Power for Air-Conditioning Units

Performance Objectives

- Know how to find the correct wire size for a refrigeration unit.
- Know the permissible maximum voltage drops in a service line.
- Know the effects of voltage variations on AC motors.
- Know how to calculate starting current values and inrush voltage drops.
- Know the code limitations on amperes per conductor.
- Know how to select and correct circuit protection.
- Know the different types of fuses and circuit breakers.
- Know the latest in modules for control of refrigeration units.
- Know some of the electronic pressure controls for refrigeration systems.
- Know how sensing of current is used for refrigeration control.

In order to operate properly, the correct voltage, amperage, and wattage must be furnished to the air-conditioning unit. A number of devices have to be utilized to keep the voltage source clean and available for efficient operation of the unit. It all starts with the choosing of the correct wire from the power pole to the house or store or school where the air-conditioning unit is used.

Choosing Wire Size

There are two criteria for choosing wire size for installation of air-conditioning or refrigeration equipment. The size of the electrical conductor wire recommended for a given appliance circuit depends upon two things: limitation on voltage loss and minimum wire size.

Copyright © 2007 by The McGraw-Hill Companies, Inc. Click here for terms of use.

Limiting voltage loss

Proper operation of an electrical device must be under the conditions for which it was designed. The wire size selected must be low in resistance per foot of length. This will assure that the full load "line loss" of the total length of the circuit does not cause low voltage of the appliance terminals. Since the length of electrical feeders varies with each installation, wire sizing to avoid excessive voltage loss becomes the responsibility of the installing contractor. The National Electrical Code or local code should be followed.

Minimum wire size

To avoid field wiring being damaged by tensile stress or overheating, national and local codes establish minimum wire sizes. The maximum amperage permitted for a given conductor limits internal heat generation so that temperature will not damage its insulation. This assumes proper fusing that will limit the maximum current flow so that the conductor will always be protected.

Wire size and voltage loss go hand in hand, so to speak. The larger the wire, the more current it can handle without voltage loss along the lines. Each conductor or wire has resistance. This resistance, measured in ohms per unit of wire length, increases as the cross-sectional area of the wire decreases. The size of the wire is indicated by gage number. The higher the gage number, the smaller the wire. American Wire Gage (AWG) is the standard used for wire size. Each gage number has a resistance value in ohms per foot of wire length. The resistance of aluminum wire is 64% greater than that for copper of the same gage number.

Wire selection

The wire size recommended for actual use should be the heavier of the two indicated by the procedures that will follow.

Local approval is usually necessary for any installation that has large current draws. The data presented here are based on the National Electrical Code. Much of the detail has been omitted in the interest of simplification. Thus, there may be areas of incompleteness not covered by a footnote or reference. In all cases it is recognized that final approval must come from the authority having local jurisdiction. The National Electrical Code sets forth minimum standards. It is an effort to establish some standard for safe operation of equipment.

Wire Size and Low Voltage

The voltage at which a motor or device should operate is stamped on the nameplate. This voltage indicates that the full capacity of the device is being utilized when that particular voltage is available. Motors operated at lower than rated voltage are unable to provide full horsepower without jeopardizing their service life. Electric heating units lose capacity even more rapidly at reduced voltages.

Low voltage can result in insufficient spark for oil burner ignition, reluctant starting of motors, and overheating of motors handling normal loads. Thus, it is not uncommon to protect electrical devices by selecting relays that will not close load circuits if the voltage is more than 15% below rating.

ARI (Air-Conditioning and Refrigeration Institute)-certified cooling units are tested to assure they will start and run at 10% above and 10% below their rating plate voltage. However, this does not imply that continuous operation at these voltages will not affect their capacity, performance, and anticipated service life. A large proportion of air-conditioning compressor burnouts can be traced to low voltage. Because the motor of a hermetic compressor is entirely enclosed within the refrigerant cycle, it is important that it not be abused either by overloading or under-voltage. Both of these can occur during peak load conditions. A national survey has shown that the most common cause of compressor low voltage is the use of undersized conductors between the utility lines and the condensing unit.

The size of the wire selected must be one that, under full load conditions, will deliver acceptable voltages to the appliance terminals. The National Electrical Code requires that conductors be sized to limit voltage drop between the outdoor-pole service tap and the appliance terminals to not in excess of 5% of rated voltage under full load conditions. This loss may be subdivided, with 3% permissible in service drops, feeders, meters, and overcurrent protectors at the distribution panel and the appliance (see Fig. 19-1).

In a 240-volt service, the wire size selected for an individual appliance circuit should cause no more than 4.8-volt drop under full load conditions. Even with this 5% limitation on voltage drop, the voltage at the equipment terminals is still very apt to be below the rating plate values. See Table 19-1.

TABLE 19-1 Permissible Maximum Voltage Drops

For a line voltage of:	120	208	240	480
Feeders to distribution panel (3%)	3.6	6.24	7.2	14.4
Branch circuit to appliance (2%)	2.4	4.16	4.8	9.6
Total voltage drop fully loaded	6	10.4	12	24
Resultant* voltage at appliance	114	197.6	228	456

*Assumes full-rated voltage where feeders connect to utility lines. If utility voltage runs low, the overall voltage drop should be further reduced so as to make available at the appliance terminals a voltage as close as practical to that voltage range specified on the appliance rating plate.

Voltage drop calculations

Just as friction creates pressure loss in water flow through pipes, so does electrical resistance create voltage drop as current flows through a conductor. The drop increases with the length of the conductor (in feet), the current flow (in amperes), and the ohms of resistance per foot of wire. This relationship may be expressed as follows:

$$\text{Voltage drop} = \text{amperes} \times \text{ohms/foot} \times \text{length of conductor}$$

Figure 19-2 illustrates how voltage drop per 100 feet of copper conductor will increase with the amount of current drawn through the conductor. The wire size

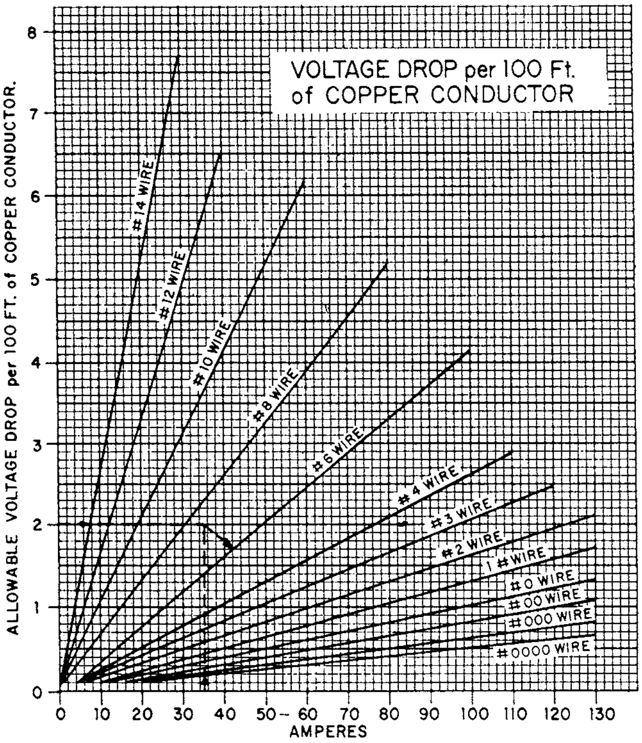

Figure 19-2 Conductor voltage drop per 100 feet.

is indicated on the straight line. Match the amperes with the wire size. Then follow over to the left column to determine the voltage drop. For instance, Fig. 19-2 shows a 2.04-volt drop per 100 feet of copper conductor for 20 ampers of current through a No. 10 wire.

The Effects of Voltage Variations on AC Motors

Motors will run at the voltage variations already mentioned. This does not imply that such operation will comply with industry standards of capacity temperature rise, or normally anticipated service life. Figure 19-3 shows general effects. Such effects are not guaranteed for specific motors.

The temperature rise and performance characteristics of motors sealed within hermetic compressor shells constitute a special case. These motors are cooled by return suction gas of varying quantity and temperature. Thus, Fig. 19-3 is not necessarily applicable to this specialized type of equipment.

The chart shows the approximate effect of voltage variations on motor characteristics. The reference base of voltage and frequency is understood to be that shown on the nameplate of the motor.

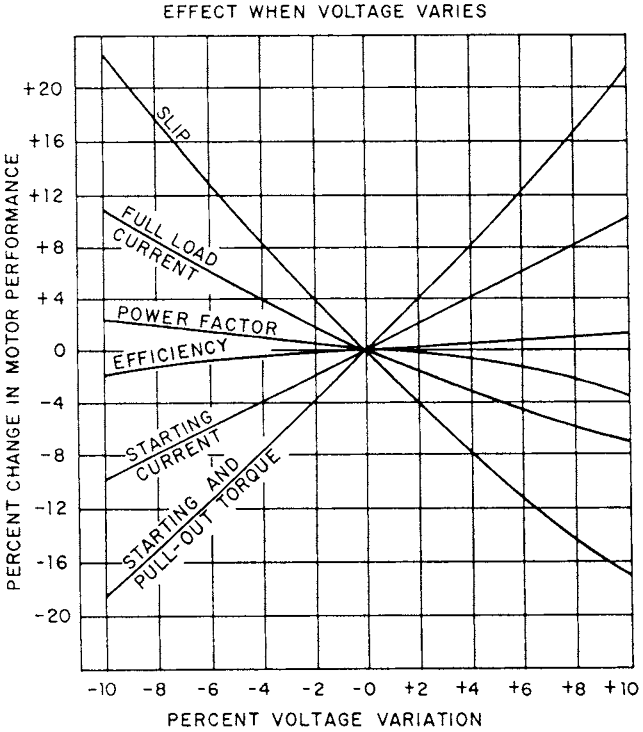

Figure 19-3 General effects of voltage variations on induction motor characteristics.

Some of the terms used in the chart are explained here.

Normal slip = synchronous speed – the rating plate speed.

Slip in the graph indicates the change in normal slip.
Synchronous speeds for 60-hertz motors are:

2-pole—3600 r/min or rpm

4-pole—1800 r/min or rpm

6-pole—1200 r/min or rpm

8-pole—900 r/min or rpm

Table 19-2 indicates the voltage drop that may be anticipated for various ampere flow rates through copper conductors of different gage size. Figure 19-2 provides the same data in graphic form.

These data are applicable to both single-phase and three-phase circuits. In each case, the wire length equals twice the distance from the power distribution panel to the appliance terminals, measured along the path of the conductors. This is twice the distance between B and C in Fig. 19-1, measured along

*To determine voltage drop for aluminum, enter the chart number then using 1.64 × actual amperes. The conductor's length is twice the length of the branch leads, whether single or three phase. Since resistance varies with temperature, it may be necessary to correct for wire temperature under load conditions if the ambient materially exceeds 80°F. If so, increase ampere values using the multiplier 1.0 + 0.002 × (ambient temperature − 80°F). Example: If current flow and environment result in conductors reaching 140°F under load conditions, the appliance ampere ratings should be increased by the multiplying factor 1.0 + 0.002 (140°F – 80°) = 1.0 + 0.12 = 1.12.

the path of the conductors. For motorized appliances, particularly those that start under loaded conditions, the voltage at the appliance terminals should not drop more than 10% below rating plate values unless approved by the manufacturer. Thus, the voltage drop permissible in the load leads must anticipate any reduction below rated voltage that may be suffered under full load conditions at the point of power source connection (point A in Fig. 19-1).

Troublesome voltage losses may also occur elsewhere if electrical joints or splices are mechanically imperfect and create unanticipated resistance. Such connections may exist in the distribution panel, the meter socket, or even where outdoor power drops are clamped to the feeder lines on poles. Where there is a wide variation between no-load voltages and operating voltage, sources of voltage drop can be determined by taking voltmeter readings at various points in the circuit. These points might be ahead of the meter, after the circuit disconnect switch, at the appliance terminals, and at other locations.

Selecting Proper Wire Size

To provide adequate voltage at the appliance terminals, anticipate the minimum voltage that may exist at the distribution panel. Then determine the allowable voltage drop acceptable in the appliance circuit. This should not exceed 2% of rated voltage. It should, for example, not exceed 4.1 volts for 208-volt service. Table 19-1 shows voltage drops for 120-, 208-, 240-, and 408-volt service.

Determine the length of feed conductor. This is twice the length of the wire path from the source to the appliance. In Fig. 19-1, this is two times the distance from B to C measured along the path of the wire. If it is single-phase or three-phase, consider two conductors in establishing the total length of the circuit.

Determine the allowable drop per 100 feet of conductor.

Example: If for a 230-volt installation, a 4.6-volt drop is permissible, and the wire path is 115 feet from the distribution panel to the appliance (this makes 230 feet of conductor), then the allowable drop per 100 feet will be:

$$4.6 \text{ volts} \times \frac{100 \text{ feet}}{230 \text{ feet}} = 2.0 \text{ volts per 100 feet}$$

Using either Table 19-2 or Fig. 19-2, determine the gage wire required. When using the graph, select the gage number closest below and to the right.

Example: The full load value is 35 amperes. The allowable voltage drop is 2.0 volts per 100 feet. See Fig. 19-2.

Table solution. (Table 19-2): Select No. 6 wire. This results in a drop of 1.44 volts per 100 ft.

Graph solution. (Fig. 19-2): Intersection lies between No. 6 wire and No. 8 wire. Select the larger of the two. In this case it would be No. 6.

Unacceptable Motor Voltages

Occasionally it becomes necessary to determine causes of unacceptable voltage conditions at motor terminals. Often this is necessary where excessive voltage drops are encountered as motors start. During this brief interval, the starting inrush current may approximate a motor's locked rotor amperage rating.

Table 19-3 shows the range of locked rotor amperes (LRA) per motor horsepower. LRA appears on the rating plates of hermetic compressors. Depending on the type of motor, its LRA may be two to six times its rated full load current. Motor-starting torque varies as the square of the voltage. Thus, only 81% of the anticipated torque is available if the voltage drops to 90% of the rating during the starting period.

The full load amperage value must be considered in choosing the proper wire size and making sure the motor has acceptable voltages. These are shown in Table 19-4.

Calculating Starting Current Values and Inrush Voltage Drops

Single-phase current

Wire size and inrush voltage drop can be calculated. The following formula can be used for single-phase current.

Example: If a single-phase 230-volts condensing unit, rated at 22 amperes full-load and having a starting current of 91 amperes is located 125 feet from the distribution panel and so utilizes 250 feet of the No. 10 copper wire, the voltage drop expected during full load operation is calculated as follows:

Refer to the lower lines of Table 19-2. Note that the resistance of No. 10 copper wire is 0.1018 ohms per 100 feet.

$$\text{Voltage drop} = 22 \text{ amperes } \times 0.1081 \times \frac{250 \text{ feet}}{100} = 5.6 \text{ volts}$$

(Note that 5.6 volts exceeds the 2% loss factor, which is 4.6 volts.) If the full 3% loss (6.9 volts) allowed ahead of the meter is present, then the voltage at the load terminal of the meter will be 223.1 volts (230 – 6.9 = 223.1). Subtract the voltage drop calculated above and there will be only 197.5 volts at the unit terminals during full load operation.

Thus,

$223.1 - 5.6 = 197.5$. With a total loss of 5.4%, ($230 - 197.5 = 12.5$, or 5.47%),

it is a common practice to move to the next largest wire size. Therefore, for this circuit, AWG No. 8 wire should be used instead of No. 10.

Insofar as motor starting and relay operation are concerned, the critical period is during the initial instant of start-up when the inrush current closely approximates the locked rotor value. For the equipment described in the above example, the voltage drop experienced at 91 amperes flow for No. 10 wire is again excessive, indicating the wisdom of using No. 8 wire.

For No. 10 wire=

$$\begin{aligned}\text{Inrush voltage drop} &= 91 \text{ amperes} \times \frac{0.1018 \text{ ohms}}{100 \text{ feet}} \times 250 \text{ feet}\\ &= 24.57 \text{ volts}\end{aligned}$$

For No. 8 wire

$$\begin{aligned}\text{Inrush voltage drop} &= 91 \text{ amperes} \times \frac{0.064 \text{ ohms}}{100 \text{ feet}} \times 250 \text{ feet}\\ &= 14.56 \text{ volts}\end{aligned}$$

For a 230-volt circuit, the 23.2 volts slightly exceeds a 10% drop between the meter and the appliance. To this must be added the voltage drop incurred in the lead-in wires from the outdoor power line. This total must then be deducted from the power line voltage on the poles, which may be less than 230 volts during utility peak load periods. Although the inrush current may exist for only an instant, this may be long enough to cause a starting relay to open, thus cutting off current to the motor. Without current flow, the voltage at the unit immediately rises enough to re-close the relay, so there is another attempt to start the motor. While the unit may get underway after the second or third attempt, such "chattering relay" operation is not good for the relay, the capacitors, or the motor.

For electrical loads such as lighting, resistance heating, and cooking, inrush current may be considered the equivalent of normal current flow. In the case of rotating machinery, it is only during that initial period or rotation that the start-up current exceeds that of final operation. The same is true of relays during the instant of "pull-in."

Three-phase circuits

Calculating the inrush voltage drop for three-phase circuits is the same as calculating the drop for single-phase circuits. Again, the value for circuit length equals twice the length of an individual conductor. Since more conductors are involved, the normal current and the starting current per conductor are smaller for a motor of a given size. Thus, lighter wire may be used.

Example: Using the same wire length as in the single-phase example and the lower values of 13.7 amperes full load and 61 amperes starting inrush per conductor for the three-phase rating of the same size compressor, the use of No. 10 conductor results in:

$$\begin{aligned}\text{Normal voltage drop} &= 13.7 \text{ amperes} \times \frac{0.1018 \text{ ohms}}{100 \text{ feet}} \times 250 \text{ feet}\\ \circ\ \circ\ \circ\ \circ\ \circ\ \circ\ \circ\ \circ\ \circ &= 3.5 \text{ volts}\\ \text{Inrush voltage drop} &= 61 \text{ amperes} \times \frac{0.1018 \text{ ohms}}{100 \text{ feet}} \times 250 \text{ feet}\\ \circ\ \circ\ \circ\ \circ\ \circ\ \circ\ \circ\ \circ\ \circ &= 15.5 \text{ volts}\end{aligned}$$

Inrush voltage drop

The actual inrush current through an appliance usually is somewhat less than the total of locked-rotor current values. Locked-rotor current is measured with rated voltage at the appliance terminals. Since voltage drop in the feed lines reduces the voltage available at the terminals, less than rated voltage can be anticipated across the electrical components. Consequently, inrush currents and voltage drops are somewhat less. This fact is illustrated in the following, which is based on the same installation as that in the previous single-phase examples. However, here the actual locked-rotor current of 101 amperes is used. The formula can be found on the previous page.

Code Limitations on Amperes Per Conductor

Varied mechanical conditions are encountered in field wiring. Thus, the National Electrical Code places certain limitations on the smallness of conductors installed in the field. Such limitations apply regardless of conductor length. They assure the following:

1. That the wire itself has ample strength to withstand the stress of pulling it through long conduits and chases. With specific exceptions, no wire lighter than No. 14 copper is permitted for field wiring of line voltage power circuits.
2. By stipulating the maximum amperage permissible for each wire gage, self-generated heat can be limited to avoid temperature damage to wire insulation. If wiring is installed in areas of high-ambient temperature, the amperage rating may need to be reduced.
3. By stipulating the maximum amperage of overload protectors for circuits, current flow is limited to safe values for the conductor used. Some equipment has momentary starting currents that trip out overload protectors sized on the basis of full load current. Here heavier fusing is permissible, but only under specific circumstances. Current flow limitations for each gage protect wire insulation from damage due to overheating.

Heat Generated Within Conductors

Heat generation due to current flow through the wire is important for the following two reasons.

1. Temperature rise increases the resistance of the wire and, therefore, the voltage drop in the circuit. Under most conditions of circuit usage, this added resistance generates additional heat in the wires. Finally, a temperature is reached where heat dissipation from the conductors equals the heat that they generate. It is desirable to keep this equilibrium temperature low.

The number of Btu generated can be found by both of the following formulas.

$$\text{Indicated locked} - \text{rotor impedance} = \frac{\text{rated voltage}}{\text{locked} - \text{rotor amperes}}$$

$$= 230 \text{ volts}/101 \text{ amperes} = 2.28 \text{ ohms}$$

$$\text{Resistance of No. 10 leads} = \text{ohms}/100 \text{ feet} \times \text{length of wire (in feet)}$$

$$= 0.1018 \text{ ohms}/100 \text{ feet} \times 250 \text{ feet} = 0.25 \text{ ohms}$$

$$\text{Total indicated load and conductor impedance} = (2.28 + 0.25) = 2.53 \text{ ohms}$$

$$\text{Inrush current} = \frac{\text{distribution panel voltage}}{\text{total indicated impedance}}$$

$$\text{Inrush current} = \frac{230 \text{ volts}}{2.53 \text{ ohms}} = 91 \text{ amperes}$$

$$\text{Calculating inrush voltage drop} = \frac{91.0 \times 0.1018 \text{ ohms} \times 250 \text{ feet}}{100 \text{ feet}}$$

$$= 23.2 \text{ volts}$$

$$\text{Locked rotor voltage drop} = \frac{101 \times 0.1018 \text{ ohms} \times 250 \text{ feet}}{100 \text{ feet}} = 25.7 \text{ volts}$$

$$\text{Btu generated} = \text{amperes}^2 \times \text{resistance in ohms} \times 3.4313^*$$

2. Temperature also damages wire insulation. The degree of damage is dependent upon the insulation's ability to withstand temperature under varying degrees of exposure, age, moisture, corrosive environment, mechanical abuse, and thickness.

Estimating the probable operating temperature of a conductor and its insulation is difficult. The rate of heat dissipation from the wiring surfaces varies with the ambient temperature, the proximity of other heat-generating conductors, the heat conductivity of the insulation and jacket material, the availability of cooling air, and other factors. Freestanding individual conductors dissipate heat more effectively. However, the typical situation of two or three conductors, each carrying equal current and enclosed in a common jacket, cable, or conduit, anticipates limitations as set forth by the National Electrical Code.

Circuit Protection

Circuits supplying power to appliances must incorporate some means for automatically disconnecting the circuit from the power source should there be abnormal current flow due to accidental grounding, equipment overload, or short circuits. Such overload devices should operate promptly enough to limit the buildup of damaging temperatures in conductors or in the electrical components of an appliance. However, devices selected to protect circuits feeding motors must be slow enough to permit the momentary inrush of heavy starting current. They must then disconnect the circuit if the motor does not start promptly, as can happen under low voltage conditions.

---

*Conversion factor

Devices heavy enough to carry continuously the motor starting current do not provide the overload protection desired. Likewise, heavily fused branch circuits do not adequately protect the low amperage components that cumulatively require the heavy fusing. For this reason some literature lists maximum allowable fuse sizes for equipment. While electrical components of factory-built appliances are individually safeguarded, the field combining of two or more units on one circuit may create a problem more complex than that normally encountered. Remember that the final authority is the local electrical inspector.

Standard rule

With a few exceptions, the ampere capacity of an overload protector cannot exceed the ampacity values listed by wire size by the NEC. (Check the National Electrical Code for these exceptions.) If the allowable ampacity of a conductor does not match the rating of a standard size fuse or nonadjustable trip-circuit breaker, the device with the next largest capacity should be used. Some of the standard sizes of fuses and nonadjustable trip-circuit breakers are: 15, 20, 25, 30, 35, 40, 45, 50, 60, 70, 80, 90, 100, 110, 125, 150, 175, 200, 225, 250, and 300 amperes.

Fuses

One-time single-element fuses

If a current of more than rated load is continued sufficiently long, the fuse link becomes overheated. This causes the center portion to melt. The melted portion drops away. However, due to the short gap, the circuit is not immediately broken. An arc continues and burns the metal at each end until the arc is stopped because of the very high increase in resistance. The material surrounding the link tends

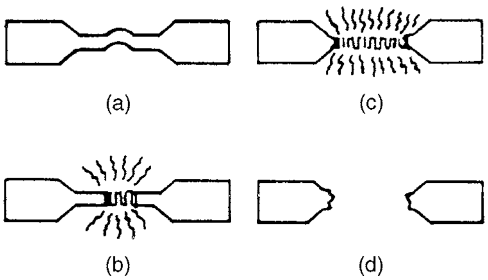

Figure 19-4 How a fuse works.

to break the arc mechanically. The center portion melts first, because it is farthest from the terminals that have the highest heat conductivity. See Fig. 19-4.

Fuses will carry a 10% overload indefinitely under laboratory-controlled conditions. However, they will blow promptly if materially overloaded. They will stand 150% of the rated amperes for the following time periods:

1 minute (fuse is 30 amperes or less).
2 minutes (fuse of 31 to 60 amperes).
4 minutes (fuse of 61 to 100 amperes).

Time-delay two-element fuses

Two-element fuses use the burnout link described previously. They also use a low-temperature soldered connection that will open under overload. This soldered joint has mass, so it does not heat quickly enough to melt if a heavy load is imposed for only a short time. However, a small but continuous overload will soften the solder so that the electrical contact can be broken.

With this type of protection against light overloads, the fusible link can be made heavier, yet blow quickly to protect against heavy overloads. This results

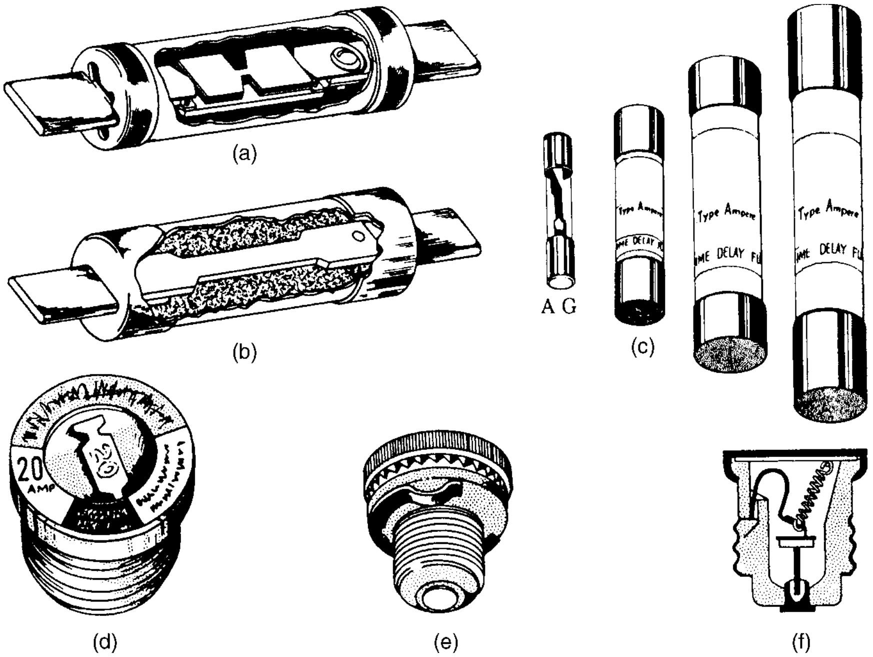

Figure 19-5 Fuse types.

in fewer nuisance burnouts and equipment shutdowns. Two types of dual-element fuses are shown in Fig. 19-5.

Types of fuses

In addition to those fuses just described, there are three general categories based on shape and size.

1. The AG (automotive glass) fuse consists of a glass cylinder with metallic end caps between which is connected a slender metal element that melts on current overload. This fuse has a length of $1^5/_{16}$ and a diameter of $^1/_4$. It is available only for low amperages. While used in specific appliances, it is not used to protect permanently installed wiring.
2. Cartridge fuses are like AG fuses. However, they are larger. The cylindrical tube is fiber, rather than glass. The metallic end pieces may be formed as lugs, blades, or cylinders to meet a variety of fuse box socket requirements. The internal metal fusible link may be enclosed in sand or powder to quench the burnout arc. Cartridge fuses are made in a variety of dimensions, based on amperage and voltage. Blade-type terminals are common above 60 amperes. Fuses used to break 600-volt arcs are longer than those for lower voltages. Fuses are available in many capacities other than the listed standard capacities, particularly in the two-element, time-delay types. Often, they are so dimensioned as to not be interchangeable with fuses of other capacities.
3. Plug fuses are limited in maximum capacity to 30 amperes. They are designed for use in circuits of not more than 150 volts above ground. Two-element time-delay types are available to fit standard screw lamp sockets. They are also available with nonstandard threads made especially for various amperage ratings.

Thermostats

The thermostat (or temperature control) stops and starts the compressor in response to room temperature requirements. Each thermostat has a charged power element containing either a volatile liquid or an active vapor charge. The temperature-sensitive part of this element (thermostat feeler bulb) is located in the return airstream. As the return air temperature rises, the pressure of the liquid or vapor inside the bulb increases. This closes the electrical contacts and starts the compressor. As the return air temperature drops, the reduced temperature of the feeler bulb causes the contacts to open and stops the compressor.

The advent of transistors and the semiconductor chips or integrated circuits produced a more accurate method of monitoring and adjusting temperatures within a system. The microprocessor makes use of the semiconductor's and chip's abilities to compare temperatures. It can also program on and off cycles, as well as monitor the duration of each cycle. This leads to more accurate temperature control.

Figure 19-6 shows a microprocessor-based thermostat. As you can see from the front of the control panel, you can adjust the program to do many things. It can also save energy, whether it is operating the furnace for heat or the air-conditioning unit for cooling. These units usually come with a battery so that the memory can retain whatever is programmed into it. The battery is also a backup for the clock so that the program is retained even if the line power is interrupted.

Thermostat as a control switch

The control switch (thermostat) may be located in the room to be cooled or heated, depending upon the particular switch selection point. The control switch (heat, off, cool, and auto) is of the sliding type and normally has four positions, marked "heat," "off," "cool," and "auto." The thermostat is taken from its socket and programmed according to the manufacturer's directions. Then it is activated by plugging it into the wall socket and replacing a couple of screws to hold it in place.

To operate the unit as a ventilator, the switch on the left is marked "fan" with an "on" and "auto" choice to select the "fan" operation. When a thermostat is installed for automatic cooling, the compressor and fans will cycle according to dial requirements.

Figure 19-7 shows the electrical circuitry for a home heat-cool thermostat. Keep in mind that the thermostat should always be on an inside partition, never on an outside wall. Do not mount the instrument on a part of the wall that has steam or hot water pipes or warm air ducts behind it. The location should be such that direct sunshine or fireplace radiation cannot strike the thermostat. Be careful that the spot selected is not likely to have a floor lamp near it or a table lamp under it. Do not locate the thermostat where heat from kitchen appliances can affect it. Do not locate it on a wall that has cold unused room on the other side.

After a thermostat has been mounted, it is wise to fill the stud space behind the instrument with insulating material. This is to prevent any circulation of cold air. Furthermore, the hole behind the thermostat for the wires should be sealed so that air cannot emerge from the stud space and blow across the thermostat element. It is quite common to find considerable air motion through this hole caused by a chimney effect in the stud space.

Service

Servicemen who have a good knowledge of refrigeration and air conditioning will be able to competently service air conditioners. Most air-conditioning units of present design contain compressors of the hermetic or sealed type. The only parts that can be serviced in the field are the relay, control switch, fan, fan motor, start and run capacitors, air filters, and cabinet parts. The refrigerating system (consisting of the cooling unit, condensers, compressors, and connecting lines) generally cannot be serviced in the field. Most servicemen will find the newer electronic-type thermostats easy to program when following the manufacturer's instructions included with every thermostat and usually given to the homeowner at closing on the house.

The unit trips if power is abnormal for 66% of interrogation time. The time delay on make is 0–10 minutes. The green LED shows that the power is on and valid and the relay is energized. ing for the end of a delay. The wiring diagram is shown in Fig. 19-10. Figure 19-11 shows the pictorial wiring of the unit.

The unit is epoxy encapsulated for use in extreme environmental conditions. The power loss detection or trip takes place within 45 milliseconds. There is a user selectable anti-short cycle (ASC) delay of 0.0 to 10 minutes. This unit also trips if the power is abnormal for 55% of interrogation period. The relay contacts can handle 6 amperes. The proper unit requires only 21 to 31 milliamperes for power operation. Table 19-6 presents a competitive cross-reference guide to various manufacturers' units.

Time Delays

Time delays also come in epoxy-encapsulated units. They will meet requirements for numerous applications. They are a simple two wire hookup usually and will work with the anticipator-type thermostat. One of those is shown in Fig. 19-12. It is specifically designed to control the circulating fan in heat pumps, air con-

Head pressure controls

The solid-state, epoxy-encapsulated head pressure control was designed specifically for HVAC and refrigeration applications. The unit is a temperature-sensitive fan motor speed control that regulates head pressure at low ambients by varying the air volume through the condenser. Its unique construction permits exceptionally quick response times to change in liquid line temperatures. See Fig. 19-13. The dimensions of the unit are shown in Fig. 19-14. It provides full torque to the motor during start-up to ensure proper fan rotation and lubrication of bearings. It also features high temperature bypass and applies full voltage to the condenser fan under normal operating conditions. It also determines the minimum RPM level at which the condenser fan should operate. The set-point hysteresis (Dead-band) prevents system oscillation which may occur with small temperature fluctuations in the liquid line. This unit can be used with a wide variety of motors.

Table 19-6 shows the head pressure control specifics and compares the Carrier or Totaline with the Hoffmann, Ranco, and Johnson Controls models of the same unit.

Line voltage head pressure controls

Preventing evaporator freeze-ups, liquid slugged compressors, and low pressure cutouts can occur during low ambient conditions. The dual line voltage input head pressure controls are ideal for refrigeration (see Fig. 19-15).

The unit controls temperature-sensitive motor fan speed. They have been designed to regulate head pressure at low ambients by varying the amount of airflow through the condenser and help to ensure sufficient pressure across the expansion valve. This unit has a dual-voltage 240/480 input transformer as part of the package. The user is able to select and adjust set points on the unit:

Totaline Sensor Probe Mounting Recommendations:

Single unit controls up to three refrigerant circuits on a single remote condenser.

High Efficiency Systems: The sensor probe should be mounted up several bends into the condenser (upper 1/3 as shown at left), to more closely monitor the condensing temperature.

Lower Efficiency Systems: The *sensor may be placed directly on the liquid line.*

Figure 19-17 Typical system diagram for pressure controls. (Courtesy of Carrier)

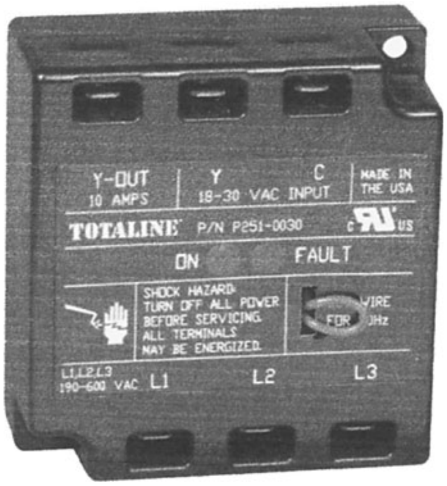

Figure 19-18 Three-phase line voltage monitor. (Courtesy of Carrier)

Hard start is 0.1 to 5 seconds adjustment possible; low temperature cutoff adjustment has adjustment for minimum pressure.

Basically, the unit prevents evaporator freeze-ups, low pressure cutouts, and liquid-slugged compressors. It provides full torque to the motor during start-up to help ensure proper fan rotation and lubrication of bearings.

It is possible to set the low temperature cutoff at the minimum rpm level at which the condenser fan should operate. And, the high temperature bypass applies full voltage to the condenser fan under normal conditions. Note the schematic drawing for connectons in Fig. 19-16. There are two models available, one operates on 120/240 volts and the other on 208/480 volts AC. Table 19-7 shows the probe resistance versus various temperatures. Figure 19-17 gives a graphic illustration of how the sensor probe is mounted. A single unit controls up to three refrigerant circuits on a single remote condenser. The sensor probe should be mounted up several bends into the condenser (upper $^1/_3$ as shown at the left) to more closely monitor condensing temperature. On lower efficiency systems, the sensor may be placed directly on the liquid line.

Three-Phase Line Voltage Monitor

The three-phase line monitor protects against phase loss, phase reversal, and phase unbalance. It is ideally suited to protect scroll and screw compressors from reverse rotation (see Fig. 19-18). A bright LED indicates faults and loads energized. There are no adjustments needed and it will operate on 190 to 600 volts AC. Its response to phase loss is less than 1 second, with an automatic reset from a fault condition.

If all three phases are relatively equal and in proper sequence, the normally open contacts (Y-Y-OUT) will close when 24 volts is applied betweeen C and Y. If the phases are out of sequence or one is missing, the contacts will never close. If a phase is lost while the unit is energized, the contacts will open immediately, and remain open until the error is corrected.

Current Sensing

The Rapid Start current sensing unit is able to engage the hard-start capacitor for precisely the correct amount of time. This is done by monitoring the compressor current upon start-up. It ensures maximum starting torque without the risk of supplying too much current into the start-winding.

The unit is a timed safety circuit that operates in the event the motor fails to start within 600 milliseconds or 0.6 seconds (see Fig. 19-22).

This easy-to-install two-wire unit is solid-state circuitry. It boosts starting torque and disengages upon start. It can fit into tight locations. Various wiring configurations and dimensions are shown in Fig. 19-23. Table 19-8 shows some Rapid Start comparisons to illustrate further the operation and properties of the current-sensing device.

Careers in Air Conditioning and Refrigeration

Performance Objectives

- Know the industries that employ air-conditioning and refrigeration mechanics.
- Know what job qualifications are needed for work in the air-conditioning/refrigeration field.
- Know the various sources of information for those in the field.
- Know the opportunities for teaching in the field.

The field of air conditioning and refrigeration offers a variety of career opportunities. Air-conditioning and refrigeration mechanics install and service air-conditioning and refrigeration equipment. There are a number of different types of equipment that require service. Some systems are complex, but are easily broken down into smaller units for repair purposes. Some mechanics specialize in a particular part of a system.

Industries that Employ Air-Conditioning and Refrigeration Mechanics

Approximately 259,000 persons work as air-conditioning and refrigeration mechanics. Cooling contractors employ most of these mechanics. Food chains, school systems, manufacturers, and other organizations use the services of air-conditioning and refrigeration mechanics. Large air-conditioning systems use many mechanics to keep the equipment operational. However, not all mechanics work for other people. About one in every seven mechanics is self-employed.

Manufacturers use refrigeration equipment for a variety of processes. Meat packers and chemical makers use refrigeration in some form. Temperature control is very important for many manufacturing processes.

Mechanics work in homes, office buildings, and factories. They work anywhere there is air conditioning or refrigeration to be installed or serviced. They bring to the job sites the tools and parts they need. During the repair season, mechanics may do considerable driving. Radio communications and cell phones may be used to dispatch them to the jobs. If major repairs are needed, mechanics will transport parts or inoperative machinery to a repair shop.

Mechanics work in buildings that are often uncomfortable. This is because the air-conditioning or refrigeration system has failed. The mechanic may have to work in a cramped position in an attic, a basement, or a crawl space.

Rooftop units are a common practice in keeping smaller installations cool. Many of the systems have at least one unit on the roof of the building. Cooling towers are usually mounted on top of a building. Thus, the mechanic may be called upon to work in high places. In summer, the rooftop may be very hot. This trade does require some hazardous work. For instance, there are the dangers of electric shock, torch burns, muscle strains, and other injuries from handling heavy equipment.

System installation calls for work with motors, compressors, condensing units, evaporators, and other components. These devices must be installed properly. This calls for the mechanic to be able to follow the designer's specification. In most instances, blueprints are used to indicate where and how the equipment is to be installed. The ability to read blueprints is essential for the air-conditioning and refrigeration mechanic. Such ability will help ensure that the ductwork, refrigerant lines, and electrical service are properly connected (see Fig. 20-1).

After making the connections, it is then necessary to charge the system with the proper refrigerant. Proper operation must be assured before the mechanic is through with the job.

Equipment installation is but one of the jobs the mechanic must perform. If the equipment fails, then the mechanic must diagnose the cause of the trouble and make the proper repairs. The mechanic must:

1. Find defects
2. Inspect parts
3. Be able to know if thermostats and relays are working correctly

During the winter, air-conditioning mechanics inspect parts such as relays and thermostats. They also perform required maintenance. Overhauling may be included if compressors need attention or recharging. They may also adjust the airflow ducts for the change of seasons.

Air-conditioning and refrigeration mechanics use a number of special tools. They also use more common tools such as hammers, wrenches, metal snips, electric drills, pipe cutters and benders, and acetylene torches. Air ducts and refrigeration lines require more specialized tools. Voltammeters are also part of the mechanic's toolbox. Electric circuits and refrigeration lines must be tested and checked. Testing of electrical components is also required. A good background in electricity is necessary for any mechanic (see Fig. 20-2).

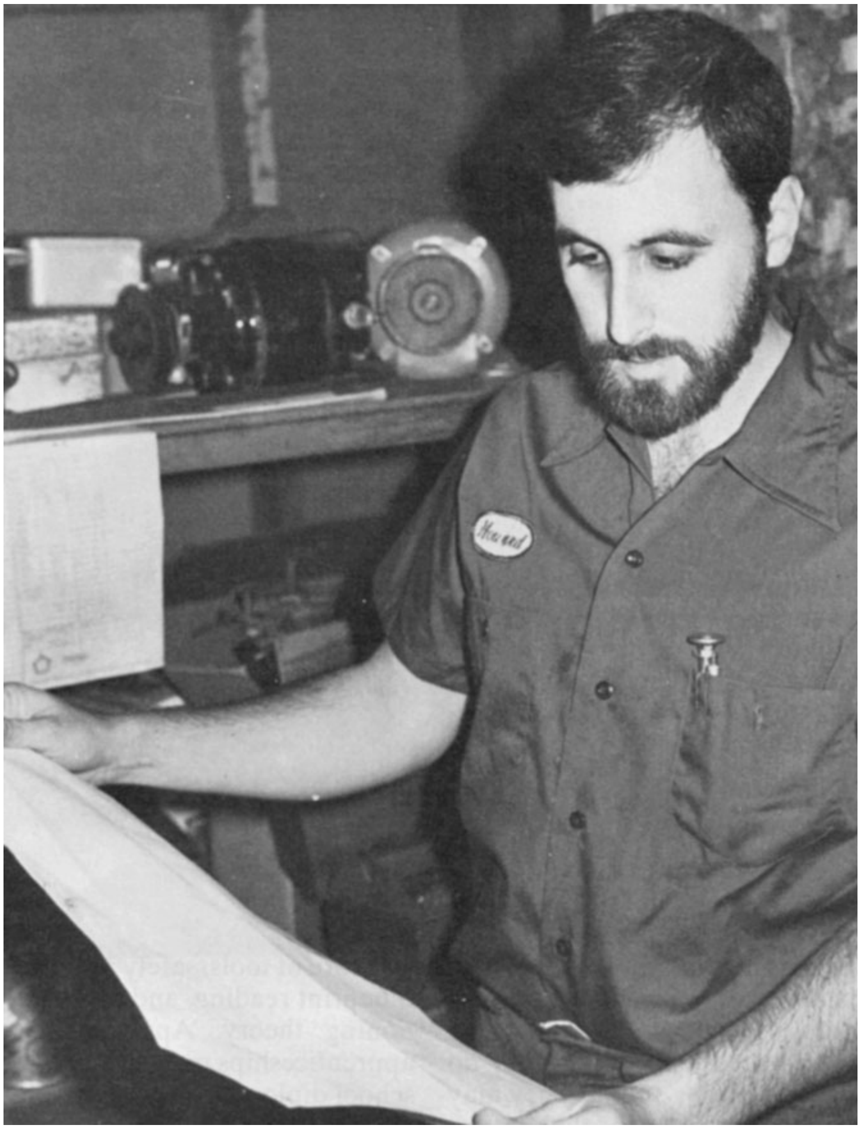

Figure 20-1 The air-conditioning and refrigeration mechanic must be familiar with blueprint symbols. Reading blueprints is essential to the proper installation of systems.

Cooling systems sometimes are installed or repaired by other craft workers. For example, on a large air-conditioning installation job, especially where people are covered by union contracts, sheet-metal specialists might do ductwork. Electricians will do electrical work. The installation of piping will be done by pipe fitters. However, in small towns or small companies, the AC man will probably have to do all these specialized skills.

Figure 20-2 The air-conditioning and refrigeration mechanic must be able to test the effectiveness of a component. This demands skill in using a variety of instruments.

Job Qualifications

Most air-conditioning and refrigeration mechanics start as helpers. They acquire their skills by working for several years with experienced mechanics. New people usually begin by assisting experienced mechanics. They do the simple jobs at first. They may carry materials or insulate refrigerant lines. In time, they do more difficult jobs, such as cutting and soldering pipes and sheet metal and checking electric circuits. In 4 or 5 years, the new mechanics are capable of making all types of repairs and installations.

The armed forces operate their own technical schools. They range from 6 months to 2 years, depending on the specialty and degree of skill needed for the military occupational specialty (MOS).

Civilian apprenticeship programs are run by unions and air-conditioning contractors. In addition to on-the-job training, apprentices receive 144 hours of classroom instruction each year. This is in related subjects. Such subjects include the use and care of tools, safety practices, blueprint reading, and air-conditioning theory. Applicants for apprenticeships must have a high school diploma. They are given a mechanical aptitude test. Apprenticeship programs last 4 to 5 years.

Many high schools, private vocational schools, and junior colleges offer programs in air conditioning and refrigeration. Students study air-conditioning and refrigeration theory and equipment design and construction. They also learn the basics of installation, maintenance, and repair. Employers may prefer to hire graduates of these programs because they require less on-the-job training.

High school graduates are preferred as helpers. If they have mechanical aptitude and have had courses in mathematics, mechanical drawing, electricity, physics, and blueprint reading, they have a better opportunity to be hired. Good physical condition is also necessary. Mechanics sometimes have to lift and move heavy equipment.

To keep up with technological change and to expand their skills, experienced mechanics may take courses, offered by a number of sources. The Refrigeration Service Engineers Society and the Air-Conditioning Contractors of America offer updating courses for mechanics. There are a number of trade magazines that help keep the mechanic up-to-date in the latest equipment and troubleshooting procedures.

Mechanics can advance to become supervisors. Some open their own contracting businesses. However, it is becoming difficult for one-person operations to operate successfully.

The Future

Employment of air-conditioning and refrigeration mechanics is expected to increase. The increase is expected to be about as fast as the average of all occupations during the past 10 years. Many openings will occur as experienced mechanics transfer to other fields of work. As experienced mechanics retire or die, they have to be replaced. The numbers will vary from year to year. However, in the United States, as people move toward the Sunbelt there will be more jobs for air-conditioning mechanics (see Fig. 20-3).

Opportunities for air-conditioning and refrigeration mechanics are expected to follow trends in residential and commercial construction. Even during periods of slow growth, many mechanics will be needed to service existing systems. Installations of new energy-saving air-conditioning systems will also create new jobs. In addition, more refrigeration equipment will be needed in the production, storage, and marketing of food and other perishables. Because these trades have attracted many people, the beginning mechanics may face competition for jobs as helpers or apprentices.

Pay and Benefits

Most mechanics work for hourly wages. These skilled air-conditioning and refrigeration specialists receive pay frequently higher than those who work in similar specialties.

Apprentices receive a percentage of the wage paid to experienced mechanics. Their percentage is about 40% at the beginning of their training. They receive 80% during their fourth year.

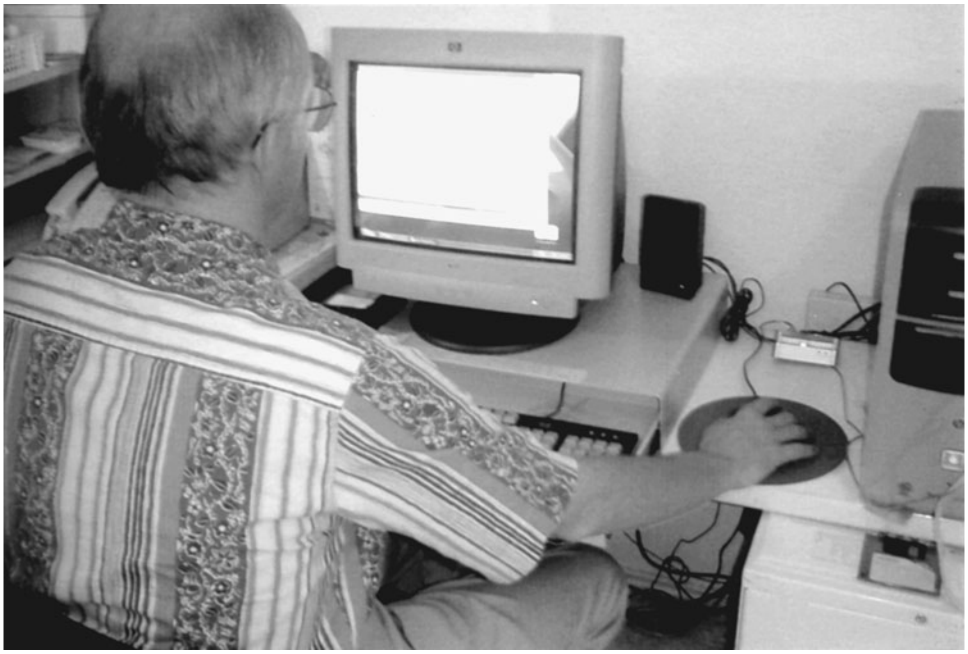

Figure 20-3 The temperature in data processing centers must be carefully controlled if the data processing equipment is to operate properly. Such equipment often generates a great deal of heat. Thus, air conditioning is essential for the equipment to function properly. This operator works in an air-conditioned room.

Mechanics usually work a 40-hour week. However, during seasonal peaks they often work overtime or irregular hours. Most employers try to provide a full workweek for the entire year. By doing this, they have mechanics when they need them most during the summer months. However, they may temporarily reduce hours or lay off some mechanics when seasonal peaks end. In most shops that service air-conditioning and refrigeration equipment, employment is largely stable throughout the year. Median hourly earnings of heating, air-conditioning, and refrigeration mechanics and installers were $16.78 in 2002. The middle 50% earned between $12.95 and $21.37 an hour. The lowest 10% earned less than $10.34, and the top 10% earned more than $26.20. Median hourly earnings in the industries employing the largest numbers of heating, air-conditioning, and refrigeration mechanics and installers in 2002 were as follows:

Merchant wholesalers	$18.78
Commercial and industrial machinery and equipment (except automotive and electronic) repair and maintenance	$17.16
Direct selling establishments	$17.14
Elementary and secondary schools	$16.80
Building equipment contactors	$16.03

Apprentices usually begin at about 40%–50% of the wage rate paid to experienced workers. As they gain experience and improve their skills, they receive periodic increases until they reach the wage rate of experienced workers. Heating, air-conditioning, and refrigeration mechanics and installers enjoy a variety of employer-sponsored benefits. In addition to typical benefits such as health insurance and pension plans, some employers pay for work-related training and provide uniforms, company vans, and tools.

About 20% of heating, air-conditioning, and refrigeration mechanics and installers are members of a union. The unions to which the greatest numbers of mechanics and installers belong are the Sheet Metal Workers International Association and the United Association of Journeymen and Apprentices of the Plumbing and Pipe-Fitting Industry of the United States and Canada.

Teaching as a Career

A person interested in passing on to others his/her knowledge of air conditioning might be to teach in vocational schools. The public schools also offer classes in air conditioning and refrigeration. Teachers of such courses often come from the trade itself. Once they have secured a position in the school, they may have to take certain college-level courses. These courses will deal with teaching methods and other subjects related to education.

Private trade schools are usually in need of good people with experience in the trade. They are needed to organize and teach apprentices. These schools may be sponsored by air-conditioning and refrigeration contractors or by unions (see Fig. 20-4).

Pay and benefits are the same as for any other teacher in the public or the private schools. Working conditionings are similar throughout the country. The demand varies with the temperature. Therefore, the climate has much to do with the demand for air-conditioning and refrigeration specialists.

Review Questions

1. How many hours of classroom instruction are received in an air-conditioning and refrigeration apprenticeship program?
2. What business employs most air-conditioning and refrigeration mechanics?
3. What percentage of the wage paid to experienced workers are paid to apprentices?
4. What does the future promise for the air-conditioning and refrigeration mechanics?
5. How many people work in this industry today?
6. What are some of the professional organizations that exist for service to the air-conditioning and refrigeration technician?

ELECTRONICS & BRAIN CONTROL

We are learning more about our gray-matter computers

BY L. GEORGE LAWRENCE

IT IS TIME that we closely examined brain control, now that scientists are actively seeking to unravel the mysteries that shroud that miniature bioelectric giant known as the human brain. Elements of brain control can already be found in anti-collision radar technology involving birds. It has also been substantiated that, by pumping energy in the gigahertz range of frequencies through human heads, subjects can suddenly "hear" without using their ears.

Much remains to be done to correlate and sift out concealed facts. We still know very little about the all-important coding events that take place in the brain's neuron-synaptic complex. How can we measure and reinforce such significant human capacities as love, will, and character? Does uncontrolled electromagnetic pollution affect the brain? These and other questions remain to be answered as scientists delve deeper and deeper into the human brain with the help of electronics.

What Is the Brain? The theory that the brain is a true electronic machine has often been proposed. To a point, the theory is true. As Dr. Wilder Penfield demonstrated some years ago, the electrical stimulation of brain tissue during skull surgery triggers lucid audio-visual recalls of past events in patients. The patient "sees" and "hears" complete increments of true life experiences, all in correct sequence.

But consider Fig. 1. Studies are enormously complicated by the fact that the human brain contains an estimated 10 billion nerve cells called "neurons" and another 100 billion of a second type called "glial" cells. The fluid bath in which these cells are suspended is a vital element in their electrochemical interactions. Is it here where emotional components and memory are stored and where we have susceptance to microwave and other electromagnetic frequencies?

Such questions guide us into the subject of "synaptic" transmission. The term "synapse" is derived from the Greek phrase "to clasp' and was introduced in 1897 by a Dr. Sherrington who used it to describe the junctional region between two nerve cells. In many cases there is a gap or cleft across a synapse. (In other cases, as in fish, a synapse is a real physical joint.)

One big neuron might have on its surface as many as 10,000 points of contact (synaptic knobs) with other neurons. When the latter are stimulated, some of the millions of ribonucleicacid (RNA) molecules inside them give orders to the glial cells to manufacture new proteins. The nature and pattern of these proteins contain an imprint of something that has been perceived and apparently gives rise to a molecular "engram."

We also find electrical dipoles in synaptic mechanisms which, when oriented and arranged in a large array, apparently can produce an electric field strong enough to drive positive ions over the junction barrier of the postsynaptic membrane (in a manner similar to that in a transistor) and thereby initiate excitation or produce depolarization. So, one comes to believe that the nature of synaptic transmission is essentially electrical, be it mediated by electrical or chemical transmitters.

By inference, then, the possibility arises of human brain control by electromagnetic forces directed at it from the outside. If such radiations can be suitably coded to elicit a synchronous response in the neuron-synaptic complex, the brain will trigger motor functions which, in turn, cause man or animal to execute a programmed act. Here we have some fascinating experiments that hold great hopes for the immediate future.

In the case of hearing, for example, we have been taught that our auditory system can respond only to acoustic energy. This "fact" is far from correct. Experiments conducted by Dr. Frey and others clearly indicate that the audio sense in man—and probably in animals, too—can respond to electromagnetic energy in at least a portion of the r-f spectrum. Data shows that, at very low power levels (to preclude biological damage) in tests like that shown in Fig. 2, there are audio sensations at frequencies as low as 200 MHz and at least as high as 3 GHz. When low-level energy was directed at them, the test subjects reported "hearing" a buzzing sound. However, they found it almost impossible to match r-f sounds to a sine wave. The apparent source of the buzzing, clicking, knocking, or hissing sounds is described as being within or immediately behind their heads. This localization persists no matter how a person rotates or twists his head in the r-f field.

It was during these studies that a profoundly important discovery was made: deaf subjects often had the ability to *hear* r-f sound. The clinical criterion was that, if a given person could hear audio above 5 kHz either by bone or air conduction, then r-f sound could be heard as well. This and related work has resulted in the manufacture of r-f type hearing aids for the deaf, one of which is made by Listening, Inc., 6 Garden St., Arlington, Mass., and is known as the Neurophone Model GPF-1. It operates at 100 kHz and employs crystal control.

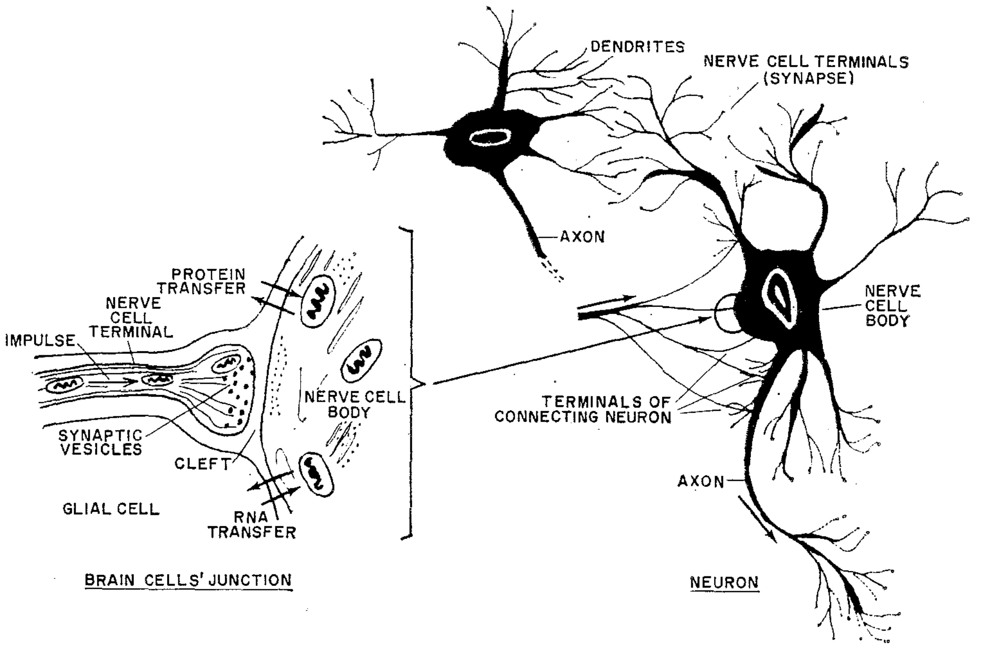

Fig. 1. Neuron/synaptic mechanism in the human nervous system.

These observations tie in with the fact that some individuals can detect radio programs through the fillings in their teeth. This phenomenon was technically verified by interposing shields between respective people who exhibited it and the modulated r-f sources. When the lower half of the head was covered, including the maxillary dental area, the r-f sound was perceived. The sound ceased upon covering the top half of the head. While the mechanism responsible for this phenomenon is only imperfectly understood, it can be assumed to be the result of direct cortical nerve fiber stimulation.

We also have another form of hearing sensations that come about when the human head is placed between two large capacitor plates that are excited by varying electrostatic potentials. "Electrophonic hearing," as it is called, apparently acts on the ear's tympanic membranes in a quasi-mechanical manner. It is useful as a new research tool in specialized psycho-physiological studies on the auditory or vibrotactile system.

Unavoidably, data of this sort begs application. Pilot studies are under way to apply effective electrodynamic brain control to animals and man himself. Consider, for example, the brain-wave proposal based on ideas put forth by the late Dr. Norbert Weiner, the acknowledged father of cybernetics.

According to Weiner, a sheet of tin suspended from the ceiling of a room and connected to a 10-Hz electrostatic generator can cause unpleasant sensations in human subjects. With a field strength of 1 or 2 volts per sq cm, the oscillating field roughly coincides with the human brain's alpha-rhythm frequency but attempts to lock it to a *fixed* frequency—that of the generator. Electronic sleep machines employ similar principles, with currents of fixed amplitude and pulse width (usually square waves) being fed by conductive face masks through the cranium and brain.

Brain Control of Birds. Radar technology is now being used to deal with the problem of birds getting in the way of fast flying aircraft. The idea is to trigger a flying bird's (or a whole flock's) brain into motor functions to initiate collision avoidance by having the bird(s) veer off the flight path of the plane. This area of research was triggered by the staggering incidence of plane/bird collisions that result in equipment damage estimated to be in the millions of dollars each year and the human lives that continue to be lost as a result of such collisions.

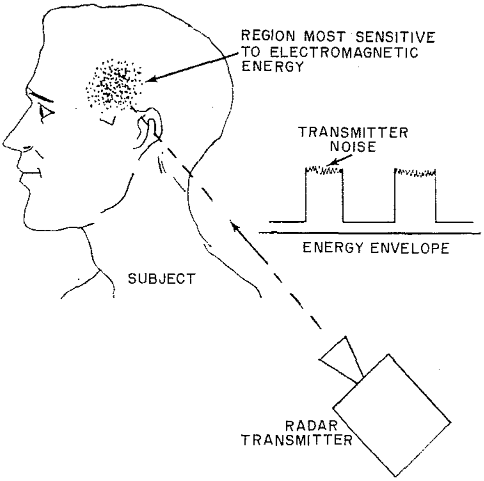

Fig. 2. Microwave susceptance area in brain.

The work being carried out by the National Research Council of Canada bears much promise in bird-brain control. The NRC's test system takes the form of a carousel of bird cages containing live chickens. (Fig. 3) Only one of the many cones suspended above the cages contains a microwave antenna. The program, headed by Dr. Alan Tanner, aims to evolve microwave brain-control systems that will have the greatest possible effect on birds while at the same time deploying the least amount of power.

When exposed to microwave radiation, birds in general exhibit escape reactions. This fact became clear during World War II. Investigators also found that in each case the microwave field through which birds were flying was of very low intensity —too low, in fact, to account for confusion and escape reactions on the basis of heat generated in the animals' bodies.

Different species of birds have different behavioral patterns. In the laboratory, a few seconds after the microwave field has been initiated, the given bird's wing outside the field of radiation became collapsed and the opposite wing became extended. Similar phenomena were observed with the legs. Sometimes the birds heeled over to the outside of the field. In the turning reaction, the outer side of the bird becomes paralyzed. In short, the microwave beam interacts with the nervous system of the test birds. Seagulls and pigeons reacted similarly, though the gulls are more inclined to initiate flight.

It is interesting to note that a bird's feathers appear to play a much greater role in the sensory complex than has been realized before. Defeathered chickens, for example, give little or no reactions to microwave fields until the twelfth day, at which time new feathers start to grow and tips protrude from the surface of the skin. In the case of fully feathered chickens whose tail feathers were exposed to microwave radiation, the birds immediately ceased exploration of their cages and exhibited mounting signs of distress after a period of 10-20 seconds. When the microwave field was switched off, the birds responded by fluffing their body feathers and active preening.

The Canadians believe that the physical properties of quill tissue—particularly the piezoelectric properties that are fundamental to living tissue–suggest mechanisms that have heretofore been overlooked. However, work carried on by Dr. Tanner and his staff as well as research conducted elsewhere should in time yield a microwave beam of the proper wavelength and modulation to cause birds to activate collision avoidance with all possible haste.

Brain-Wave Detection. Some 40-odd years ago, university professor F. Cazzamalli started publishing papers on the subject of brain-wave detection and implied that he had detected radiations from the mind. As shown in Fig. 4, he placed subjects in a shielded room (or Faraday cage), emanated vhf radiowaves through their heads, and claimed to have recorded "beat frequencies" obtained with an untuned receiver consisting of a galena crystal or diode tube, a fixed capacitor, an antenna, and a sensitive light-beam galvanometer.

The trouble is that Cazzamalli never mentioned transmitter power in his somewhat unprofessional papers. His oscillograms meant to show variations of the "beat" when his subjects were emotionally aroused or engaged in creative tasks when they were in the Faraday cage. Later, he told an astounded world that his subjects would hallucinate when under the influence of his "oscillatori telegrafica," its frequency being about 300 MHz at the time.

Tom Jaski, a noted science writer and engineer, duplicated some of Cazzamalli's work with a modern low-power oscillator that was swept from 300 MHz to 600 MHz. His subjects could not see the dial. They were told to sound off as soon as they felt something unusual. At a certain frequency range—varying between 380 MHz and 500 MHz—the subjects repeatedly indicated points with exact accuracy in as many as 14 out of 15 trials. At these "individual"

frequencies, the same subjects announced having experienced pulsing sensations in the brain, ringing in the ears, and an odd desire to *bite* the experimenters. The oscillator's output power was only a few milliwatts, while the oscillator itself was located several feet away from the subjects.

The Conclusions. Considering the ingredients of the few sample discussions presented above, it appears that both humans and animals have brains sensitive to r-f energy. The correlating mechanisms are only imperfectly known, but they apparently reside within the neuron-synaptic complex. Nor will we know how this susceptance affects our longevity without proceeding with a great deal more research.

Just how electromagnetic radiation affects our social structure has led to a great deal of speculation in the past. For example, the late Dr. Goldman once insisted that r-f energy allows the id, or primitive brain, to take control over human affairs. Such considerations might open a Pandora's box when applied to an explanation of our sharply increasing crime rates and decline of social fidelity. So, before we rush pell-mell into electromagnetically contaminating our environment, it would serve us well once and for all to discover what adverse effects, if any, it will have on our lives. ◆

ELEC 201: INTRODUCTION TO ENGINEERING DESIGN

Department of Electrical and Computer Engineering,
Rice University, P.O. Box 1892, Houston, TX 77251
www.owlnet.rice.edu/legolab

This manual[1] introduces electronic assembly, provides step-by-step instructions for the assembly of the ELEC 201 RoboBoard, and gives wiring and other information for the electronic hardware used in the course. We assume the reader has no prior electronics background. This document is organized into the following sections:

1. Electronic Assembly Technique
2. RoboBoard Assembly Instructions
3. Battery and Charger System
4. Infrared Beacon
5. Cable and Connector Wiring
6. Sensor Wiring
7. Motor Mounting and Wiring

All of this information, except for Section 2, is also in the Course Notes on the ELEC 201 web site.

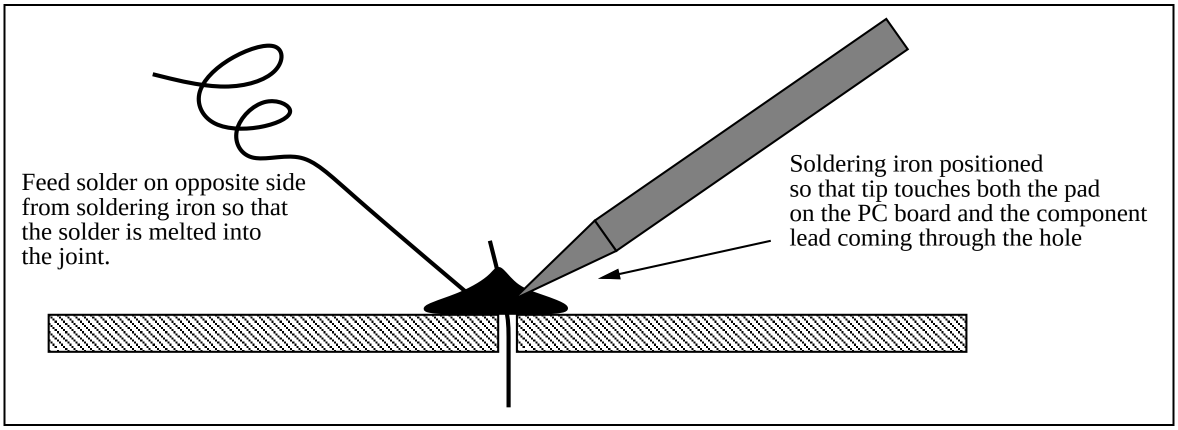
1 Electronic Assembly Technique

If there are places in life where neatness counts, electronic assembly is certainly one of them. A neatly-built and carefully soldered board will perform well for years; a sloppily- and hastily-assembled board will cause ongoing problems and failures. While building your board your team should switch tasks frequently to avoid fatigue. Mistakes are very easy to make when you are tired, and can be difficult and costly to fix.

The basics of electronic assembly are covered here: proper soldering technique, component mounting technique, and component polarities. Following these instructions and guidelines should make future debugging less frustrating.

1.1 Soldering Technique



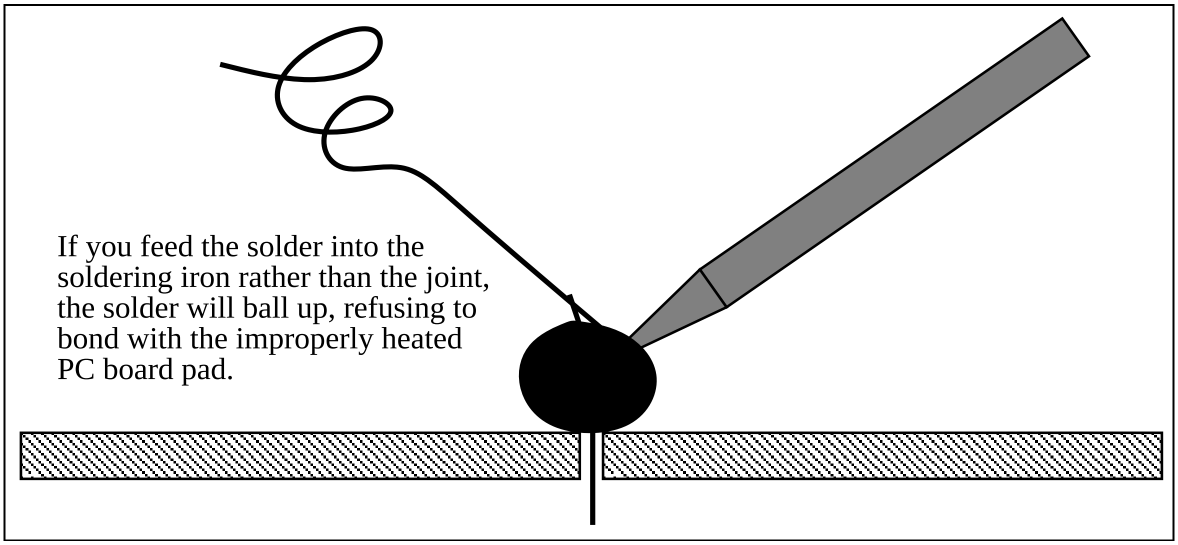
Feed solder on opposite side
from soldering iron so that
the solder is melted into
the joint.
Soldering iron positioned
so that tip touches both the pad
on the PC board and the component
lead coming through the hole

Figure 1: Proper Soldering Technique

Figure 1 shows proper soldering technique: the tip of the soldering iron is inserted into the joint such that it touches both the lead being soldered *and* the surface of the PC board. Use the side of the tip when soldering. The increased surface area will transfer heat more quickly.

Then solder is applied into the joint, *not* to the iron directly. The solder is melted *by the joint*, and both metal surfaces of the joint (the lead and the PC pad) are heated to the necessary temperature to bond chemically with the solder. Once solder flows into the joint, lift the soldering iron tip straight up, so that the finished soldered joint appears cone-shaped. This also tends to wipe excess solder along the part of the component lead that will be cut off.

Figure 2 shows what happens if the solder is “painted” onto the joint after being applied to the iron directly. The solder has “balled up,” refusing to bond with the pad (which did not receive enough heat from the iron).



If you feed the solder into the soldering iron rather than the joint, the solder will ball up, refusing to bond with the improperly heated PC board pad.

Figure 2: Improper Soldering Technique

With this technique in mind, please read the following list of pointers about electronic assembly. All of these items are important and will help develop good assembly skills:

1. Keep the soldering iron tip away from everything (including hair) except the point to be soldered. The iron is *extremely* hot and can easily damage parts, cause burns, or even start a fire. The soldering iron should be kept in its holder when not being held.

2. For cleaning off and tinning the tip, a damp sponge should be on hand. Soldering is basically a chemical process, and even a small amount of contaminants can prevent a good joint from being made. “Damp” means wet the sponge and squeeze out all excess moisture.

3. Always make sure that the tip is *tinned* when the iron is on. Tinning protects the tip and improves heat transfer.

   To tin the iron, clean the tip by wiping it on the damp sponge and then immediately melting some fresh solder onto it. Then wipe it on the sponge again. The tip should be shiny and coated with solder.

   If the iron has been idle awhile, always clean and then re-tin the tip before continuing.

4. The tip of the iron is nickel-plated and therefore should not be filed; this would remove the protective plating on the tip.

5. A *cold solder joint* is a joint containing an air bubble or other impurity that entered as the joint was cooling. Cold solder joints can be identified by their

dull and mottled finish. The solder does not flow and wrap around the terminal like it should.

Cold joints are brittle and make poor electrical connections. To fix such a joint, apply the tip (and perhaps a *very* small amount of solder) at the joint until the solder re-melts and flows into the terminal. If a cold solder joint reappears, remove solder with desoldering wick, and re-solder the joint.

6. Do not hold the iron against the joint for longer than 3-4 seconds, since many electronic components can be damaged by prolonged or excessive heat. Too much heat can also cause the traces on the printed circuit board to peel up or even burn off.

   Components that are particularly sensitive to heat damage include diodes, integrated circuits, LEDs, transistors and voltage regulators.

1.2 Desoldering Technique

It takes about ten times as long to desolder a component as it does to solder it in the first place. This is a good reason to be careful when assembling boards. However, errors will inevitably occur, and it is important to know how to fix them. The primary reasons for performing desoldering are removing an incorrectly-placed component, removing a defective component, and removing solder from a cold solder joint to try again with fresh solder.

The most common methods for removing solder are desoldering pumps and desoldering wick. The ELEC 201 lab kit includes a desoldering pump and desoldering wick as standard equipment.

To use the desoldering wick, simply place the wick between the soldering iron and the excess solder, being very careful not to apply heat for too long.

To use a desoldering pump, first load the pump by depressing the plunger until it latches. Grasp the pump in one hand and the soldering iron the other, and apply heat to the bad joint. When the solder melts, quickly remove the soldering iron and bring in the pump in one continuous motion. Trigger the pump to suck up the solder while it is still molten. This takes a little practice to get right, even for experienced builders.

Adding additional solder to a troublesome joint can be helpful in removing the last traces of solder. This works because the additional solder helps the heat to flow fully into the joint. The additional solder should be applied and de-soldered as quickly as possible. Don't wait for the solder to cool off before attempting to suck it away.

The desoldering pump tip is made of Teflon. While Teflon is heat-resistant, it is not invincible, so the Teflon tip should not be jammed directly into the soldering iron. Solder will not stick to Teflon, so the desoldering operation should suck the solder into the body of the pump. You may need to open the desoldering pump occasionally and empty out accumulated solder.

1.3 Component Types and Polarity

A variety of electronic components will be in use when assembling the boards. The following section provides a brief introduction to these components – how to properly identify and install these parts when building the boards.

1.3.1 Component Polarity

Polarity refers to the fact that many electronic components are not symmetric electrically. Reversing a polarized component in a circuit will result in very different, often undesired effects. For example, passing current through an LED in one direction (forward biased direction) will cause the LED to light up. Reversing the LED will stop current flow up to a certain, often much higher, voltage. Incorrectly mounted polarized devices will not work, and in some cases will be damaged or may damage other parts of the circuit. The following components are always polarized:

- all diodes (LEDs, standard diodes, zener diodes)
- transistors and voltage regulators
- integrated circuits

Capacitors are an interesting case, because some are polarized while others are not. As a general rule, large capacitors (values 1 μF and greater) are usually polarized, while smaller ones are not.

Resistors are not polarized, meaning it does not matter in which direction electricity flows through them. However, it is usual to mount them so their markings all face the same way to make it easier to work on the circuit. (It is also prettty.) The RoboBoard also contains *resistor single-in-line packages* (SIPs), and these have non-symmetric internal wiring configurations, making them polarized from a mounting point of view.

The following paragraphs discuss these components individually, explaining standardized component markings for identifying a component's polarity.

Resistors Individual resistors are small cylindrical devices with color-coded bands indicating their value (how to read color-coding is explained in Figure 10). Most of the resistors in the ELEC 201 kit are rated for $\frac{1}{8}$ watts, which is a very low power rating; hence they are very small devices. A few resistors are much larger: A 1 watt resistor has a large cylindrical shape, while a 5 watt resistor has a large, rectangular package.

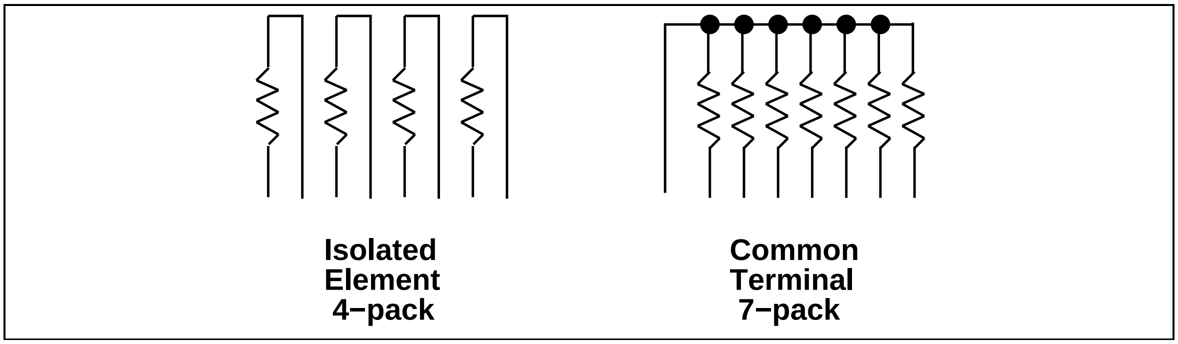


Figure 3: Resistor Pack Internal Wiring

Resistor Packs Resistor packs (or packages) are flat, rectangular packages with four, six, eight, or ten leads. There are two basic types of resistor packs:

Isolated Element. Discrete resistors; usually three, four, or five per package.

Common Terminal. One end of each resistor is tied to a common pin, and the other end is free. The package may contain from three to nine resistors.

Figure 3 illustrates the internal wiring for each style of 8-pin resistor pack.

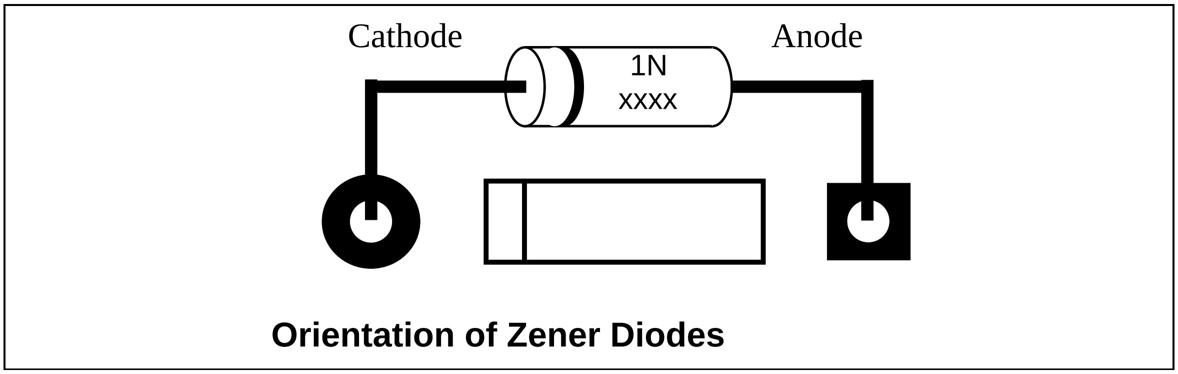

Figure 4: Zener Diode Orientation

All diodes (including the zener diodes and standard diodes used on the RoboBoard) have two leads, called the *anode* and *cathode*. When the anode is connected to positive voltage with respect to the cathode, current can flow through the diode; if polarity is reversed, no current flows. Zener diodes add a twist: at a particular value of reverse polarity voltage (called its "zener," or avalanche voltage), the diode conducts again. This functionality is useful in the design of voltage regulators and (the RoboBoard use) for precise over-voltage protection.

A diode package usually provides a marking that is closer to one lead than the other (a band around a cylindrical package, for example). This marked lead is always the *cathode*, and is always inserted into Pin 2 (the end *opposite* the square pad on the RoboBoard).

Figure 4 shows a the correct orientation of the 1Nxxxx (where "xxxx" is a four digit number denoting the specific diode type) zener diodes used on the RoboBoard and on the battery charger board.

LEDs *LED* is short for "light-emitting diode." An LED's cathode is marked either by a small flat edge along the circumference of the diode casing, or the shorter of two leads. The latter case is the one present in the ELEC 201 kit. Figure 5 shows a typical LED package.

Figure 6: Top View of 14-pin DIP

Integrated Circuits Integrated circuits, or ICs, come in a variety of package styles. Two common types, both of which are used in the RoboBoard design, are called the *DIP* (for dual-inline package), and the *PLCC* (for plastic leadless chip carrier).

In both types, a marking on the component package signifies "pin 1" of the component's circuit. This marking may be a small dot, notch, or ridge in the package. After pin 1 is identified, pin numbering proceeds sequentially in a counter-clockwise direction around the chip package, when looking from the top.

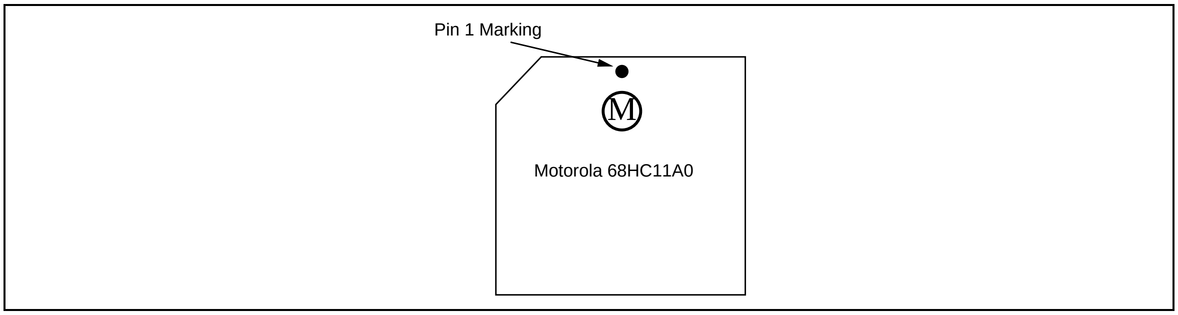

Figure 7: Top View of 52-pin PLCC

Figure 6 shows the typical marking on a DIP package. Figure 7 is a drawing of the PLCC package.

DIP sockets All of the integrated circuits (ICs) on the RoboBoard (except the voltage regulators) are socketed. This means that they are not permanently soldered to the ELEC 201 RoboBoard, but installed in sockets. Components that are socketed can be easily removed if they are damaged or defective. Sockets are also used to avoid the need to solder directly to ICs, reducing the likelihood of heat damage.

Do not place the components into the sockets before you mount the sockets onto the board!

DIP sockets have similar markings to those found on the component that they hold. DIP sockets are not mechanically polarized, but the marking indicates how the chip should be mounted into the socket after the socket has been soldered into the board.

PLCC Sockets sockets *are* polarized, however: a PLCC chip can only be inserted into the socket the "correct" way. Of course, this way is only correct if the socket is mounted right in the first place. When assembling the ELEC 201 RoboBoard, a marking printed onto the board indicates the correct orientation of the PLCC socket.

Capacitors Several different kinds of capacitors are made, each having different properties. There are four different types of capacitors in the ELEC 201 kit:

- **Monolithic.** These are very small-sized capacitors that are about the size and shape of the head of a match from a matchbook. They are excellent for use when small values are needed (0.1 μF and less). They are inexpensive and a fairly new capacitor technology. Monolithic capacitors are never polarized.

- **Electrolytic.** These capacitors look like miniature tin cans with a plastic wrapper. They are good for large values (1.0 μF or greater). They become bulky as the values increase, but they are the most inexpensive for large capacitances.

Electrolytics can have very large values (100 μF and up). They are usually polarized except for special cases; all the electrolytics in the ELEC 201 kit are polarized.

- **Tantalum.** These capacitors are compact, bulb-shaped units. They are excellent for larger values (1.0 μF or greater), as they are smaller and more reliable than electrolytic capacitors. Unfortunately they are decidedly more expensive. Tantalum capacitors are always polarized.
- **Ceramic.** Most often the smallest capacitors in both size and value. Their values are most often measured in picofarads. Ceramic capacitors are never polarized.

As indicated, some capacitors are polarized and will therefore require special attention when mounting. This is very important.

On the ELEC 201 boards, all polarized capacitor placements are marked with a plus symbol (+). The capacitors themselves sometimes are obviously marked and sometimes are not. One or both of the positive or negative leads may be marked, using (+) and (−) symbols. In this case, install the lead marked (+) in the hole marked (+). The (+) hole is also the hole with the square pad. Some capacitors may not be marked with (+) and (−) symbols. In this case, the positive (+) lead will be marked with a dot or a vertical bar.

Polarized capacitors mounted backwards won't work. In fact, they often **overheat and explode**. They should be mounted carefully. When in doubt, ask.

Inductors The inductors used in the ELEC 201 kit are a miniature coil of wire wound around a small ferrite core. They are about the size of a pencil eraser. Some inductors are coated with epoxy and look a lot like resistors. Others are big bulky coils with iron cores. Inductors usually are not polarized.

Transistors and Voltage Regulators The transistors and voltage regulators used in the ELEC 201 kit are small, three-wire devices. They stand out since they are the only three-wire devices used. Transistors and voltage regulators are polarized.

The table shown in Figure 8 summarizes this discussion with regard to polarity issues.

1.4 Component Mounting

When mounting components, the general rule is to try to mount them as close to the board as possible. The main exceptions are components that must be spaced away from the board before being soldered; some resistors fall into this category.

Device	**Polarized?**	**Effect of Mounting Incorrectly**
Resistor	no	
Isolated R-Pack	no	
Common R-Pack	yes	circuit doesn't work
Diode	yes	circuit doesn't work
LED	yes	device doesn't work (no light)

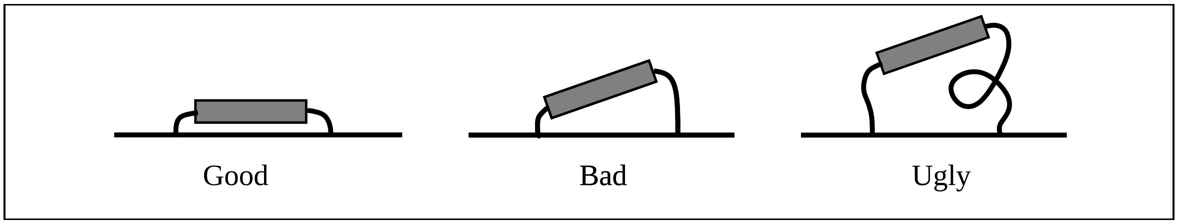

Figure 9: Flat Component Mounting

All LEDs used in the ELEC 201 kit are mounted upright while all resistors are intended to lay flat. See Figure 9 for clarification.

1.5 Component Value Markings

Various electronic components have their values marked on them in different ways. For example, value markings on some resistors are based on a color code (see Figure 10). Other devices, such as transistors and integrated circuits, have their part number printed on the device package. Still others may have several numbers printed on them, some of which are unrelated to their value.

1.5.1 Resistors

The largest resistors – in terms of wattage, not resistive value – simply have their value printed on them.

Other resistors are labeled using a standard *color code*. This color code consists of three value bands (four for a 1% resistor) plus a tolerance band. The first two of the three value bands form the value mantissa. The final value band is the exponent.

It is easiest to locate the tolerance band first. This is a metallic silver-, gold-, or brown-colored band. If it is silver, the resistor has a tolerance of 10%, if gold, the resistor has a tolerance of 5%, and if brown, the resistor has a tolerance of 1%. If the tolerance band is missing, the tolerance is 20%.

The more significant mantissa band begins opposite the tolerance band. If there is no tolerance band, the more significant mantissa band is the one nearer to an end of the resistor. Figure 10 shows the meaning of the colors used in reading resistors.

Color	**Mantissa Value**	**Multiplier Value**
Black	0	1
Brown	1	10
Red	2	100
Orange	3	1000
Yellow	4	10,000
Green	5	100,000
Blue	6	1,000,000
Violet	7	
Grey	8	
White	9	

Figure 10: Resistor Color Code Table

A few examples should make this clear. (See figure 11 for help)

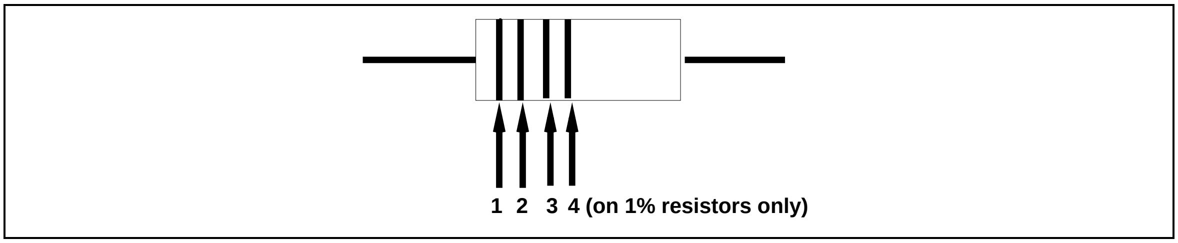

Figure 11: Resistor with Bands

- *brown, black, red*:

  First band: brown-1

  Second band: black-0

  Third band (multiplier value): red-(× 100)

  So have 10 × 100 = 1,000 ohms, or 1kΩ.

- *yellow, violet, orange*:

  First band: yellow-4

  Second band: violet-7

  Third band: orange-(× 1000)

  So have 47 × 1000 = 47,000 ohms, or 47kΩ.

- *brown, black, orange*:

  First band: brown-1

  Second band: black-0

  Third band: orange-(× 1000)

  So have 10,000 ohms, or 10kΩ.

- *brown, black, black, red*:

  First band: brown-1

  Second band: black-0

  Third band: black-0

  Fourth band (multiplier value): black-(× 100)

  So have 100 × 100 = 10,000 ohms, or 10kΩ(for a 1% resistor).

1.5.2 Capacitors

Reading capacitor values can be confusing because there often are numbers printed on the capacitor that have nothing to do with its value. So the first task is to determine which are the relevant numbers and which are the irrelevant ones.

For large capacitors (values of 1μF and greater), the value is often printed plainly on the package; for example, "4.7μF". Sometimes the "μ" symbol acts as a decimal point; e.g., "4μ7" for a 4.7μF value. Capacitors smaller than 1μF have their values printed in picofarads (pF). There are 1,000,000 pF in one μF, and 1,000,000 μF in one Farad.

Capacitor values are similar to resistor values in that there are two digits of mantissa followed by one digit of exponent. Hence the value "472" indicates 47×10^2 picofarads, which is 4700 picofarads or 0.0047 μF.

2 Assembling the ELEC 201 RoboBoard

The ELEC 201 RoboBoard[2] is the heart of the ELEC 201 Robot Controller system. It uses a Motorola 68HC11 family microprocessor coupled with 32K of non-volatile memory. It has outputs to drive six motors, inputs for a variety of sensors, a serial communications port for downloading programs and user interaction, and many other features.

2.1 Assembly Instructions

Before beginning assembly, make sure to have a well-lighted, well-ventilated workspace. Make sure that all of the electronic assembly tools are available. Turn on the light at your workstation.

All of the ELEC 201 boards have component placements silkscreened directly onto the board. In addition, diagrams in these instructions will provide copies of the diagrams printed on the boards, often at better resolution. Refer to the printed diagrams as often as necessary to be sure that components are being placed correctly. **Correct component placement is absolutely critical. A few minutes spent checking placement and orientation prior to soldering will save hours of debugging and rework later.**

Figure 12 illustrates the component placement on the microprocessor board. The component numbering for parts on the microprocessor board increments in a counter-clockwise fashion around the board for resistors, capacitors, and resistor packs.

Each section of the instructions, or the individual listing of the component contains a reference to the bin in the parts kit where the component can be found. The instruction checklist may be marked off as each step is completed.

1–☐ **Get the ELEC 201 V4.1 RoboBoard, and determine which is the "component side."** The RoboBoard is the largest of the ELEC 201 boards.

[2] These instructions are for Versions 4.0 and 4.1 of the RoboBoard. Versions 1.0, 1.1, 2.0, and 3.0 of the RoboBoard use different assembly instructions.

Figure 12: ELEC 201 RoboBoard Component Placement

The side of the board that has been printed with component markings is the "component side." This means that components are mounted by inserting them down from the printed side; then they are soldered on the opposite, unprinted side.

Make sure that the components are mounted on the proper side of the board!

2–☐ Measure the resistance between Power and Ground

Using the multimeter set to resistance ("Ω"), touch the red lead to Pin 20 of U19, and the black lead to Pin 10 (refer to Figure 6 if you do not remember the pin numbering scheme.) The value read should be higher than 10 megaohms. If this is not the case, contact your lab assistant *before* proceeding.

If the reading on the multimeter does not change (e.g. the meter reads "O.L"), all is well. However, to ensure that the meter is working properly, connect the probes together. You should get a low resistance reading.

3–☐ IC Sockets.

Mount the DIP sockets such that the notch in the socket lines up with the notch marking in the rectangular outline printed on the PC board. In the list that follows, "DIP5" means the DIP socket used for integrated circuit U5.

Note that there are two varieties of 16-pin DIP socket. One type has an integral bypass capacitor and costs about four times as much as the standard variety. None of the 8-pin sockets have integral bypass capacitors.

A caddy-cornering soldering technique technique should be used. After inserting a DIP socket into the board, solder its two opposite-corner pins first. This will hold the chip in place. Look at it carefully to check for correct orientation, and that it is level and down as far as it can go. If not, it is easy to heat one or both pins and adjust the socket. Only when everything is correct, solder the other pins.

If you are sure of your technique, a time-saving method is to place all of the sockets where they belong, then hold a book against the top of the board (and therefore the sockets) while the board is turned over. Then solder two pins on each socket, and check them all before soldering the rest of the pins.

NOTE: U13 and U14 are *not* socketed. They will be installed later.

4–☐ **Resistor Packs.**

Install the resistor packs. Most of the resistor packs are polarized: the common terminal end is marked with a dot or band. On the ELEC 201 RoboBoard, find a *square metal pad* at one end of the area that each resistor pack will mount. *Insert the resistor pack such that the marked end mounts in the square hole.* (The square hole is sometimes more easily seen on the unprinted solder side of the board.)

The "caddy-cornering" technique of soldering the two end terminals first is helpful here also; check the orientation *before* soldering the other pins. **Bin B**

- ○ **RS7**–1kΩ×3, 6 pins, non-polarized, *marked "63R1K."*

5–☐ **Non-polarized Capacitors.** These capacitors may be mounted in either orientation. To keep each component in place while soldering, bend the leads slightly out after inserting into the pad. After installing, solder and clip leads close to the board at the edge of the solder joint. **Always hold the end of the lead being clipped, so that the lead cannot become a projectile.**

Bin E

- ○ **C1**–10 pF, *marked "10."* **Caution:** The label "C1" on the board is not printed in quite the right place. It is located on an oval with "X1" in the center; *This is not where C1 goes.* You will solder a crystal here later. Look above and slightly to the right of the printed C1 and find another oval with nothing printed in it. Put C1 there. Ask a laboratory assistant if you have any questions.

- ○ **C25**–0.1 μF, *marked "104K." (or "104")*

6–☐ Microprocessor Socket (U3) (Bin A).

- ○ Install **PLCC1**, a 52-pin square socket for the 68HC11 (U3). The Pin 1 marking is indicated by the numeral "1" and an arrow in the socket; this marking mounts nearest to **C9** (next to the edge). There should be a beveled notch in the lower-right corner of the chip and the outline printed on the board, with respect to the pin 1 marking. *Be absolutely sure to mount this socket correctly; the socket is polarized and will only let you mount the chip into it one way.* Solder.

7–☐ Male and Female Socket Headers.

To cut sections of header, it is usually best to destroy one unit of header. For example, if you are cutting a 3-long single female strip, count three units and cut through the fourth. After cutting you can trim the excess header with diagonal cutters, or by smoothing with sandpaper.

When mounting the headers, pay attention to how well they are lining up vertically. Sometimes reversing the way a strip is mounted will help its connections to line up better with the others. It may be helpful to insert a strip of male header into the socket to hold them at proper horizontal and vertical placement before soldering.

Both single- and double-wide female header strips are used in the following assembly instructions.

Refer to Figure 13 for placement of these parts.

Figure 13: ELEC 201 RoboBoard Header Placement

- ○ The motor chips have special, pre-cut female header of 7 and 8 pin lengths. Each chip requires one seven pin and one eight pin header. Install the motor mount hardware **(Bin J)** for **U10**, **U11**, and **U12**.
- ○ Cut three 8-long double female strips, and select three additional pre-cut 8-long single female strips (Bin J). Install the **J5**, **J6**, and **J7** connector blocks. Solder.
- ○ Cut one 2-long double female strip, and one 2-long single female strip. Install the **J8** connector block. Solder.
- ○ Cut two 2-long single female strips, and two 1-long single female strips. Install the **J4** and **J21** connector blocks. Solder.
- ○ Cut three 2-long male strips and three 1-long male strips. They will be installed in groups of three (a triangular pattern of three pins). Install the **J2**, **J3**, and **J9** connector blocks. Solder. The ordering of the two pieces of header is not really important, but it is best to be consistent. For example, put the 1-long strips into pin 1 and the 2-long strips into pins 2 and 3.
- ○ Cut six 3-long single female strips. Install the **J11**, **J12**, **J13**, **J14**, **J15**, and **J16** connector blocks. Solder.

- ○ Cut one 14-long single female strip. Install the **J19** connector. Solder.
- ○ Cut one 1-long single female strip. Install the **J1** connector. Solder.

8–☐ **LEDs.**

LEDs must be mounted so that the *long lead* (the anode) is inserted into the *square* (as opposed to round) pad of the LED footprint.

Be sure to mount LEDs properly as it is very difficult to desolder them without damage if they are mounted backward.

To aid in soldering, bend the leads a little bit after inserting into the board to hold in the LED. **Remember, LEDs are heat-sensitive, so do not hold the soldering iron on the pad too long.** Also, after soldering in one pin of an LED, give it a few seconds to cool down. Check that the recently soldered pad is cool to the touch, *carefully!*, before soldering the other lead. **Bin G**

9–☐ Resistors.

All resistors (except **R6** and **R7**) mount flat against the RoboBoard; try to get the body of the resistor very close to the board. These components are not polarized; however, we suggest that resistors be mounted uniformly – with each resistor's tolerance band closest to the top of the board.

If you have trouble discerning colors, you may wish to have your colleagues handle this task. Actually, it is fairly difficult to read the color bands from $\frac{1}{8}$ watt resistors, even for the trained eye. The blue body of some resistors seem to distort the color of the bands. The best technique is to check the value of each resistor with the Digital Multi-Meter.

After soldering each resistor, check the component side of the joint to ensure that the solder flowed all the way through the joint. If it hasn't, turn the board back over to the solder side, and touch the joint again with the iron briefly– this usually helps. Once the resistor is successfully soldered in place, clip the leads. (Again, be sure to hold each lead while clipping to prevent possibly hazardous projectile wires.)

Make sure that you use 1% resistors where they are called for.

10–☐ Electrolytic and Tantalum Capacitors.

All of these capacitors are polarized. Make sure that the longer lead (marked (+)) on the capacitor goes into the square pad (marked (+)). If the capacitor leads are not marked (+) or (−), a dot or bar will indicate the (+) lead. Be sure on the polarity of these capacitors. The results are pretty spectacular if these are put in backwards.

11–☐ Transistors and Voltage Regulators

Transistors and voltage regulators are polarized. Install them so that their flat edge is above the flat edge of the placement marking. *Transistors and voltage regulators are* very *heat sensitive.* Put your finger (have one of your partners feed solder into the pad for you) on the top to gauge heat while soldering, and wait awhile after soldering each lead to let the device cool down.

- ○ **U14**–TL750M05 (the large rectangular version of this device). Install the slip-on heatsink for the TL750M05 regulator (**U14**). First, obtain some thermal compound from your lab assistant. Place a *small* amount of this compound on the metal side of the regulator (facing the board). Then gently press the slip-on heat sink onto the regulator. Guide the regulator pins and heatsink pin into the board until both are snug. Ensure a snug fit, solder and trim the support pin of the heat sink. Solder the regulator pins and trim.

12–☐ 8 MHz Crystal (Bin K)

Crystals are not polarized. Install **X1**, the 8 MHz. crystal.

13–☐ Inductors. (Bin K)

Inductors are not polarized. Install **L1** and **L2**, 12 uH.

- ○ **L1**–12 uH (may be marked "120K")

○ **VR1**, 100kΩ.

○ **VR2**, 10kΩ.

16–☐ Power Receptacle. (Bin H)

Install **J20**, DC power receptacle. When soldering, feed ample amounts of solder into the joint, so that solder completely fills the mounting pads. Try not to melt the receptacle.

17–☐ RJ-11 Top-Entry RJ11 Receptacle. (Bin K)

The top-entry RJ11 phone receptacle needs to be modified before it can be mounted on the RoboBoard. The correct procedure is important. Ask your lab assistant if you have any questions.

Hold the receptacle such that the connecting and mounting pins are pointing downward and the notch is facing you and the row of vertical lines is on the opposite side. Locate the larger triangular mounting pins on your left hand side. The inside mounting pin (the one closest to you) needs to be clipped. Bend this pin outwards to form a right angle. Using the diagonal cutters, clip this mounting pin close to the plastic package.

Install **J22**, the one-position RJ11 receptacle in the space nearest to the center of the board, where it will cover the “J22” mark. The notch should be closest to the edge of the board. Use care in aligning the pins. Be extra careful when inserting not to damage the pins. Solder the mounting pins as well.

18–☐ Piezo beeper. (Bin K)

The beeper is polarized, so mount the Piezo beeper with the long lead in the square pad, and make sure that it is centered on the circular outline.

19–☐ Diodes

Zener diodes are polarized. Install them so that the black band on the diode is in the same orientation as white band marked on the RoboBoard (see Figure 4). *Correct orientation is critical!* If in doubt, ask. Zener diodes *are* *very heat sensitive.* Put your finger on the top to gauge heat while soldering, and wait awhile after soldering each lead to let the device cool down.

CONGRATULATIONS! You have completed basic assembly of the RoboBoard.

2.2 Final Assembly of the RoboBoard

This section explains a few simple tests to be performed *before* installing the ICs in the sockets.

Full board testing and debugging will be handled in the laboratory.

1–☐ Check the solder side of the board for proper solder connections. Specifically: look for solder bridges and cold solder joints.

Solder bridging is when a piece of solder "bridges" across to adjacent terminals that should not be connected.

Cold solder joints are recognized by their dull luster. A cold solder joint typically makes a poor electrical connection. Make sure that all of the solder joints are shiny with a silver color. Everyone in your team should check the board, and then ask a lab assistant or the instructor for a final check.

2–☐ Install the eight shunts onto the male headers as follows (see Figure 14 for how pins are numbered):

Bin H

○ **J2** – pin 2 to pin 3 (pin 1 is the square pin)
○ **J3** – pin 1 to pin 3
○ **J9** – pin 1 to pin 3
○ **J23** – pin 1 to pin 2
○ **J24** – pin 1 to pin 2
○ **J25** – pin 1 to pin 2
○ **J26** – pin 1 to pin 2
○ **J27** – pin 1 to pin 2

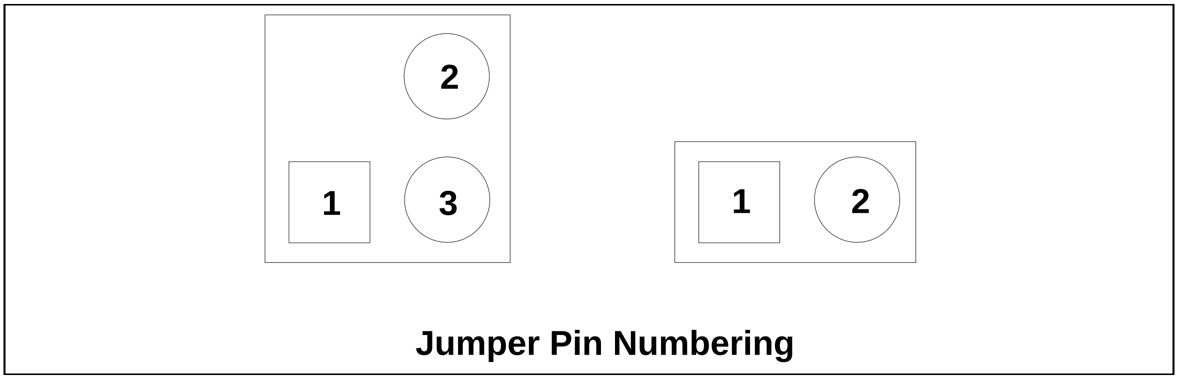

Figure 14: RoboBoard Jumper Pin Numbering

3–☐ Using the multimeter set to resistance ("Ω"), touch the red lead to Pin 20 of U19, and the black lead to Pin 10.

Resistance should increase as the capacitors charge. The board resistance should measure between 1kΩ and 10kΩ. *If a reading of zero ohms is observed, the board probably has a power to ground short.* Do not proceed with testing until this is corrected.

4–☐ Ask a lab assistant for a battery and cable, and note their instructions on how to connect it. Connect battery power to the board.

5–☐ Slide the board power switch to "ON".

6–☐ Measure the board voltages. Using the multimeter set to DC Volts ("DC"), touch the red lead to Pin 20 of **U19**, and the black lead to Pin 10. You should read approximately 5.0 volts.

Then touch the red lead to pin 3 of **U13** (pin 3 is in the outside round pad closest to **U12**). You should read approximately 5.0 volts.

7–☐ Slide the board power switch to "OFF".

8–☐ Disconnect the battery.

9–☐ Install the socketed ICs into their sockets on the board. *Be careful not to damage the component leads when installing the chips into their sockets!* Make sure to get the orientation correct (the notched end of the chip should match the notch on the socket and board)—refer to Figure 12 if necessary. **Always touch the board with a part of your body** *before* **bringing the IC in contact with the socket.** This ensures that any static charge that may be present will discharge through you, rather than through the more delicate integrated circuit.

Pushing ICs into sockets can be difficult. It is usually helpful to bend the leads slightly before insertion; ask a lab assistant to show you how. Make sure that all pins of the IC go into the socket, as they sometimes get bent underneath the chip and are difficult to see. If you are having trouble pushing the ICs into the sockets, take the needle nose pliers and *gently* bend the pins inward so the chip will socket easier. Also, make sure to apply even pressure to both sides of the chip so that both sides go into the socket at the same time. It is difficult to put in one side after the other has been inserted.

Again, double-check to ensure correct orientation, because if they are in the wrong orientation when you turn on the power, they are usually destroyed.

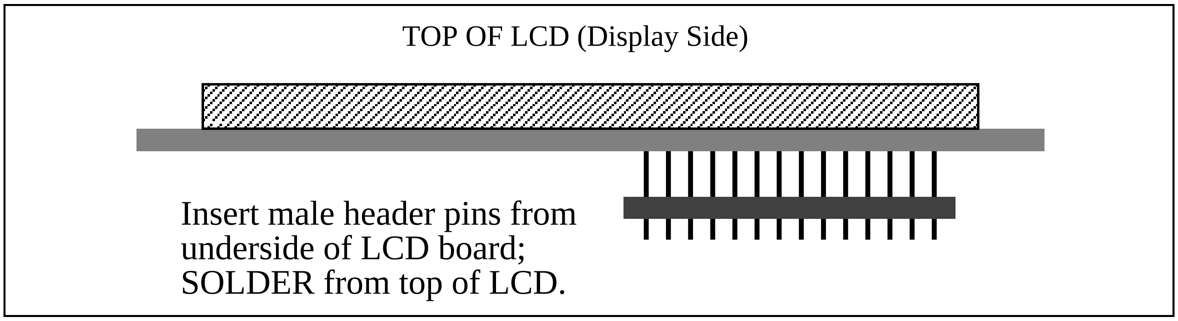
2.3 Preliminary Testing

To test the basic functionality of your RoboBoard, borrow an assembled LCD unit from a lab assistant and install it (without screws) into the board. Connect your board to the battery and to the computer as described in the Class Notes on the web. Follow the steps described to load IC, and then test some of the simple IC commands.

2.4 LCD Installation

The LCD display provided in the ELEC 201 kit can display two rows of 16 characters. The system software makes it easy to write code that prints messages to this display, for status, debugging, or entertainment purposes. The LCD installation should be performed only after the board has been demonstrated to work properly. It is difficult to debug a board once the LCD display has been bolted on.



TOP OF LCD (Display Side)
Insert male header pins from underside of LCD board; SOLDER from top of LCD.

Figure 15: LCD Connector Mounting

The display needs to have a 14-pin male header soldered to its interface. Figure 15 shows how these pins should be installed. You may receive an LCD that is already soldered to a header strip. In that case, you can skip the second and third steps below.

1–☐ Mount four threaded nylon spacers to the RoboBoard with 6-32 nylon screws (do not overtighten!)

2–☐ The LCD mounting holes at the corners need to be drilled larger to fit the mounting screws. If you receive a new display, ask a lab assistant to do this.

3–☐ Cut a 14-long single male LCD header strip; the long pins are 0.31 inches long. Insert the *short* side of the header into **J19**, then mount the LCD as indicated in the figure, putting the top header pins through the holes in the LCD board.

4–☐ Attach the LCD display to the spacers with four more 6-32 nylon screws. The LCD display will now be in correct position and alignment. Solder the 14 header pins to the LCD board. To remove the LCD display, simply remove the four 6-32 nylon screws holding the display to the spacers, and gently pull the LCD display and attached male header away from **J19**. Remember, never overtighten nylon screws. They are much softer than steel.

2.5 Testing the Completed RoboBoard

After you have completed and installed the LCD display, you are ready to test all of the features of your RoboBoard. It is better to ensure that all of your ports work now, rather than to discover later that they are faulty. We have written several programs to do this. One is called *testports.lis.* To download, or install, this program perform the following steps.

1. Make sure that the board has been initialized and that p-code has been downloaded to the board. If you do not know how to do this ask a lab assistant or see the Class Notes on the web page.
2. Start IC.
3. Type `load testports.lis` at the IC prompt. This will load the testports program into the RoboBoard.
4. Using *testports*, check every port on your RoboBoard to see if it is working properly. If this is not the case, consult a lab assistant.

Testports provides instructions for use on the RoboBoard's LCD. If you have any questions about how to use the program, please ask a lab assistant. The program QT.c is another test program that is particularly useful for testing all the motor ports quickly.

2.6 Mounting the RoboBoard

The RoboBoard can be LEGOized by using the threaded axles and a long LEGO beam. LEGOizing the RoboBoard could make it easier to mount to your robot. Figure 16 shows a RoboBoard mounted to a 16-Long LEGO beam. The threaded axles are slipped through the mounting holes on the RoboBoard and one of the holes in the LEGO beam. The threaded axles are then secured using two axle nuts. The side of the board with the LCD display can be mounted on LEGO by using one threaded axle and a 1 inch nylon screw. If you wish to do this, ask your lab assistant for a 1 inch nylon screw.

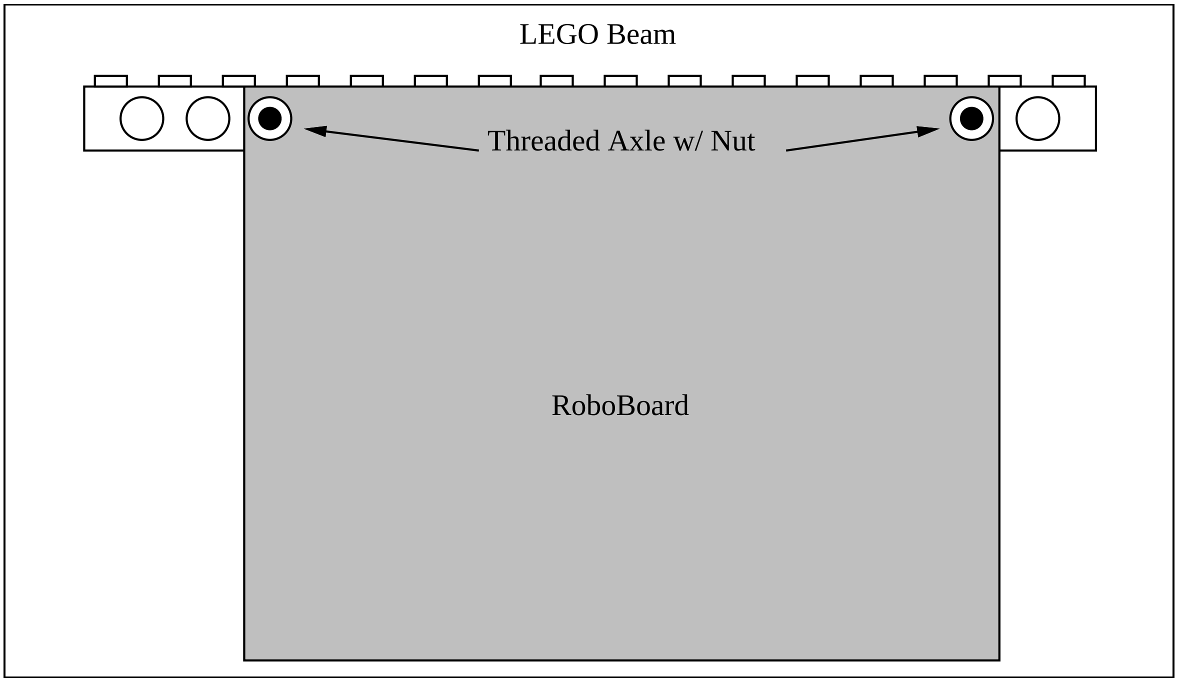


Figure 16: Mounting the RoboBoard on LEGO

2.7 Debugging a Non-working RoboBoard

It is possible that after your best efforts, your RoboBoard is non-functional. This section provides some help to isolating and correcting the cause of the failure. A good working knowledge of the logical design of the RoboBoard and of the function of the various chips is invaluable in finding a fault, so read the chapter of the notes on the ELEC 201 hardware carefully. The steps below will give you additional insight on the operation of the RoboBoard and its components, so read the entire section before starting. Also invaluable is a working RoboBoard, which can provide a comparison for measurements, but most importantly, provides a source of *known-working* chips for substitution. The donor RoboBoard should be loaded with p-code and optionally with a test program like testports. The two different cases of a board that has never worked, and a previously operating board that has failed, are treated separately below. However, there are a few common checks that should be done in any case.

- First, put out the fire. Just kidding, although it has happened. If nothing shows on the display, first check the contrast adjustment pot; also check its value, as it (10KΩ) and the roboknob (100KΩ) are sometimes interchanged.

- More importantly, sometimes a board will act crazy or dead when you turn it on because it is trying to run some (perhaps disfunctional) `main()` program that has been downloaded. It could be waiting for a start light, for example. To avoid this, hold down the CHOOSE button while turning on the power, which bypasses the `main()` function and goes directly to the IC prompt/heartbeat. Also, unfortunately, p-code often gets trashed by an error from a user program and causes problems. Reloading p-code will solve both problems and is a good test. If this doesn't help, or the board is really dead, proceed to the next step.

- Disconnect everything connected to the board.

- Be careful about what you set the board down on. Bench tops are often covered with bits of wire and solder that can short pins. Put the board on a clean piece of paper.

- Measure the battery voltage and polarity.

- Turn on the board and measure the output of the 5 V logic power supply. If the logic supply is low, a bad component or a short is probably drawing too much current. While regulators do fail, they are quite rugged. Note that the regulator will shut off to protect itself if the current draw is too high, in which case the regulator, U14, will be *very* hot, so be careful. A good way to check the regulator is to remove the jumper next to it, J27. This isolates the regulator output from all the components on the board except the filter capacitors C6, C7, and C17. Check them for correct installed polarity and shorts. If the output voltage is still not correct (check right on the pins of the regulator), the regulator is probably bad; replace and recheck. If removing J27 does result in a 5 V output, then the task is to find the component or short that is causing the current draw. Removing all the chips is a good starting point, then proceed, monitoring the current draw at J27, while replacing first the Minimum Functional Chip Set (see below). After that, follow the rest of the steps below as appropriate.

- Measure the output of the 5 V supply, at U13, for the motor chips. If this is low, pull the motor chips and remeasure. If the output is still low or zero, the regulator probably needs to be replaced, as there really is nothing else connected to the output, but check the filter capacitors C18 and C19 as well for correct polarity and shorts.

2.7.1 Failure at Initial Operation

The usual cause of a failure at first startup is an error in construction. So the primary steps involve looking for common errors, and then uncommon errors. First be sure to perform the power supply checks listed above.

- Make sure J27 is in place, or no logic power will get to the board.
- Inspect each chip location carefully to verify that each has the correct chip, that it is oriented properly, and that all pins are actually inserted into the socket (and not bent under the package).
- Check the polarity of all the electrolytic capacitors for correct installation. Installation backwards can cause excess current draw and occasionally sparks, but sometimes no problem will show up for some time.
- Check the polarity of all the zener diodes, both at the motor ports and the data input ports.
- Inspect the soldering for shorts and cold solder joints. In really bad cases, you just have to go over all the joints again and redo them.
- Trim off excess lead length on the solder side of the board with diagonal cutters.

If none of the above helps, go on to the next steps.

2.7.2 Failure of a Previously Working Board

If the source of a problem is not obvious from such information as voltage checks and the nature of the problem, one technique is to pull out chips to get to the minimum working configuration, and then to replace chips sequentially with known-good ones from a working donor board.

The Minimum Functional Chip Set will run the IC logo and heartbeat on the display. The set consists of:

1. The processor, U3, 68HC11.
2. The memory, U2, DS1230Y *loaded with p-code* from a donor board.
3. The 74HC373, U1, memory address latch.
4. The PAL16L8 chip, U19, to provide memory enable on pin 19.
5. The MAX 704, U5, for the reset function on power application.

6. The 74HC245, U15, which senses the CHOOSE button.
7. The LCD, which supplies a status return to the processor.

- Pull all the chips except the Minimum Functional Set above. Use a known-good LCD, and check the contrast pot adjustment.
- Turn on the power; the display should show the IC heartbeat, indicating all the chips are good.
- If "Halted" appears on the display, replace the 74HC245 and try again.
- If nothing appears on the display, start substituting chips from a working donor board. My order is processor, 74HC373, PAL, and MAX 704 (rarely a problem). When you find the problem you can back substitute to verify the bad chip. If you substitute *all* of the Minimum Functional Chip Set from a working donor board, and the voltages are correct, and the board still does not work, you have a big problem: a board fault or a bad on-board component. Fortunately, this is rare, especially if the board has worked previously. Check the solder joints first, and then everything else carefully. Call for help.
- Assuming the board now works minimally, add the next functionality, downloading and digital inputs, by adding the MAX 220, which rarely fails.
- You should now be able to download p-code, robo.lis, and use IC to beep(), etc. Note, if there is no beep, it could be the beeper (jumper in another) or Q4, the driver transistor (check the base drive and output), or a missing jumper J26.
- Digital inputs #0, 1, and 30 should work as they go directly to the processor. Check them from the keyboard; if there is a problem, replace the processor.
- Check digital input ports #2–7. These make use of additional capability of the 74HC245, so if there is a problem, replace it.
- Add *both* the 74HC4051 chips to add the analog input function. U9 supports ports #20–27, and U10 supports ports #28 and 29 plus the roboknob, dip switches, and battery voltage measuring functions. Check all and replace the responsible chip as necessary. Now you can load the program testports.lis for more testing.
- Now add U7, the 74HC574 chip to enable the LED output drivers. Pins 12 and 13 drive the 2N4401 driving transistors, which do burn out if abused. Check the drive at the transistor bases to see if the problem is U7 or the transistor.
- Add IR beacon functionality by installing the 74HC390 chip. This is not necessary for board operation but it checks additional PAL chip functionalities (pin 12). The driver transistor Q3 could also be bad.

- Provide motor port function. First double check the zener diode orientations, then add the three 74HC574 latches; use known-good chips. Add the motor driver chips. Check all the motor ports, both forward and reverse. If nothing works, the problem could be the PAL, which provides enable signals out of pins 16, 17, and 18. Replace the motor driver chips as necessary, and give thanks that they are in sockets in this version of the board. If everything works, you can go back and check the original latches.

- Finally, check the LCD display. Put in the original one, and recheck the contrast adjustment pot. The processor will halt if it does not receive a status signal from the display. Check that the pins *really* insert fully into the socket on the board—a problem if the longer male header was not used. The LCD driver chips are on the LCD board, so replacement of the display is the only option if it is still not working.

And that is all there is, so the RoboBoard should be fully functional at this point. In some cases, and with practice, you can skip some of the steps above if the problem is obviously limited to a particular area, like the motor drivers (a common problem). In that case, just pull the driver chips and the 574 latches and see if everything else works OK. If it does, just substitute latches and motor drivers. For other problems, jump into the sequence above at the appropriate point.

Finally, please destroy and discard all chips found to be bad. Then fill up your donor RoboBoard with new chips as necessary, load it with p-code and testports, and test it, so you will be ready for the next problem.

3 The Battery and Charger System

The ELEC 201 Robot Controller system uses a Panasonic 12 volt lead-acid battery rated for 1.3 ampere-hours of operation. These batteries are rechargeable. The battery is connected to the RoboBoard through the power receptacle J20, just below the power switch.

Lead-acid cells are extremely powerful devices. Car batteries are constructed of similar lead-acid technology. *When handling the batteries, be extremely careful not to short the (+) and (−) terminals of the battery together.* A huge surge of current will flow, melting the wire and causing burns. In extreme cases, batteries can explode and cause serious injury.

3.1 The Battery Charger

The Version 4.1 battery charger is designed to charge one 12 Volt DC battery at a constant charging rate until the battery is fully charged. When the battery is fully charged, the battery charger automatically shuts off. This automatic shut-off feature means that the battery can be left on the charger overnight or longer without risk. A red LED on the board lights up brightly when the battery is charged. You will receive an assembled battery charger board and 12 VDC adapter, but you may need to repair or replace cables. (If you need to build a new charger you will receive additional parts and the assembly instructions.)

3.2 Wiring the Battery Cable

Ask a lab assistant for a battery and cable if you do not already have one. Your battery cable is pre-assembled, but in case you have to repair it, or make a new one, here are instructions.

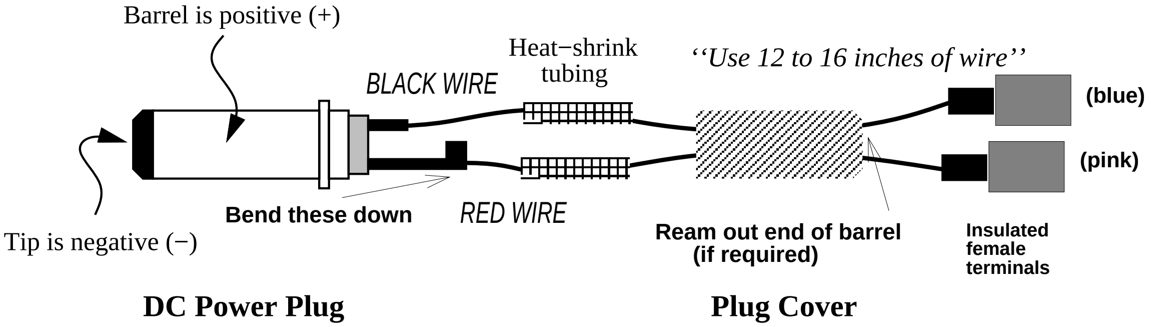

Figure 17: Battery Plug and Cable Wiring Diagram

Figure 17 illustrates how to wire the battery plug and cable assembly.

○ Cut a 12" to 16" length of the black/red twin cable for use in making the battery cable. Strip and tin the wire ends at both ends of the cable. One end should have about $\frac{1}{4}$ inch of exposed tinned wire; the other end (which will be connected to the power plug) should have about $\frac{1}{4}$ inch exposed. At this end the red wire should be about $\frac{1}{16}$ inch shorter than the black wire.

○ If your power jack has a hexagonal barrel and a flexible sleeve there is no need to ream the jack. Proceed to the next step. Otherwise, use the reaming tool borrowed from the lab assistant, enlarge the small end of the black annular connector cover. Return the tool to the lab assistant. Slide the cover, reamed end first, onto the tinned leads. Push back about six inches.

○ Heat-shrink tubing is used on both terminals of the DC power plug. The tubing acts as an insulator to minimize the likelihood of an electrical short at the plug terminals. *It is essential that this wiring be performed carefully because a short in the power plug will short out the battery terminals and create a serious hazard.* Place a $\frac{3}{8}$ inch long piece of heat shrink tubing on each wire before soldering to the power plug. Be sure to keep the heat shrink tubing well away from the point of soldering or it will shrink prematurely.

○ **Proper polarity is important.** The use of red wire to signify the (+) terminal and black wire to signify the (−) terminal is an international standard. Using the "helping hands", position the black wire under the short terminal and solder. Then position the red wire inside the long terminal and bend down the tabs to ensure a good mechanical connection. Solder.

○ After soldering, slide the heat-shrink tubing down over both terminals and shrink.

○ Screw the plug cover onto the plug.

○ Place the pink shielded terminal on the $\frac{1}{4}$ inch of exposed tinned wire of the red lead. Place the blue shielded terminal on the $\frac{1}{4}$ inch of exposed tinned wire of the black lead. Use the crimping tool (borrowed from a lab assistant) to crimp the terminals onto the wire. Use the "red dot" location on the crimping tool, and squeeze the tool until it releases (this takes *a lot* of pressure). *Be sure to return the tool when you are finished!*

○ *Before installing the cable onto a battery, use an ohmmeter to make absolutely sure that the cable is not shorted.* The cable should measure open circuit or infinite resistance. If a conductor is placed across the terminals of lead-acid batteries, a huge surge of current will flow, melting the wire responsible for the short circuit and possibly causing the battery to explode.

○ **Make sure to connect the red wire (pink terminal) to the + terminal of the battery.**

3.3 Wiring the 12 VDC Adaptor

You should have a pre-assembled 12 VDC adaptor. Nevertheless, before using your adaptor, use a voltmeter to make absolutely sure that the connections are correct. Plug in the adaptor to a wall outlet, and and set your multimeter to the DC voltage postion. Place the black multimeter probe inside the barrel of the power connector, and the red probe on the outside of the barrel. You should read **positive** voltage. If not, ask a lab assistant to verify the measurement, and then you will need to put on a new plug, following the directions below.

Figure 18 illustrates how to wire the 12 volt DC adaptor and cable assembly. **NOTE: The adaptor may come out of the box with a plug that looks correct, but it probably has opposite polarity from that required.**

○ Examine the 12 Volt DC power adapter. Clip off and discard the existing power plug near the base of the plug (this may have already been done for you). Strip

$\frac{1}{8}$ inches of insulation from power wires and tin. At this end the non-ribbed wire should be about $\frac{1}{16}$ inch shorter than the black wire.

○ If your female power jack has a hexagonal barrel and a flexible sleeve there is no need to ream the jack. Proceed to the next step. Otherwise, use the reaming tool borrowed from the lab assistant, enlarge the small end of the black annular connector cover. Return the tool to the lab assistant. Slide the cover, reamed end first, onto the tinned leads. Push back about six inches.

○ Heat-shrink tubing is used on both terminals of the DC power plug. The tubing acts as an insulator to minimize the likelihood of an electrical short at the plug terminals. *It is essential that this wiring be performed carefully because a short in the power plug will short out the battery terminals and create a serious hazard.* Place a $\frac{3}{8}$ inch long piece of heat shrink tubing on each wire before soldering to the power plug. Be sure to keep the heat shrink tubing well away from the point of soldering or it will shrink prematurely.

○ We use different models of adapters and the wire markings vary. **Use your volt meter to determine which lead is Positive and which is Negative,** and make a note on the figure, *which may label the wires incorrectly!*

Using the “helping hands”, position the **Negative** wire under the short terminal and solder. Then position the **Positive** wire inside the long terminal and bend down the tabs to ensure a good mechanical connection. Solder. *It is essential that this wiring be performed carefully because a short in the power plug will short out the DC adaptor.*

○ After soldering, slide the heat-shrink tubing down over both terminals and shrink.

○ Screw the plug cover onto the plug.

○ *Before using the modified adaptor, use a voltmeter to make absolutely sure that the connections are correct.* Plug in the adaptor to a wall outlet and place the black voltmeter probe inside the barrel of the power connector, and the red lead on the outside of the barrel. You should read **positive** voltage.

4 The Infrared Beacon

The infrared (IR) transmitter board emits modulated infrared light that can be detected by the Sharp GP1U52X IR sensors. The IR board features eight infrared emitting diodes positioned in a circle to generate a 360 degree signal. The diodes are driven by an oscillator circuit (the 74HC390 chip) and a transistor amplifier on the RoboBoard.

The infrared LEDs are wired in series to minimize the current draw from the battery. The board also contains a visible LED, that when lighted, indicates all IR LEDs are transmitting. An unlit LED indicates problems with the board. You will receive an assembled IR transmitter, but you may need to add, repair, or replace the cable and connector. (If you need to build a new IR beacon you will receive additional parts and assembly instructions.)

4.1 Cable and Connector

Use two strands from the rainbow colored ribbon wire; the actual color of the wires is not important. Just pick one color for the positive connection, and the other one for the negative connection. In these instructions we will just call them *pos-color* and *neg-color*, respectively.

○ Cut the 2-conductor piece of ribbon cable to the necessary length for your robot; longer is better than too short. Strip $\frac{1}{4}$" of insulation from the wire on both ends and tin.

○ From *underside* of IR board, insert the pos-color wire into the hole marked (+) and the neg-color wire into the hole marked (−). Solder from the *top* of the board.

○ Mount other end of the wire to outside pins of a four-pin male connector with one pin removed (see Figure 19). The pos-color wire goes to the isolated end-pin (no adjacent pin). Use the guidelines shown in Section 5. Be sure to place heat-shrink tubing on the wires, well away from the connection, *before* soldering. After soldering, slide the heat-shrink tubing down over the pins to make a neat connection. Then apply heat.

The infrared transmitter plugs into the connector labeled IR XMIT on the RoboBoard (see Figure 13), with the positive lead inserted into the end marked (+) on the board.

5 Cable and Connector Wiring

This section explains how to build reliable cables and connectors for the motors and sensors that will plug into the robot's controller board. It also gives instructions for building a cable to connect the RoboBoard to a PC.

Sturdy and reliable connectors are critical to the success of a robot. If a robot's connectors are built sloppily, hardware problems will occur. Well-built connectors will help make the robot more reliable overall, and will ease development difficulties.

Figure 19: Standard Connector Plug Configurations

Sensors and motors are built with fixed wiring; that is, a sensor or motor will have a fixed length of wire terminating in a connector. It is possible to build extension cables, but it is more time-efficient to build cables that are the proper length initially.

The average robot has its control electronics near the physical center of the robot; hence, motors and sensor cables need to reach from the center of the robot to their mounting position. Given this geometry, most robots will need sensor and motor cables between 6 and 12 inches long.

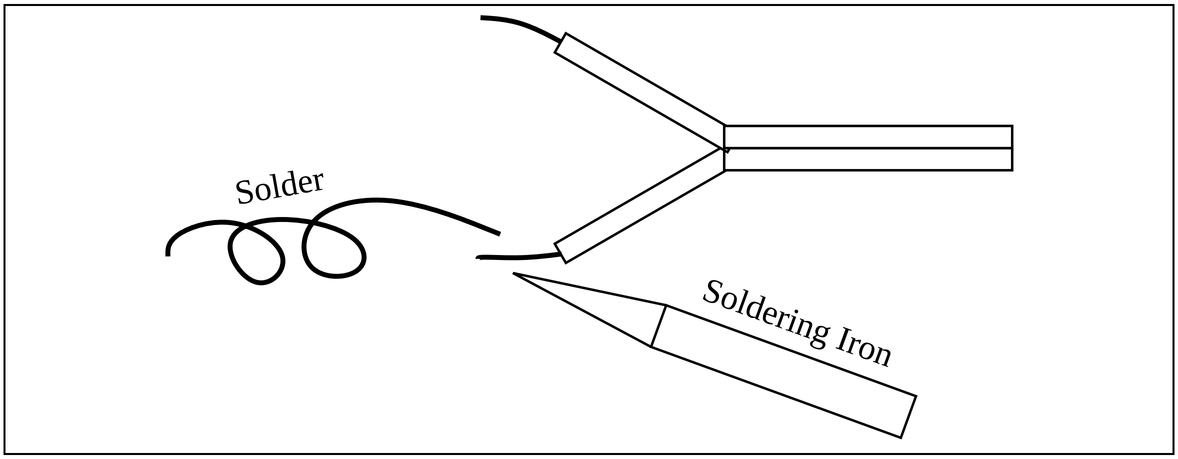
Several different connector styles are used depending on the device that is being connected to the robot. Figure 19 shows the connector configurations used for bidirectional motors, unidirectional motors, sensors, and the infrared beacon.

The ribbon cable provided in the ELEC 201 kit is best for making sensor and motor cables. Use the "helping hands" to hold the connectors while soldering.

Figures 20 through 23 illustrate the recommended method for wiring to a connector plug. When assembled properly, this method will provide for a sturdy, well-insulated connector that will be reliable over a long period of use.

Be sure to place heat-shrink tubing on the wires, well away from the connection, *before* soldering. After soldering, slide the heat-shrink tubing down over the pins to make a neat connection. Then apply heat.

The example shows wiring to opposite ends of a three-pin plug, as would commonly be used when wiring to a motor. The method, however, is suitable for all kinds of connectors.



Strip a small amount of insulation off the wire ends. Tin the wire ends by applying a thin coat of solder to them.

Cut the male connector to size. This example shows a plug that can be used to wire a motor or the infrared transmitter. Cut $\frac{1}{2}$ inch length pieces of heat-shrink tubing, and slide over tinned wires, well away from the point of soldering.

5.1 Computer Cable Wiring

Each of the computers in the ELEC 201 lab has a cable from the serial port to a modular phone plug, known as a RJ-11 plug. You may want to make a similar cable for your own computer. You can obtain the parts from a lab assistant. Refer to Figure 24 for wiring details. New Apple computers require an adapter to provide a standard PC DB-9 serial port.

6 Sensor Wiring

Sensors are a critical part of your robot. They provide the information that your control program requires to make navigation, action, and strategy decisions during the game. Poorly mounted or wired sensors are prone to breaking, resulting in no, or worse, incorrect, information to the RoboBoard. Bad sensors are usually a major cause of robot failures. The course notes on the class web site shows many mounting ideas, plus you can look at the robots on display in the lab for ideas (good and bad). However, feel free to experiment and come up with new ideas. Pay particular attention to ruggedness and reliability.

This section shows wiring diagrams for the following sensors:

- Touch sensors
- Mercury Tilt Switch
- Photocell light sensor
- Infrared reflectance sensor
- Sharp infrared sensor
- Potentiometer position sensors
- slotted optical switch
- Magnetic Switches

In most cases, some discussion of the sensor's principle of operation accompanies the wiring diagram. Further information on the use of all sensors is found in the Class Notes. Examples of correctly wired sensors are available for your inspection. As a general rule, do not wire a sensor until it is needed. This will conserve material, and will result in cable lengths appropriate for your robot.

6.1 Touch Sensors

Several switches in the ELEC 201 kit may be used to make touch sensors. Diagrams for the white "ALPS" switch, the small red push-button switch, the Burgess lever switch, the lever switch, the mock roller switch, and the roller switch are shown.

6.2 Photocell Light Sensor

The photocell is a special type of resistor whose resistance varies in proportion to the impinging light. The more light hitting the photocell, the lower its resistance.

Photocells are resistors whose resistance varies with light. In the dark, they have a resistance of about 6.7Mohms. In bright light, they have a resistance of about 100 ohms.

This circuit is a voltage divider. When the photocell is in dark, resistance is high, and signal output is high (near 5v). In strong light, photocell resistance is low, and signal output is low (near 0v).

Photocells are analog sensors. Plug into an Analog Input.

The output signal of the photocell is n analog voltage corresponding to the amount of light hitting the cell. Higher values correspond to less light.

6.5 Infrared Reflectance Sensor

IR reflectance sensors contain a matched infrared transmitter and infrared receiver pair. These devices work by measuring the amount of light that is reflected into the receiver. Because the receiver also responds to ambient light, the device works best when well shielded from ambient light, and when the distance between the sensor and the reflective surface is small (less than 5mm). IR reflectance sensors are used primarily to detect white and black surfaces. As you would imagine, white surfaces generally reflect well, while black surfaces reflect poorly.

The output signal of the phototransistor receiver is an analog voltage corresponding to the amount of light hitting the phototransistor. Higher values correspond to less light, and hence a smaller degree of surface reflectivity.

6.6 Sharp Infrared Sensor

The Sharp GP1U52X sensor detects infrared light modulated (e.g., blinking on and off) at 40,000 Hz. It has an active low digital output, meaning that when it detects the infrared light, its output is zero volts.

The metal case of the sensor must be wired to circuit ground, as indicated in the diagram. This makes the metal case act as a Faraday cage, protecting the sensor from electromagnetic noise.

An explanation of the infrared system, and use of the Sharp sensor is given in the Class Notes.

6.7 Slotted Optical Switch

Like the IR reflective sensor, the slotted optical switch contains a matched infrared transmitter and infrared receiver. The slotted optical switch also works by measuring the amount of light transmitted from the transmitter to the receiver, but in this case the transmission is direct, rather than reflected. Best results are again achieved when ambient light is shielded from the device. We recommend that you examine the sample before attempting to wire a slotted optical switch.

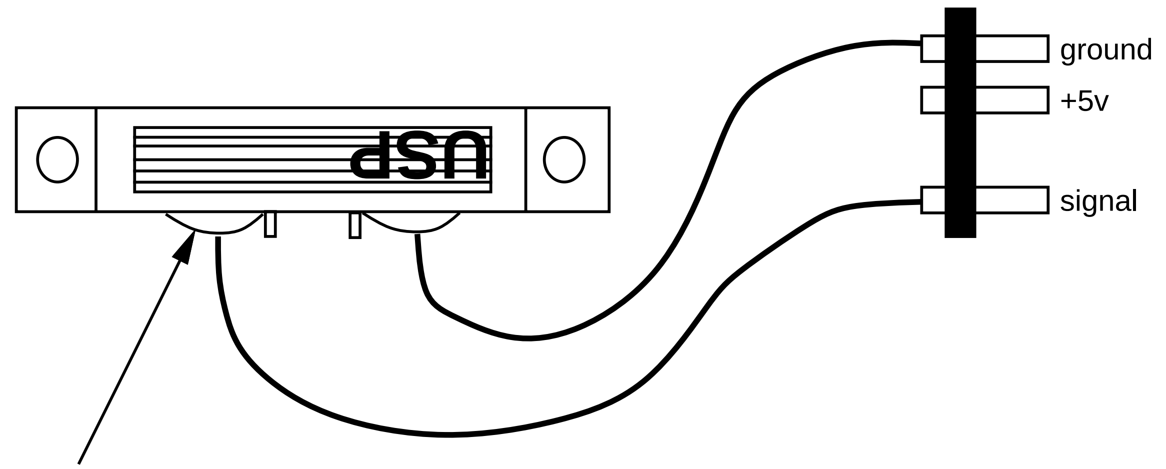
The output signal of phototransistor element is an analog voltage that corresponds to the amount of light hitting the phototransistor. Higher values indicate less light. Generally, however, the slotted switch is used as a digital sensor, with the two states Blocked and Unblocked.

6.8 Magnetic Switches

These magnetic switches are used as window sensors in home security systems. The switch will close when it comes within 1” of its companion magnet.



To attach wires to screw terminals, loosen screws, place stripped and tinned wire under screws and tighten the screws. No soldering is required.

7 Motor Mounting and Wiring

Several types of motors are available, but they all are either round, or oblate (round with two flat sides). See the course notes on the class web site for the different motor’s characteristics and for instructions on how to mount them to LEGO pieces. It is important to get the motor aligned correctly so that the gears will mesh properly, with minimum friction.

In addition to mounting the motor on a LEGO piece, you must also attach a gear to the shaft. You will find some motors in the lab that use heat shrink tubing and glue to attach an eight-tooth gear to the motor shaft. We now use a method that is more reliable and more versatile. We attach a small section of LEGO axle to the shaft, and then any gear (and other parts) can be easily attached. Since the adapter will go through a beam hole, you can attach it before mounting the motor; in fact this is the best procedure. The same technique is used for all the motors, but you must use the correct adapter piece because the motor shafts have different diameters.

7.1 LEGOizing Motor Shafts

○ Score the motor shaft slightly with sandpaper, *taking great care not to get sand inside the motor.* Point the motor shaft-down, grip it with a piece of sandpaper near the motor, and pull down away from the motor, so you are putting scratches along the length of the shaft. Repeat several times.

○ Clean the shaft with alcohol. Scoring and cleaning are especially important if you are re-working an old motor, so that the shaft is clean and the glue will adhere.

○ Obtain the correct motor-axle adapter piece. This is a piece of LEGO axle with a hole drilled through the center. The motor shaft is a *snug* fit in the hole. Different motors have different shaft diameters, so there are multiple adapters. *Be sure to use the correct one!*

○ Put a drop of instant glue (Loctite 409) on the end of the motor shaft; spread it around the shaft circumference. Only about 4mm or 3/16 inch of the shaft end needs to be coated.

○ It's best to have two people for the final step. Have your partner hold the motor on the bench with the shaft pointing up; place it on a LEGO beam so you will not bend the contacts or put pressure on the shaft. Your partner should also hold a LEGO beam so the motor shaft goes through a hole and the beam is flat against the brass motor bearing. This will indicate how far to push the adapter onto the shaft.

○ Hold the adapter with needle nose pliers, and put it on the motor shaft. You will have to tap it with a small hammer, or screwdriver handle, etc. Drive it down until it just clears the beam mounting guide.

○ Remove the beam, and give the glue a few minutes to dry.

7.2 Wiring a Cable and Plug to a Motor

○ Motor cables should be constructed with two strands of ribbon cable wire. Cut an 8-inch to 12-inch length of the wire.

○ Strip and tin both ends of the wire.

○ On the side of the motor there should be two metal lead/pads. Solder one wire lead to each pad. After proper soldering, hot glue may be used to hold the wire to the side of the motor for a stress relief.

○ Motor plugs should be wired for bidirectional use, as shown in Figure 19.

For the following steps, cut three-long strips of male socket header as needed.

○ Using the connector plug wiring technique shown in Figure 20 through Figure 23, wire the motor plug. Polarity does not matter since the plug may be inserted into a motor power jack in either orientation. However, placing a tag of tape on one of the wires just above the header, or marking one side of the plug with paint, will keep the motor orientation consistent. Even though the motors will operate when plugged in backwards, labeling the motor leads means your robot really will go forward when you tell it to, and not backwards.

Quicktest

The Quicktest is ideal for electrical shops, factories, labs and service and test departments.

With the lid open the wires of a plug-less lead are inserted into the insulated clips. When the lid is closed, current passes to the equipment demonstrated or tested.

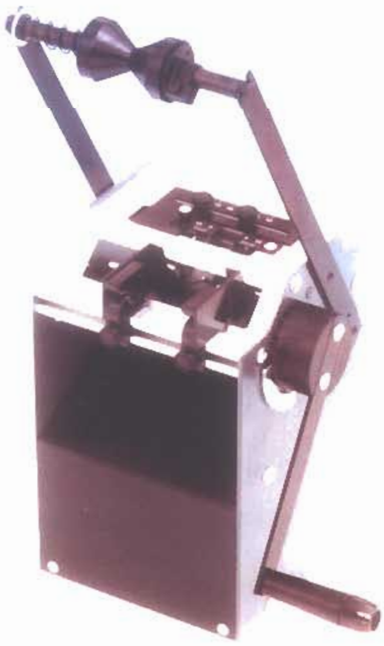
A neon light shows that the connector is live and ready to use. The 13 Amp fuse (BS 1362) is easily accessible for replacement.

The connector is made of tough safe materials. The base is phenolic moulded for insulation and rigidity. The lid is flame retardant glass filled thermo plastic.

The insulated clips are colour coded for easy identification. The flexible cable grip will take any normal mains cable. Only one small screwdriver is needed for both the base entry and the terminal screws.

Part Number CL1850 CE

PM-1 Pre-Forming Machine



The PM-1 component pre forming machine is designed to cut to length and pre form axial lead components ready for fitting into PC boards. The components may be fed in bandolier form (assuming a 5 mm pitch between components or multiples thereof), or loose by the means of the built in chute slots.

Finished components are collected in a standard size storage box which may be located under the cutter head or in front of the machine.

All adjustments are carried out on the top of the machine, with setting instructions clearly displayed near the setting point.

The general construction features anodised aluminium body with heavy steel sides. The free running blades are 35mm in diameter and produced in M2 high speed steel. The cutting and bending wheels are produced in high carbon steel and are hardened and tempered as appropriate.

The machine will cut and pre form components at a rate of 40,000 per hour.

Guards are fitted all around the cutting and bending wheels to ensure the operator can work safely.

The PM-2 variation has the above features but is designed only to rapidly cut components out of a bandolier producing loose components with straight wires.

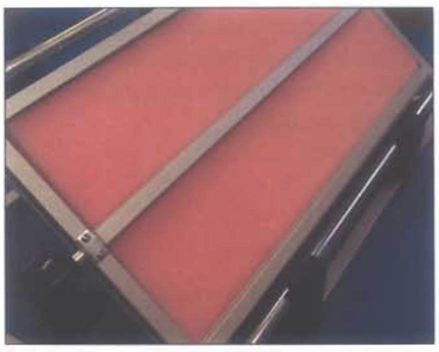
Workframe



PC workframes are designed to facilitate components loading and soldering of small batch runs of assembled printed circuits. The different size models will hold most common Euro norm sized PCB's in one or two rows depending on the PCB dimensions and size of frame. The working angle is adjustable from vertical to 45 degrees. Components are held in place by an antistatic foam sheet. The PCB's are retained in slots in spring loaded adjustable bars. The PCB's can be removed by just springing the bars—once they have been set correctly for the PCB size. This enables rapid loading / unloading in a production situation

CLIFFUME®

Compact Fumes Extractor

CLIFFUME SFE/1 is a low cost, compact, bench top fumes extractor system. It is primarily designed to be used to be used adjacent to hand soldering operations, where it will remove much of the smoke and fumes away from the operator. It can also be used in a gluing environment. *(note some solvents may attack the case and filter).*

The unit needs to be located as close to the fumes source as is practical, usually 10-20cm. The optimum position can be found by looking for the maximum smoke collection. The stand is designed to hold the fan at an angle, and assist smoke collection.

SFE/1 contains a filter element comprising activated charcoal filled reticulated foam. This will absorb particles down to about 5 microns. Filters are low cost and easily changed. Replace the filter when soiled, or when fume collection is observed as significantly reduced. The case is made from antistatic ABS. The stand can be earthed for optimum static dissipation.

SIMPLE AF OSCILLATOR USES TWO LOW COST ICs

Here is the design for an easy to build audio oscillator which uses only two low cost ICs. It generates both sine and square waves at low distortion, covering the frequency range from 3Hz to 30kHz. You can power it from batteries, or from a simple mains supply.

Looking through a recent edition of "Radio Communication", my interest was aroused by a very simple Wien bridge oscillator circuit by D.S. Jones. The circuit uses the ever popular and very low priced type 741 IC op amp. The supply suggested is 12 volts and the current just a few milliamps. Tuning is by a ganged 10k potentiometer and the frequency coverage is from 3Hz to 40kHz in four ranges. This looked like a good starting point for a low cost, simple, yet very worthwhile, economy audio oscillator.

By rearranging some of the time constants in the Wien bridge, the frequency coverage could easily be changed to go from 3Hz to 30kHz in four ranges. Instead of a 12V DC supply, this has been increased to 15V and could even be increased further to 18V. Hopefully, the increase in supply voltage would reduce the harmonic distortion to some degree.

As this audio oscillator set out to be an economy unit, a fairly obvious saving would be to do without a level meter. However, by taking some other quite inexpensive steps, the output voltage may be determined with quite good accuracy without the use of a meter.

The sine wave output is over one volt and by adding a preset potentiometer in series with the output load, the voltage across the load could be adjusted to one volt against a suitable meter. As the output voltage is almost constant over the entire range, it is then only necessary to provide a means of voltage division and the output voltage can be attenuated by a known amount.

By suitable switching, the sine wave output can be put through a type 555 IC used as a Schmitt trigger to give a square wave output. As the output of this stage is also in excess of one volt, the same procedure has been adopted to reduce the output to one volt and this is attenuated in the same way as for the sine wave output.

The oscillator circuit is the Wien bridge and for those unfamiliar with this arrangement it is shown in principle in Figure 1. As may be seen it consists of a high-gain differential amplifier with two separate feedback circuits. One circuit, consisting of resistors R1 and R2 and capacitors C1 and C2, connects from the amplifier output back to the "+" input and so provides positive feedback. The other circuit consists of resistor R3 and the thermistor (negative temperature-coefficient resistor), and is connected between the output and the "–" input to provide negative feedback.

The configuration R1, R2, C1 and C2 is known as the "Wien network". At a particular frequency determined largely by the values of the four elements, the transmission loss of the network falls to a minimum while the phase shift also passes through zero.

If R1 and R2 are equal in value, and C1 and C2 also equal in value, the frequency of oscillation is equal to the reciprocal of 2piRC. Under these conditions, the transmission loss falls to a minimum of 3. In other words, there is a maximum transmission gain of 0.33.

To produce sustained oscillations, the overall loop gain must be at least unity and the phase shift either zero or a multiple of 360 degrees. For the circuit of Figure 1 to produce continuous oscillations, the amplifier gain must be at least 3 to compensate for the loss in the Wien network.

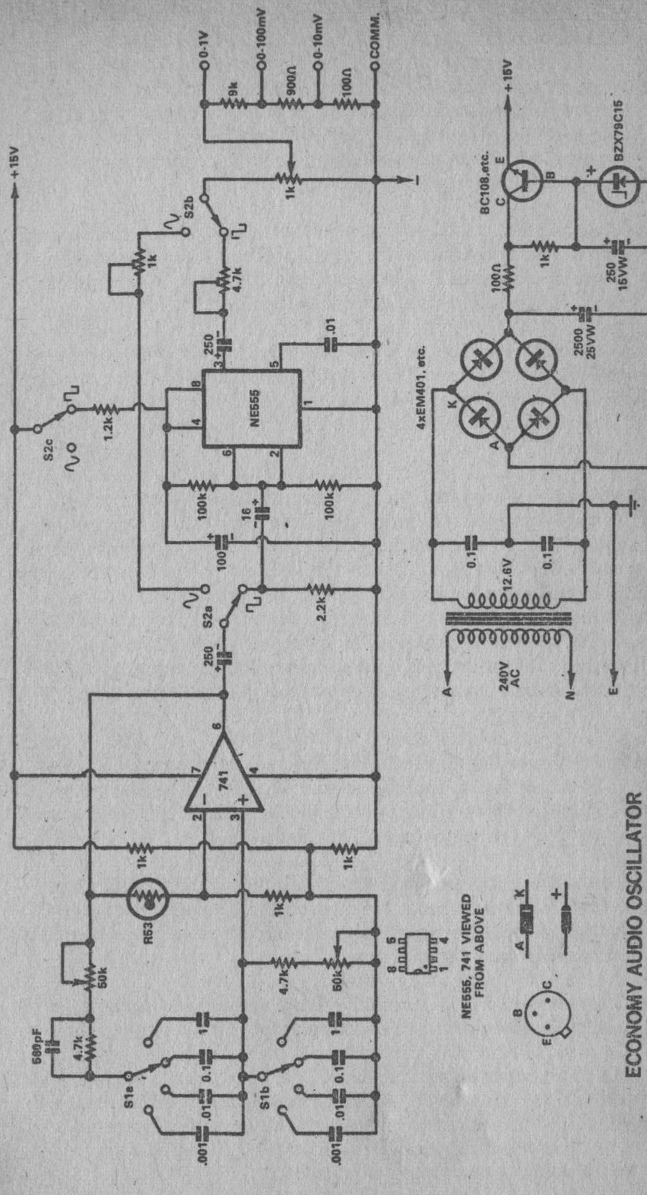
It is necessary for the amplifier to have an overall loop gain of at least unity for sustained oscillations. But if the gain is more than one, the oscillations will continue to grow until the amplifier is driven into clipping. To keep the gain at unity and oscillation at constant amplitude, a thermistor is used in the negative feedback network.

Since the thermistor has a negative temperature coefficient of resistance, its resistance falls as its temperature rises. When power is first applied to the circuit the thermistor will have a relatively high resistance and so there will be little negative feedback. The resulting high gain around the positive feedback loop will rapidly build up oscillation.

As the oscillations grow, the temperature of the thermistor rises, as this and resistor R3 are effectively connected in series across the amplifier output and so draw signal current. Hence the resistance of the thermistor falls, negative feedback increases and the effective amplifier gain drops.

Consequently an equilibrium is reached, as the output amplitude can only rise to the point where the thermistor has increased the negative feedback to correspond to an effective gain of three – giving unity loop gain. If the oscillations tend to rise above this level, the thermistor will reduce the loop gain and the oscillations will begin to die away. Conversely, if the amplitude tends to fall, the thermistor will increase the loop gain slightly above unity to correct it.

In short, the non-linear negative feedback action produced by the thermistor acts to continuously and automatically maintain the loop gain at unity, and the oscillation amplitude constant. By using a suitable thermistor the output amplitude may be maintained at a level well below limiting, giving an output waveform with low distortion.



ECONOMY AUDIO OSCILLATOR

The circuit of our economy audio oscillator uses two low cost ICs and offers low distortion.

Looking now at the main circuit, the relative parts may be clearly seen with reference to the foregoing description of the theoretical aspects of this type of circuit. The positive and negative feedback circuits are easy to see, along with the two resistors and capacitors for each frequency range. Before leaving the oscillator section of the circuit, it may be seen that one of the 4.7k resistors is shunted with a 560pF capacitor. This is to compensate in some measure for stray capacitance in the circuit, which becomes significant at the higher frequencies.

The oscillator circuit is followed by a Schmitt trigger which can be used to convert the sine wave output from the oscillator to a corresponding square wave. The Schmitt trigger uses a type 555 timer IC as suggested by Walter G. Jung and the circuit performs this task adequately.

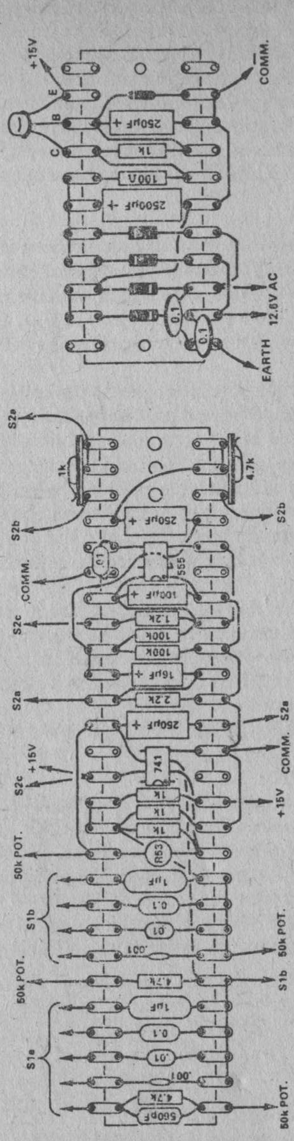
In order to select either sine or square wave output, a three-pole two-position toggle switch is used. This diverts the sine wave either through or around the Schmitt trigger. At the same time, the positive supply rail is switched on or off in accordance with the requirements of the Schmitt trigger.

Whichever output is selected, it is fed into a 1k linear potentiometer. Before being fed into this potentiometer, it is passed through a variable resistor in the form of a preset pot, which is set to give a predetermined output level. More will be said about this later on. To give a wider range of control over the output level, the output of the 1k pot is fed into a voltage divider. The divider provides for divisions of 1, 10 and 100, corresponding to attenuations of 0dB, 20dB and 40dB, respectively. In addition, the 1k pot is fitted with a knob calibrated 0 to 10, which means that attenuations may be achieved fairly accurately down to 60dB.

With the preset pots just referred to adjusted so that we have a level of one volt across the 1k pot, we are able to make settings between 0 to 1V, 0 to 100mV and 0 to 10mV. We may therefore set the output level fairly accurately anywhere between 1mW and 1V.

We elected to incorporate a power supply within the unit, although it would be quite possible to run it from batteries. The power supply is regulated at 15V and although it is a simple circuit, steps have been taken to keep hum and noise to a minimum.

The transformer has a 12.6V secondary winding rated at 150mA. Four diodes in a bridge give about 18V DC across the 2500µF filter capacitor. A BC108 transistor is used in a simple series regulator circuit which is referred to a 15V zener diode in its base. The two 0.1µF capacitors, one on each side of the secondary of the transformer help to reduce noise from the mains. The negative supply line is left floating as is normal practice with this type of instrument. Metal parts of the case are connected to the mains earthing system.



These two wiring diagrams should make construction a straight-forward process. The oscillator tagboard is shown at left, whilst the simple regulated power supply is shown at right. Make sure that the thermistor is firmly secured in position.

Some comments on the more important components may be helpful. Perhaps the item of most interest is the 50k linear ganged potentiometer. In the interest of economy, we used an imported deposited carbon unit under the name of Soanar. This has proved to be quite satisfactory; we have tried a number of them in the circuit and each one follows the calibrations well enough for all practical purposes. For readers who decide to use this potentiometer, we are printing a full size copy of the scale which may be used in any way that is considered best.

Before leaving the subject of carbon potentiometers, we can see no reason why some other brands of potentiometer should not be tried. However, it may be that the scale which we have calibrated against the Soanar unit may not suit another brand. In this, and other circumstances yet to be touched on, it would be necessary to calibrate your own scale.

When considering what potentiometer to use initially, we invested the idea of using a moulded carbon unit but as near as we can ascertain, these are not available in the type and resistance value required. In past projects we have used a wire would potentiometer, made by Naunton. These are still available and may be used if any reader so desires. However, there are two points worth considering. It would be necessary to calibrate your own scale, and the price could be rather daunting. The choice of course is up to the individual.

The output level control is a 1k moulded carbon potentiometer in the prototype. While an ordinary carbon pot may be quite satisfactory, we considered that the moulded element would be more reliable from a linearity point of view. This is important as we have fitted a knob to this control which is calibrated 0 to 10. This facility, in conjunction with the output divider, makes it possible to set the output level with reasonably good accuracy.

The output divider just mentioned is made up of a number of resistors to give the correct ratios. The bottom element is 100 ohms and this presents no problem as it is a preferred value. The next section calls for 900 ohms and this is made up with 220 ohms and 680 ohms in series. The top section has a value of 9k and this is made up with 2.2k and 6.8k in series. We used Philips ½ watt types here and although we did not specify close tolerance, we have found them to be quite satisfactory.

The set of capacitors for the frequency ranges should be of good quality and preferably of 1 percent tolerance. The tolerance applies to all except the 1µF. Although it would be ideal to have this in the same tolerance, it would be quite expensive and we understand that availability is open to question. We found that with 10 percent tolerance units in circuit the amount of error was not significant for normal purposes.

The thermistor is an STC type R53 and this does an excellent job in this circuit. While we have not tried other types, we feel that it would be wise not to substitute for this item.

Both ICs are readily available. The type 741 comes in a number of brands but the 555 IC timer is only available from Signetics. Both ICs are 8-pin DIL are used in the prototype but other packages are also available if required. For our purpose, the smaller package is more convenient.

The prototype was built into a plastic case with an aluminium front panel and one which we have used a number of times before.

Most of the components are mounted on either one of two miniature tag boards and these are shown in diagram form. Care should be taken with the thermistor to stabilise it mechanically and this may be done by simply tying or gluing it to the adjacent 1µF capacitor. Sockets for the two ICs are fixed to the board by drilling either holes on the board carefully with a fine drill. Lugs of the sockets are pushed through the board and leads taken as shown in the diagram. The photographs show the location of all major components. The boards are stood off the case by 5mm or so by means of spacers, or by using a couple of extra nuts on each of the mounting screws.

The power transformer which we used had a centre tap on the secondary winding, but this is not required. We simply cut it off to about 10mm long and located it so that it was not likely to come into contact with any other parts of the unit when it was all assembled. A lead which should not be forgotten is from the mains earth termination to a lug on the metal front panel.

Once the unit is assembled it is ready for adjustment and calibration. Before going ahead with these operations, a simple check that it is working would be in order. Feed the output into a CRO or listen on a pair of headphones. If you choose the latter method, make sure that the oscillator is operating at a frequency which is covered by the phones in use. Assuming that you get sine waves and square waves on the CRO, or sounds resembling a flute with the switch in the sine wave position and sounds like a clarinet when the switch is in the square wave position, you are in a position to carry out adjustments.

Set the dial knob assembly on the potentiometer spindle such that the pointer corresponds with the marks on the scale for extreme limits of travel. Set the output knob on the output pot spindle so that 0 and 10 correspond with minimum and maximum output, respectively.

Set the range switch and frequency dial to give an output of about 100Hz. Set the output level control to 10 and take the output from sockets "E" and "0–1V" and connect to an AC voltmeter of good accuracy and high impedance. Set the toggle switch to sine wave output and adjust the 1k preset pot to give a reading of 1 volt. Set the toggle switch to square wave output and adjust the 4.7k preset pot to give a reading of 1 volt.

These Lissajous figures show (left to right) vertical to horizontal frequency ratios of 1:1, 2:1, and 3:1.

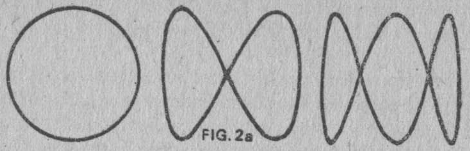


FIG. 2a

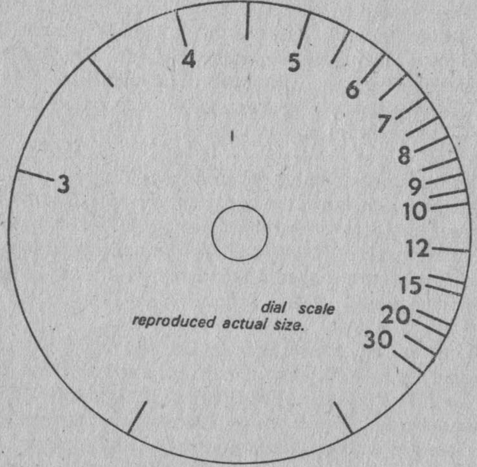

dial scale reproduced actual size.

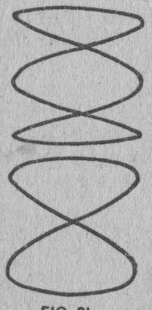

FIG. 2b

These Lissajous figures show vertical to horizontal frequency ratios of 1:3 (top) and 1:2 (bottom).

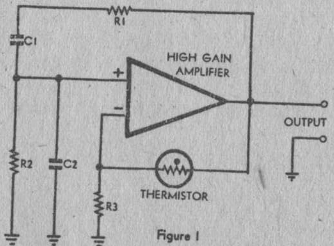

Figure I

Above is the schematic of a Wien bridge oscillator showing the high gain amplifier and its associated positive and negative feedback networks.

If you have access to a calibrated CRO, the two preset pots just mentioned may be set against the CRO graticule. For sine wave output, the level should be set to give a reading of 2.8V peak-to-peak and for square waves, a reading of 2V peak-to-peak should be obtained.

If you have used the same type of 2-gang potentiometer as for the prototype, together with a copy of our scale, then you will not have to carry out any further calibrations. For readers who have used the wire wound, or some type of pot different from that on the prototype, then it will be necessary to calibrate for one range. This could conveniently be from 30 to 300Hz, with the range switch set to "X10".

If you are fortunate enough to have access to a digital frequency meter, then the job may be done quite easily. Another method is to generate Lissajous figures with the aid of an oscilloscope and another known source of audio frequency. The second source could be an accurately calibrated oscillator, a test record, an electronic organ or the mains frequency of 50Hz.

For those not familiar with the Lissajous figure method of frequency comparison, the following briefly outlines the procedure. The output of the known frequency source is fed to the horizontal amplifier of the CRO and the output of the oscillator to be calibrated is fed to the vertical amplifier. When the gains of the two deflection amplifiers are suitably adjusted, a series of patterns known as Lissajous figures are produced. Typical frequency patterns are shown. These enable the unknown frequency to be calibrated easily.

These figures differ from the normal pattern produced by a sine wave oscillator, since the horizontal deflection signal is a sine wave and not the normal sawtooth produced by the oscilloscope timebase generator.

Some examples of Lissajous figures are shown in Figure 2a. Each represents a different frequency ratio – 1:1. 2:1 and 3:1. Each ratio is that of the vertical frequency to the horizontal frequency. If the signal applied to the horizontal amplifier is 50Hz and the resulting ratio is 2:1, then the vertical frequency will be 100Hz.

The method of determining the ratio is to count the loops along the top of the pattern and the number of loops along one side. The ratio of the two numbers if the frequency ratio.

This basic rule makes it possible to identify a variety of ratios. For example, five loops along the top and two at the side would indicate a ratio of 5:2 and, related to 50Hz, this would indicate a frequency of 125Hz. Incidentally, submultiples can be identified in the same way and Figure 2b indicates the pattern shape for ½ and 1/3 of 50Hz, corresponding to 25Hz and 16.7Hz.

If you attempt to simulate these patterns on a CRO you will find that the patterns tend to drift. This is because the phase relationship of the two frequencies is changing because of small frequency drift of the two sources. Unless the two sources are very stable, the circle pattern will slowly change to an ellipse to a straight line as the phase relationship of the two signals changes. A circle represents a phase difference of 90 or 270 degrees while a straight line represents a phase difference of zero or 180 degrees. This drift in the pattern is only a portion of a cycle and so it has negligible effect on calibration accuracy.

The foregoing information on Lissajous patterns may be used to calibrate your oscillator and this may be applied most easily to the range 30 to 300Hz, as mentioned earlier. Once you get the easy points, such as 50Hz, 100Hz, 150Hz, etc., other intermediate and less obvious patterns will become obvious by virtue of interpolation of the already determined points. It is not a difficult operation and indeed, can be quite fascinating.

TTL PULSE DETECTOR USES INEXPENSIVE IC, LED

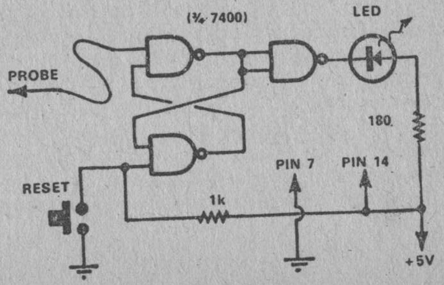
When one is testing an experimental logic circuit, or troubleshooting in a completed digital instrument or system, it is often necessary to detect single, fast pulses. At times this can be surprisingly difficult even using a wideband scope with extensive triggering facilities. Some logic probes have provision for "stretching" short pulses, but even this can be of limited help.

I have found that this simple circuit is very useful in this sort of situation. It will only detect negative-going pulses, but in practice this has not proved a problem as it is usually possible to look for a pulse where it is negative going.

As you can see, it is a simple R-S slip-flop formed from two gates of a 7400 IC. A third gate is used as an inverting driver for the indicating LED. The circuit is reset before each "search" by pressing the pushbutton.

If the probe is taken down to the low logic level (0. 8V or less) for even as short a time as about 10 nanoseconds, the circuit will quickly flip over to the set state and latch there, indicating that a pulse occurred.

Almost any low cost LED can be used.



HIGH IMPEDANCE VOLTMETER BASED ON LOW COST OP AMP

Here is an easily built high impedance electronic voltmeter using a single 741 op amp IC. While the basic instrument is designed for DC measurements, probes are also described to allow its use for measuring both RF and low frequency AC signals.

Specifications

Ranges: DC – 0-1, 0-10, 0-100 volts. AC and RF – 0-1, 0-10 volts RMS.
Input impedance: On DC – 22 megohms, all ranges.
On AC and RF – 5 megohms approx., both ranges.
Frequency: 20Hz to 50MHz, using two probes.
Power supply: 2 x 9V batteries. Drain approx. 2mA.

When working on solid-state circuits there are many occasions when a DC voltmeter of really high resistance is very useful, because it can give substantially true readings in high-resistance circuits without upsetting their working conditions to any serious extent.

Needing such an instrument wuickly and having no calibrated vacuum-tube voltmeter handy, the writer considered what might be done by using a 1-milliamp FSD meter which was on hand, in conjunction with an inexpensive linear integrated circuit. Such an arrangement has the advantage, apart from the possibility of high input resistance, that calibration is unnecessary if accurate resistors are available, because a reading of one milliamp full scale can easily be made to mean one volt, with other ranges in proportion merely by switching one resistor. Accuracy and stability can be very good because of the large amount on negative feedback employed with the integrated circuit. Furthermore, a 1-milliamp meter is cheaper and much more robust than those of ten or twenty times greater sensitivity which are usually found in normal high-resistance voltmeters – which, in any case, will have a resistance seldom exceeding half a megohm on the lower ranges.

Having worked out the details of such a DC instrument, the idea of extending its usefulness to radio-frequencies and, consequently, to AC voltage measurements present itself. The need here was for an RF voltmeter of low losses, low capacity, and an input impedance of several megohms, which could be applied to a tuned circuit or oscillator while leaving its "Q" almost unaffected. Therefore it was arranged that an AC or RF probe on a long flexible lead could be plugged into the DC instrument, the probe containing a full-wave peak-to-peak rectifier circuit using low-loss materials. It was then only necessary to change one resistor in series with the meter movement by a DC-AC switch to have the meter show RMS values of AC voltage, with the original linear scale remaining accurate throughout except for the first one-third of the 1-volt scale where the curvature of the rectifier characteristic produces increasing non-linearity. A calibration curve for this part of the scale is shown hereafter.

At first sight it seemed that one AC probe would suffice for both audio and radio frequencies. However, it was desired to extend the audio range with full accuracy down to 20Hz and this required capacitors of $1\mu F$ in the rectifier circuit. Flat lacquered polyester-foil capacitors were used here and were quite satisfactory at the lower frequencies, but it was feared that their losses would be too high at radio frequencies, where much smaller capacity would in any case be sufficient.

Since low RF losses were an essential requirement of the project, a second probe was made for this work, using small polystyrene-foil capacitors and glass-fibre insulation, designed for frequencies from 100kHz upwards; while the other probe covers the range 20Hz to 200kHz.

Figure 1 shows the circuit of the DC instrument and Figure 2 the two probe circuits. Note that the low-frequency probe has a DC-AC switch so that it can be used for both purposes. AC and RF measurements are confined to the 1-volt and 10-volt ranges only, as anything exceeding 40 volts RMS could break down the rectifier diodes in the probes.

The Integrated Circuit

For readers who may not be very familiar with these devices, a very brief explanation may be in order. The type of IC used here is called an operational amplifier. Originally devised for carrying out certain mathematical operations in computer work, it is now used increasingly for all sorts of linear amplification purposes in both DC and AC circuits, and for these purposes it has potent advantages in space, cost, simplicity, stability and economy of working current.

An operational amplifier of this type is, in essentials, a direct-coupled multi-stage DC transistor amplifier of very high overall gain, intended specifically to be used with very heavy negative feedback. The initial gain, called open-loop gain, may be anything from around 2000 times to 200,000 times or more, depending on the type chosen, but the gain after feedback is applied, called the closed-loop gain, is seldom required to be more than 1000 times and is commonly much less.

This massive negative feedback not only extends the frequency response and reduces distortion and noise in the usual manner of NFB; it also makes the whole circuit largely independent of manufacturing tolerances in the IC itself and in its supply voltages. As a result, its performance in a given circuit can be predicted and determined almost completely by the choice of the external feedback components. Feedback can be either DC as in the present design, or AC as in the case of pre-amplifiers for audio frequency work, or both. There are, however, frequency limitations depending upon the type of IC chosen and very few are useful beyond a megahertz or so irrespective of the amount of feedback used. They are, as previously said, primarily DC amplifiers.

Usually an operational amplifier, or "op-amp", has two inputs and one output, plus a few other connections for supply voltages and other purposes. The input connections are called "inverting" and "non-inverting" inputs respectively, meaning simply that an input signal applied to either of them will appear at the output terminal either with the same or with the opposite polarity, according to choice of input terminal. To avoid drawing the whole complex internal circuit of the IC, the symbol shown in Figure 3 is used to represent it, namely, a triangle placed sideways with inputs on the left and output at the apex on the right. The inputs are labelled "+" for the non-inverting one and "–" for the inverting one. A signal applied to the "+" input appears at the output in phase with the input; if applied to the "–" input the output is in phase op-position; i.e. there is phase reversal.

Figure 3 shows the two basic circuits for an "op-amp". In 3a showing the "inverted" circuit, the input goes through R1 to the inverting terminal and negative feedback is applied through R2 to the same terminal. If the source of the signal has low impedance, the closed-loop gain of this system is, practically, R2/R1 and by varying R2 it can be made almost anything from unity up to the full open-loop gain. The input impedance of this arrangement is relatively low – virtually equp to R1 – and its output impedance fairly high; these properties are useful in many circuits but not for the present application where we need very high input and low output impedances, the latter to suit the low resistance of the milliammeter.

We therefore turn to Figure 3b, showing the non-inverting configuration. Here we feed the signal into the "+" terminal, but the feedback remains connected to the inverting terminal. The closed-loop gain will now be equal to R3/R2 and the input impedance will be high – several megohms at least – and output impedance 75 ohms or less. These characteristics evidently suit our present purpose and this circuit was chosen.

Several types of linear op-amps are available at moderate prices having widely-different characteristics. For this instrument the popular type 741 seemed most suitable. This is quite a complex affair containing twenty transistors, many resistors and a capacitor for frequency compensation and having a typical open-loop gain of 200,000 times. It is available either in a TO99 round can or as 14-pin or 8-pin dual-in-line packages; the 14-pin version was chosen. A second version, type 741C, is often available and sometimes at a rather lower price; this appears to be a so-called "Commercial" version with somewhat looser tolerances,

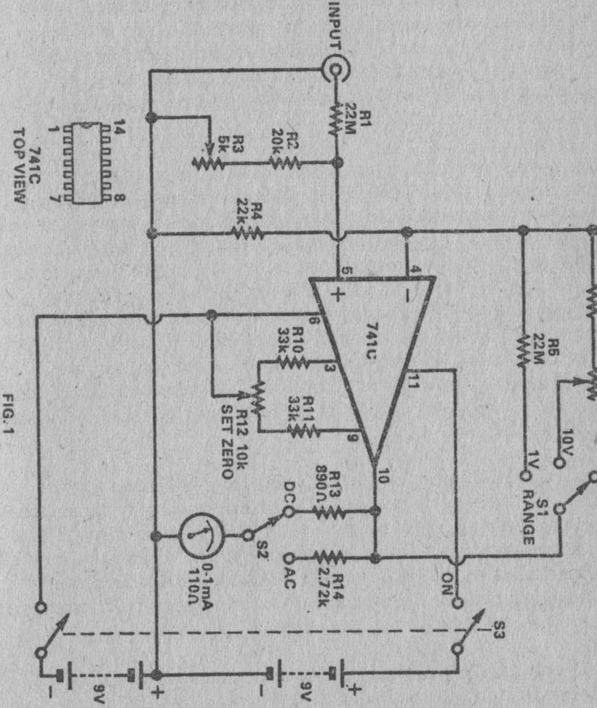

FIG. 1

quite satisfactory and is used in this instrument. A constructor may use whichever type suits him or is procurable, and the package version desired.

The practical circuit evolved into that shown in Figure 1. Starting with the meter, we connect in series with it a resistor of a value which, together with the meter's internal resistance, will total 1000 ohms and thus give a full-scale deflection (1mA) with 1 volt applied across them. This will be the output required from the op-amp on all ranges and the meter scale divisions can be read as volts or fractions of a volt, multiplied by the range switch setting. The meter used here is an imported one of SEW make, type MR-85P with square face measuring $4\frac{5}{8} \times 4\frac{3}{16}$ inches, and its measured resistance was 110 ohms, requiring a series resistor of 890 ohms. This can be made with sufficient accuracy from 820 ohms and 68 ohms in series, both of 1pc tolerance, these being preferred values. (R13 Figure 1.)

While a large meter like this one is nice to work with, easily read and robust, any 1mA meter can be used. If its internal resistance is not known or cannot be measured, it can be calibrated in terms of whatever 1 volt standard meter may be available, using a variable pre-set trimmer resistor of around 2000 ohms as the series resistor; the accuracy will then be no better than that of the standard voltmeter used.

It was desired to have a DC input resistance of at least 20 megohms, this being determined by R1. The nearest preferred value is 22 megohms, and the required tolerance is 1pc; this being difficult to procure, it was made up from two 10 megohm and one 2 megohm units of 1pc in series. Both input circuits of the op-amp have to be returned to the earth line through resistors of only moderate value and of the same resistance, otherwise the slightly differing input currents can set up standing voltages large enough to make zero-balancing difficult. Thus R2 and R3, taken together, form a voltage-divider with R1 which reduces the input signal applied to the op-amp; a value of 22k was considered the highest desirable. Thus an input of 1 volt will be reduced to 1 millivolt at the input of the 741.

Since this must produce an output of 1 volt for application to the meter, the 741 must give a gain of 1000 for this range and the feedback circuit on the inverting input must be proportioned accordingly. This input, as above-mentioned, must be returned to the earth line through a resistance similar to R2 + R3, namely 22k. Thus R4 is determined and the feedback resistor R5 then automatically becomes 22 megohms, the ratio of R4 to R5 producing the required gain of 1000.

For the 10-volt and 100-volt ranges it is only necessary to change the feedback resistor to increase feedback and reduce gain in the required ratio; thus R6 + R7 becomes 2.2 megohms for the 10-volt range and

FIG. 3

The final circuit is based on (b). This gives a high input and low output impedance, ideal for this requirement.

R8 + R9 becomes 220k to give the 100-volt range. These three conditions are shown in Figure 4 with the respective input and output voltages and gains indicated.

All resistors so far mentioned should ideally be of 1pc tolerance, and if these are available the accuracy of the instrument will be dependent only on that of the meter movement without further calibration. However, close tolerance resistors may sometimes be hard to get, so variable pre-set resistors have been added at the signal input (R3) and the 10-volt and 100-volt feedback resistors (R7 and R9) to permit exact adjustment, either to the required tolerance on a bridge or by direct comparison with another voltmeter. These can be miniature carbon trim-pots if low cost is important but they are awkward for precise adjustment and of doubtful stability of setting. A much better solution is the miniature Cermet trim-pot of the 10-turn type as made by Spectrol, Beckman, Morganite and others; these are probably worth the extra cost in terms of accuracy and stability.

It is necessary, in order to bring the output voltage to zero in the absence of an input signal, to balance the input currents of the two input terminals. Provision is made for this in the internal circuit by connecting a potentiometer (R12) across terminals 3 and 9, with its slider going to the negative supply rail (terminal 6). Additional resistors R10 and R11 were found desirable to make the adjustment less critical. R12 is a panel control with a suitable knob, used to set the meter reading to zero on the 1-volt DC scale only; this setting holds good on all other ranges; It is quite stable and shows very little drift after a few minutes' warmup, but it may be checked occasionally when great accuracy is called for.

AC and RF Ranges

As stated earlier, the rectifier system in the probes actually produces a DC output proportional to the peak-to-peak value of the measured AC voltage, which is roughly 2.83 times the RMS voltage. If applied to the DC voltmeter circuit as it stands, the scale readings would have to be divided by this factor, a very awkward procedure, or else the meter would have to be re-calibrated with an additional peak-to-peak AC scale; both expedients to be avoided. The alternative is to reduce the milliammeter sensitivity until it reads the RMS value of the peak-to-peak voltage, thus preserving the original single scale for all purposes. This can be easily done by changing the multiplying resistor in series with the meter, and switch S2 does this by bringing in R14 to replace R13. Its value can easily be calculated.

The combined resistance of the meter and R14 must now be 1000 × 2.83, or 2830 ohms; subtracting the meter's internal resistance of 110 ohms (in this case) give 2720 ohms for R14. If desired, this could be made a variable resistor to permit fullscale deflection to be adjusted on

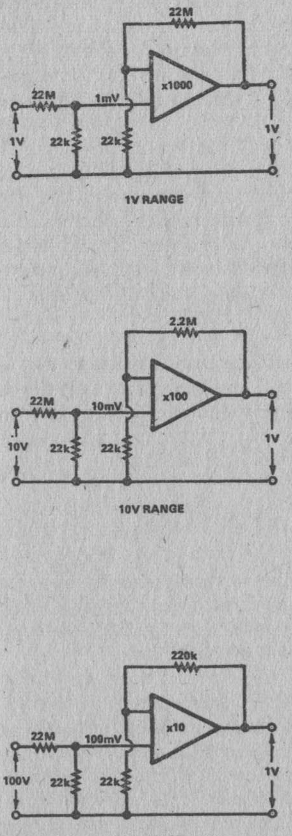

FIG: 4

the 10-volt scale by comparison with another AC voltmeter, but most such voltmeters (of the rectifier type) are not accurate to better than 4 or 5pc and the use of the calculated resistor value is likely to give greater accuracy.

As mentioned earlier, the lower one-third of the 1V AC scale becomes non-linear, but the curve of Figure 5 shows that this is not serious. Nevertheless, the curve gives quite accurate correction down to 0.1V RMS at least.

It is worth remembering that by leaving S2 in the DC position while measuring AC, one gets, effectively, the peak-to-peak reading instead of RMS. In other words the sensitivity is increased by the factor 2.83 and although the scale is not calibrated for it, this increase is often quite useful for comparative readings of RF voltages too small to be read comfortably on the RMS scale.

The effective input impedance is lower when using the RF and AF probes. For the peak-to-peak rectifier arrangement used the effective load presented to the circuit under measurement is usually taken to be one-quarter of the DC load resistance, in this case 22 megohms (R1). Thus the AC and RF probes load the circuit under measurement with about 5 megohms, with a few picofarads of capacity in parallel; this is negligible for most tuned circuits.

Two small 9-volt transistor radio batteries are adequate for the supply and as the total drain is only around 2 milliamps their life will be long. Lower voltages down to perhaps 3 volts could be used without much effect on performance bu the 9-volt supplies are recommended. Note that both positive and negative supplies are needed.

RF and AC Probes

These are of similar construction, the only difference being in the size of the capacitors, the insulation used and the provision of an AC-DC switch on the AC probe, allowing it to be used for DC measurements without changing cables. Figure 2 shows the circuits.

Each probe is assembled in a square IF transformer can about $1\frac{1}{8}$in square by $2\frac{1}{2}$in high. The open end carries the insulating panel supporting the whole circuit assembly and a sharp $1\frac{1}{4}$in spike to serve as a prod, while the shielded coaxial cable carrying the DC output to the meter is brought out through a hole in the solid end of the can. The shielded coax cable is essential here to avoid pick-up of spurious signals, hum, etc, because of the very high input resistance of the meter circuit. It is about two feet long for convenience and is terminated at the meter end with any small coaxial connector of good insulation resistance, to suit a matching socket on the front panel.

The diodes in both probes are type OA91, of the germanium point-contact type, with a peak voltage rating of about 115 volts. They are chosen in preference to silicon types, firstly because point-contact types are usable to higher radio-frequencies than other constructions; secondly, because their conductivity starts at lower voltage than silicon types, thus contributing to better sensitivity and scale linearity; and thirdly, because their slightly higher leakage gives faster response and quicker recovery after a momentary overload. Silicon diodes of good quality have such low leakage that if the probe capacitors accumulate an overload charge it takes quite a time to leak away, and in the meantime the meter is paralysed.

Capacitors in the RF probe are small tubular polystyrene types (not polyester) of excellent "Q" and insulation. Uncased silvered-mica types would be equally good but probably more bulky, and most available mica capacitors seem to come in "moulded mud" cases whose RF losses are not to be trusted. Ceramic capacitors are quite unsuitable because of high RF losses and should not be used.

The AC-DC probe uses flat lacquer-coated polyester foil capacitors of 1μF which fit the can fairly snugly; the writer used "ELNA" brand. This probe has a miniature slide-switch of the smallest available size mounted on one side wall, to change the probe from AC to DC operation simply by shorting input to output. The prod consists of a $1\frac{1}{2}$in length of 6BA threaded brass rod, sharpened to a point at one end and mounted at the other by nuts in the centre of a square panel of insulating material. The latter is mounted over the open end of the can by whatever mounting means are provided – lugs, spade bolts, or whatever.

The AC-DC probe used $\frac{1}{16}$in bakelite sheet for this panel, but in the RF probe a piece of polyester-glass-fibre sheet salvaged from a high-quality printed circuit was used. Sheet polystyrene would have lower losses, but is hard to find and ceramic materials, also good, are too difficult to work.

Inside the can the components are supported on a vertical panel of the same material, cut to fit the internal dimensions of the can and mounted to the top panel by a generous fillet of Araldite adhesive or else by small lugs and bolts. No specific constructional details are given as so much depends on the components actually available.

The AC-DC probe will need careful arrangement to leave room for the switch without fouling the rather large capacitors. For the screened leads the writer used PVC insulated, screened and PVC sheathed coaxial cable of 3.5mm overall diameter – a pleasantly flexible size which imposes minimum strain on the meter. A short length of tinned-copper braid equipped with an alligator clip is attached to the probe can to serve as earth connection to the circuit being measured.

A useful accessory is a further alligator clip provided with a 6BA nut mounted coaxially on its shank; this can be screwed onto the prod when a temporary connection is needed to a circuit, so leaving both hands free.

Construction

The prototype is assembled on a sloping panel measuring 7¼ x 6in, set at a 30-degree angle on the front of a pine-board box of sufficient depth to house the batteries. Figure 6 gives the panel layout.

The 741 IC is best used in a 14-pin DIL socket to avoid soldering directly to the IC pins, which can be a tricky job. These sockets exactly match the holes in 0.1in matrixboard or Veroboard, and their pins can easily be soldered to wires or strips on the reverse side. The writer favours Veroboard for this, and a suitable connection scheme for the circuit of Figure 1 is easily arrived at. If suitably dimensioned, this board, carrying most of the components, can be mounted directly on the meter terminals by loops of 18-gauge tinned copper wire.

Note carefully the small notch at one end of the 741 to identify it with the pin numbering diagram (see Figure 1). The socket should have a similar small notch at one end and the 741 must be inserted with the notches coinciding. There is nothing else to prevent the 741 being inserted back to front, which may do it no good at all. And when inserting or removing it, be very careful to do so with an absolutely straight pull or push, otherwise the fragile pins are almost certain to be crumpled or otherwise damaged, perhaps beyond repair. Once safely in its socket, the less it is moved the better, but the ability to remove it during servicing or circuit changes is a great advantage over permanent soldering into the circuit.

The Range Switch S1 should preferably be a miniature rotary wafer type to conserve space. The "ON-OFF" switch S3 must be a double-pole type, to switch both batteries. For this and also for S2 the writer used small slide switches, again to save panel space.

Because the instrument is virtually self-calibrating if 1pc resistors have been used throughout, no special instructions are needed in that case.

If the suggested variable resistors have been included, two courses are open. If a Wheatstone Bridge is available or can be borrowed, each combination of fixed and variable resistor can be set up to the exact value needed before wiring into the circuit and further calibration is then unnecessary. The values required are

R2 + R3 = 22k
R6 + R7 = 2.2 megohms
R8 + R9 = 220k.

R4 and R5 cannot well be made adjustable without badly complicating the scale-setting procedure; they must be of 1pc tolerance.

Failing the bridge, each DC range can be set at full-scale deflection by comparison with another voltmeter, starting with the 1-volt range. A supply of finely-adjustable voltage, or a potentiometer across a fixed supply can be used. The 1-volt range is best set up by feeding in an accurate one volt DC and adjusting R3 for full-scale reading, having first zeroed the pointer using the Zero Set knob R12. The 10-volt and 100-volt ranges can then be set up in succession by adjusting the appropriate resistor in the feedback chain (R7 and R9 respectively.)

With the DC ranges correct, the AC ranges should not need further calibration. However, if an AC voltmeter of known accuracy at 10 volts is available for comparison the 10-volt AC range can, if desired, be set correctly at 10 volts full scale by using, say, a 5k variable resistor for R14. The 1-volt scale will then also be correct and both will be accurate when using the RF probe over its designed frequency range.

SQUARE WAVE OSCILLATOR/PULSE GENERATOR USES 555 IC

With a little care, the popular 555 or Tandy Archer RS276-1723 monolithic timer IC can be used as a square wave oscillator or variable duty cycle pulse generator. The circuits and design details are given in this short note.

The popular 555 timer IC can be connected as an oscillator, as shown in Figure 1. The capacitor C is charged by current flowing through R1 and R2 in series, and the time the output is high will be given by:

$$T1 = 0.685(R1 + R2)C \text{ seconds}$$

where the resistance is in megohms and the capacitance in microfarads.

At the end of this time, a ground is applied to pin 7 from within the device, and the capacitor is discharged through R2 in a time:

$$T2 = 0.685R2C \text{ seconds.}$$

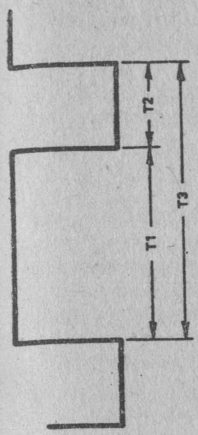
The pulse repetition time will therefore be:

$$T3 = 0.685(R1 + 2R2)C \text{ seconds.}$$

With this simple circuit, the duty cycle, or the ratio of the pulse "ON" time to repetition time will be:

$$(R1 + R2)/(R1 + 2R2).$$

The duty cycle can be set from slightly more than 50pc to nearly 100pc by a suitable choice of the values of R1 and R2. The lowest value of R2 will be determined by the maximum current that may flow into pin 7 without exceeding the dissipation rating, when it is held low during the discharge cycle.



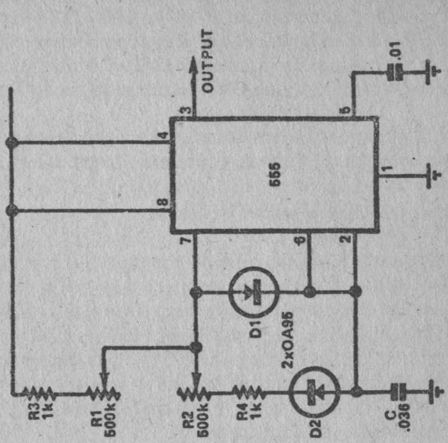


FIG. 3

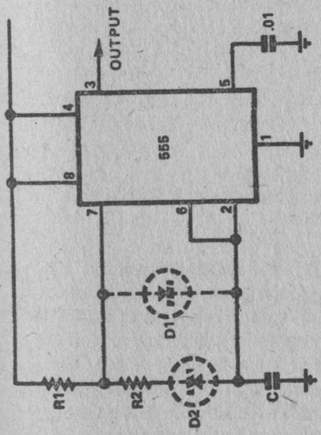

FIG. 1

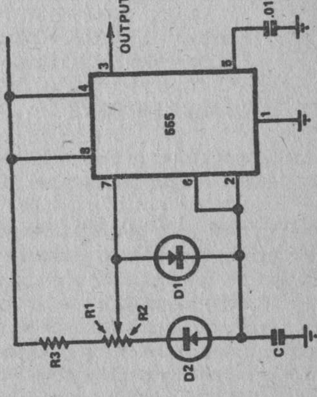

FIG. 2

The addition of the diode D1 (shown dotted) between pins 6 and 7, allows the capacitor to charge through R1 only, and discharge through R2, so the duty cycle is now R1/(R1 + R2). It can therefore be varied over almost the full range from 0 to 100pc. The charge time will not be completely independent of R2, as some current will flow through it due to the voltage drop across D1. This problem can be overcome by inserting a second diode D2 in series with the lower end of R2.

Two applications of this circuit are a fixed frequency, variable pulse width oscillator, Figure 2, and a wide range square wave generator, Figure 3.

Variable Pulse Width Oscillator

As the repetition time is set by the sum of R1 + R2, and the duty cycle by R1/(R1 + R2), the two resistors may be replaced by a potentiometer so that the duty cycle may be varied from 0 to 100pc without changing the repetition time (or frequency). R3 must be included to limit the maximum current into pin 7, and this will determine the minimum pulse width. In practice there is a small variation in the repetition rate, but this is of little importance in applications such as a pulse width control to vary the speed of a DC motor.

Wide Range Wave Generator

If R1 and R2 in Figure 1 are both varied, but remain equal in value, the repetition rate will be varied, while the output remains a square wave. A suitable circuit is shown in Figure 3. Resistor R3 is again added to limit the maximum current into pin 7, and R4 must then be included to balance its effect so that $(R1 + R3) = (R2 + R4)$.

The limits of the frequency range are given by

$$F \text{ min} = 0.73/(R1 + R3) \text{ Hz.}$$
$$F \text{ max} = 0.73/R3C \text{ Hz.}$$

and their ratio is $(R1 + R3)/R3$.

For the values shown in Figure 3, the lowest frequency is 40Hz, and the highest 20kHz, with a range of 500:1.

The output will only be a square wave if R1 and R2 track exactly. The maximum error is likely to occur if a log. potentiometer is used, to avoid crowding the frequencies at one end of the scale. This type of potentiometer is usually made with two linear segments so that it approximates a logarithmic curve and the tracking error is likely to be biggest at the crossover between the two segments. In practice, the ratio of off to on time may vary to as much as 40:60 instead of 50:50 over this part of the range. If a reasonably accurate square wave is needed over the full range, linear potentiometers will provide closer tracking.

THE DIGI DESIGNER

If you're involved with logic circuit design using digital ICs, you'll find this little unit irresistible. It provides all the basic requirements for fast and easy lash-up of new circuits, yet also doubles as a logic trainer.

A breadboarding aid of one sort or another is almost essential when one is attempting to try out even a simple circuit using the usual dual in-line ICs. Without such an aid, progress tends to be painfully slow, and the ICs and other components are likely to be damaged due to repeated lead bending and soldering operations. If you've tried it, you'll know what I mean.

In its most basic form, a digital bread-boarding aid may be little more than a scheme which allows the ICs to be plugged into sockets, with their connections brought out to convenient solder pads or terminals. But before it can be put to much use, this basic setup must be supplemented with a power supply, a source of test signals, provision for monitoring logic levels and a means of setting control signals.

With the Digi Designer, we have provided not just a basic breadboard aid, but all of these supplementary facilities as well. Although it measures only 19 x 21.6 x 10.2 cm. the Digi Designer combines a multi-device breadboard socket, a power supply, four logic level monitors with lamps, a dual-polarity clock generator with six switched frequencies, four logic level switches and two dual polarity pushbutton pulsers with bounce suppression.

It thus forms a complete miniature logic laboratory, with which you can easily and quickly lash up – and test – any number of possible circuits and logic configurations. All you need is the ICs and some lengths of hookup wire, and away you go!

Needless to say, it would also be very suitable for use as a logic trainer in schools and colleges. Provided with a few standard gate and flip-flop ICs, it can readily be used to demonstrate virtually all of the basic laws of digital logic.

Heart of the Digi Designer is a multiway breadboard socket, Based on a precision moulding of high-impact plastic, the socket provides some 328 nickel-silver spring contact clips, grouped to allow multiple connections to IC pins and other devices.

The clips are designed to provide low resistance contact with IC pins, transistor leads, component pigtails and solid-core hookup wire from 22 to 26 gauge. At the same time they require only a relatively low insertion force, which should avoid strain to multi-pin ICs and similar devices.

The fact that ordinary solid-core hookup wire may be used for the interconnections makes the unit very convenient in use. There are

DIODES : 1N914 OR 1N4148
TRANSISTORS (LESS Q3) : 2N3643

The circuit of the Digi Designer is shown above. While simple and straightforward, it provides all of the required features with no sacrifice in performance. Note the dual polarity clock generator.

no special patchcords to become lost or broken, and leads of any length may be fabricated with a minimum of effort right on the spot.

The socket is mounted centrally on the aluminium front panel of the Digi Designer, with the lamp monitors, clock generator and mains switch, pilot and fuse above it. On the lower part of the panel are the logic switches, the pushbutton pulsers and a coax socket/pin jack combination which may be used either to feed external signals into the unit, or extract signals from it.
Immediately adjacent to the breadboard socket are pin jacks supplying plus 5V and ground, also four pairs of pin jacks connected to screw terminals. The latter again provide a convenient means of interfacing the circuitry with external instruments or other Digi Designers.

The circuit of the unit regeals a very practical engineering approach to its design. Considering the functions performed, there are surprisingly few parts and the wiring is quite straightforward. In fact the Digi Designer is a good example of the all-too-often forgotten art of "getting the most from the least".
The power supply is a fairly conventional series regulator using a plastic version of the well-known 2N3055. Two normal silicon diodes are used as the reference, with a third in the feedback divider presumably for temperature compensation.

The clock generator uses three of the inverters from a 7405 IC in cascade, with a capacitor across the centre element. The capacitor value is switched to provide the six frequencies: 1, 10 and 100Hz, and 1, 10 and 100kHz. Two discrete transistors are used as output buffer stages, with a fourth inverter from the 7405 used to provide the complementary output.
The lamp indicator circuits are very simple, each comprising only a 6V/50mA lamp, an input resistor and two general purpose NPN transistors connected in the Darlington configuration.

In contrast with these, the pushbutton pulser circuits seem to reveal a BBbelt and braces" design philosophy. Each uses two gates from a 7400 IC as a simple R-S flip flop, which is normally quite capable of giving full suppression of button contact bounce. But just be sure, the designer has also fitted the inputs with R-C integrator circuits. This may not be a case of gliding the lily, though, as the SPDT buttons used are of a rather simple and rudimentary type.

Inside the case, all the components are mounted on the rear of the front panel – including the power transformer. The power supply and clock generator wiring are on a fairly large printed wiring board, while the lamp drivers and pushbutton circuits are mounted on two much smaller boards. These are supported solely by the wiring, but this should cause no problems in view of their modest size and weight.

5-STAGE LOGIC PROBE HAS 7-SEGMENT READOUT

For anyone working with logic circuits, it should be invaluable. Detecting no less than five distinct logic conditions, it indicates them simply and elegantly using a 7-segment readout.

The logic probe described is the latest in a line of probes I have constructed. Working with industrial control equipment using TTL devices I have tried most available logic probes and noted the following.

Probes including pulse stretching circuitry can be a problem as it often proves necessary to move the probe supply leads to the IC being tested, to prevent false triggering. Where stretching is included, provision to disable should also be provided.

Secondly the probe must show a large number of logic states or it will be put aside for an oscilloscope.

Finally the probe must obtain power from the circuit under test, be hand held, and have protection on the input and output against the most common forms of abuse.

The probe developed is unusual in that it will detect 5 logic states and display these on a 7-segment LED display. For details of the display and logic states covered, see Figure 1.

Pulse stretching circuitry was omitted from this device, as I use a separate probe for this form of measurement.

Input Detection

Individual detectors for the following 4 logic states are provided.

1. Short to positive (TR2 & 3)
2. True logic '1' (TR4)
3. True logic '0' (Gate B1)
4. Short to negative (TR6 & 7)

The 5th state (open circuit or incorrect logic level) is displayed if all the above states are absent.

Detecting a short to positive or a short to negative relies on a similar arrangement, and only the short to negative circuit will be detailed.

Transistors TR6 & 7 form a Schmitt-Trigger with TR6 normally in conduction. Placing the probe on a voltage less than the 50mV dropped across the 10 ohm emitter resistor, diverts base current from TR6, taking it out of saturation, bring TR7 into conduction.

The complete probe circuit. There are four detectors, two for the "short to rail" states. Circuit is fully protected.

Transistor TR5 has a dual role, normally behaving as a blocking diode, but when forward biased cancelling the base emitter drop of TR6.

To activate the Schmitt-Trigger the probe must contact a potential below 50mV with a shunt resistance less than 10 ohms.

To detect logic '1' the emitter follower TR4 drives a standard TTL input. Whereas a gate will respond to logic '1' and open circuit in a similar manner, TR4 will only follow a true logic '1'. The base emitter drop of TR4 also ensures a full logic level must occur to initiate a change of state.

Logic level '0' is taken to a standard 74 series gate input for detection. Including a diode in series with the gate reduce the '0' level accepted to the worst cas level.

Overvoltage Protection

The input probe is by-passed by a zener diode, thereby limiting the maximum voltage to reach the input detectors to 6 volt positive and 0.5 volt negative. Lamp L1 is the load for the zener, having resistance below 2 ohms in normal use, but increasing to 25 ohms with 20 volts on the probe. Fusing of the lamp takes place as the voltage increases. These components are for protection only and voltages above 5 volts should be avoided in normal operation.

Protection from reversal of the supply takes the form of a diode in series with the IC positive pin. Provided the reverse voltage does not exceed 5 volts it is not necessary to similarly protect the input detectors – indeed the short to positive detector would cease to function with diode protection.

Output Decoding

With detection of the input states completed the information enters a gate network for decoding to a form suitable for the 7-segment display. The gates determine which segment (or segments) should be illuminated for a given input. In addition, only one level must be displayed at a time.

The short to negative or positive rail is only a specialized instance of a logic '0' or '1' and hence more than one input detector will be activated by a short condition. However the gating is arranged so the short detectors override the normal logic detectors.

Four gates decode segments 'A' through 'F' while segment 'G' (open circuit indication) is controlled by TR8. The latter transistor by-passes all current from segment 'G' while any other segment is illuminated.

The display segments are driven directly from the TTL outputs, current limiting being effected by the internal level '1' gate resistance. The circuit has been arranged so that the power dissipation is divided equally between ICs A and B.

The brightness difference that should in theory result from operating certain segments in parallel while others are driven singly, is not discernible in operation.

General Information

A few points may not be clear from the foregoing description.

A short to rail value of 50mV/10 ohms was taken rather than a true short circuit. This overcomes any voltage drop on the supply lines and enables input protection to be incorporated. In practice the '0' level will always exceed 50mV and a '1' level – even in open collector applications – will be many times this value below the rail voltage.

The input loading of this device is 1UL for all conditions excepting a short to positive or negative rail. It is assumed any short to rail will pass the extra 5mA required for these detectors.

Supply current for this probe can reach 100mA, and while in most instances this will be available from the unit under test, it can be provided by a separate battery or supply. However if this is done, ensure that the negative of the extra supply is interconnected with the negative of the unit under test.

The 7-segment display legend, while being easily interpreted is also capable of being read upside down. To prevent ambiguity the top and bottom should be identified by a red dot placed adjacent to segment 'a' and a green dot placed adjacent to segment 'd'.

Construction Details

The accompanying photographs give an idea of construction used for the prototype. The components are mounted on two PC boards measuring 28mm wide by 50mm long. A miniature plastic torch case is used as a housing, requiring only the addition of a probe at the reflector end, and a hole for the 7-segment display to be viewed at the opposite end.

Approximately a metre of shielded cable is provided or the power lead, this terminating with E.Z. mini hooks or similar.

Detail of the PC boards and their assembly is given in Figures 2 and 3. Care should be taken to keep all components as close to the PC boards as possible or trouble may occur when fitting the boards into the housing. Metal can transistors will require an insulating sleeve to prevent adjacent cans shorting.

REPAIRING A CRACKED BOARD

A cracked printed wiring board may usually be repaired with a little care. If both the base and the copper are cracked, drill small holes through each run of copper, on opposite sides of the crack.

From thin tinned copper wire, make up a staple for each pair of holes. The staples should be just wide enough to bridge the two holes when the crack is closed. Make the sides of the staple fairly long.

Push the two halves of the board together, push one staple through the holes from the copper side, then gently twist the ends of the staple together on the component side, with a pair of pliers. Solder the twist, and clip off the surplus. Solder the tinned copper wire to the copper pattern. Where more than one staple is required, insert alternate staples from opposite sides.

LOW COST SCALER EXTENDS DIGITAL COUNTERS TO 200MHz

Here is a new design which should be of special interest to lab workers, mobile two-way radio technicians and VHF radio amateurs. It is easily built at low cost, and uses a state-of-the-art ECL integrated circuit to extend the range of your present DFM or counter to beyond 200MHz.

You may remember, I described our first frequency scaler to extend the range of existing digital counters. It used some of the first emitter-coupled logic (ECL) integrated circuits, which had then just been released. By using some seven of these devices I was able to achieve a maximum frequency of slightly more than 120MHz, with a division ratio of either 10:1 or 20:1 to cope with counters with maximum counting rates as low as 6MHz.

The performance of this design was considered quite good at the time, particularly in view of its modest cost, and many of the units were built up. They have been used in many research, development and teaching laboratories as well as by mobile radio technicians and VHF radio amateurs. However, integrated circuit technology is progressing at a very high rate, and it is not surprising that since the original unit was developed, higher performance devices have been produced.

This fact made itself evident some weeks ago when I was looking through literature describing some of the recently released devices. Despite the relatively short time that has elapsed since it was described, the 1969 scaler is now well and truly obsolete. Hence the reason for developing the new design described in this article.

The new scaler is completely different from the old one in terms of circuit configuration. It uses only three ICs, two transistors and five diodes – three of which are in the power supply. In terms of cost and complexity, it should be both cheaper and easier to build than its predecessor.

Yet at the same time its performance is significantly improved. The upper frequency limit is now slightly above 200MHz, thus extending well past the 144-148MHz amateur band and the upper VHF mobile radio band. The frequency division ratio is now 100:1, so that the scaler will extend to 200MHz any counter capable of counting up to 2MHz at present.

Input sensitivity is high, less than 800mV peak-to-peak input being required for reliable division up to 200MHz. Input impedance is low, approximately 50 ohms, but at VHF this is generally no problem. In most cases a small "sniffer loop" or length of wire for capacitive pickup at the end of the input cable will be quite sufficient. The input is protected from overload damage.

Output from the scaler is approximately 4.5V peak-to-peak, with a low output impedance. This should be more than adequate for all but the most insensitive counters.

Basically the scaler consists of two cascaded decade divider stages, a very high speed input stage followed by a lower speed stage. If the unit is to be used with a counter having a basic frequency capability of 20MHz or better, the second decade may be omitted, reducing the cost and simplifying the unit still further.

In this "shortened" form the scaler may easily be built into existing 70MHz frequency meters to convert them at low cost into full 200MHz instruments. This is a simple procedure, and is described later in the article.

Heart of the scaler in both its "long" and "short" versions is a new ultra-high speed ECL decade divider IC, which performs the input divider function. This device is the Fairchild Semiconductor type 95H90, for which Philips also have an equivalent, type GHJ121.

The 95H90 is a medium-scale integration (MSI) device which contains four very high speed J-K fip-flops. These use ECL circuitry and are arranged for either BCD decade counting, 10:1 frequency division, modulo-11 counting, or 11:1 frequency division. It has a guaranteed minimum input counting rate of 220MHz, and typical devices can exceed 300MHz in a suitable circuit configuration.

Here the device is used for straight 10:1 frequency division, and the simple circuit configuration tends to limit operation to about 210MHz.

The 95H90 is not a cheap device, costing around $15 plus tax. However as it needs only the addition of a few minor components to provide a full 200MHz-plus counting or divider decade, it is still significantly cheaper than any other alternative approach.

The input of the scaler connects to the input of the 95H90 via two coupling capacitors in series, with the junction of the capacitors connected to ground via inverse-parallel diodes. These protect the 95H90 against input overload damage.

A DC bias voltage is also fed to the input of the device to set the conditions for maximum input sensitivity. The bias circuit is decoupled by a ferrite bead and a small RF choke. Without these components, spurious coupling back through the supply line tends to degrade the 95H90 performance and reduce the maximum frequency of operation.

The second decade of the scaler uses TTL (transistor-transistor logic) devices: a 9001 and a 7490 or 9390 or FJJ141. The 7490 / 9390 / FJJ141 is actually a full MSI decade divider itself, but with a guaranteed maximum counting rate of 10MHz. Used alone for the second decade, it could in the worst case limit the upper frequency of the scaler to 100MHz. For this reason the input flip-flop of the device is left unused, and a type 9001 flip-flop IC used instead. With a typical maximum counting rate of 50MHz, the 9001 ensures that the upper frequency limit of the scaler is set solely by the 95H90 input device.

200MHz DIGITAL SCALER

The circuit of the scaler, which uses only three ICs and two transistors.

Because the second decade uses TTL devices whose logic levels are different from those of ECL, level translation is required between the two stages despite the operation of both from a common positive-ground 5V supply. The translator used is a simple inverter using a 2N4258 very high speed PNP switching transistor.

To prevent disturbance of the second divider decade due to output loading, a buffer stage is used between the 7490 and the output connector. The buffer uses a 2N3565, BC108 or similar general-purpose NPN silicon transistor.

Power for the scaler circuits is provided by a simple supply using a full-wave rectifier connected to a centre-tapped 12.6V transformer winding. A 400mW zener diode is used to stabilise the supply to the ICs to a nominal 5.1V. The current drain of the scaler circuits is approximately 210mA.

With the exception of the power transformer, mains switch, pilot lamp and input / output connectors, all of the scaler components and wiring are mounted on a small printed wiring for ease of assembly. The board measures 4½ x 2¾in (114 x 70mm) and is coded 72 / s10.

The prototype of the "long" version of the unit was built in a small plastic-and-aluminium instrument case,

Inside the case the printed board is attached to the rear of the front aluminium panel, via four 1¼ x ⅛in Whitworth screws with multiple nuts used for spacing. The lower two screws are also each used to fasten one side of the input and output connectors, to reduce the number of screw heads visible on the front panel. The power transformer is mounted on the bottom of the plastic case, as far to the rear as possible to provide maximum clearance between it and the wiring board.

The prototype "short" version of the scaler has been built into the original 70MHz digital frequency meter. Here it simply consists of the "front half" of the board, mounted in the DFM in place of the small board originally used to perform 2:1 input frequency division. The scaler board is simply sawn in half along a line drawn between two "notches" which have been provided for this purpose in the etched copper pattern. The notches are approximately midway along the long edges of the board.

The scaler board has been designed with its width the same as the small divider board in the original DFM, and with its mounting hole centres also the same. It is therefore a simple drop-in replacement.

Because the input gate and first counting decade of the DFM already use ECL devices, there is no need for the scaler's logic translator stage. Thus in this short form the scaler consists simply of the 95H90 device and its power supply and input biasing components. It is powered from the−5V supply already provided in the DFM for the other ECL devices.

The lower input frequency limit for reliable operation of the 95H90 device with sinewave inputs is approximately 1MHz, so that it is really not suitable for use with all input signals. However, on the other hand, the existing input shaping circuitry of the DFM is not capable of working at VHF, so that it also cannot be used with all input signals. A switch must therefore be used to connect either into circuit alternatively between the DFM input connector and the gating circuitry. The switch may logically be marked "HF-VHF".

Note that the correct position of this switch will depend purely on the frequency of the input signal, and not on the range selected. Even when one switches down to lower ranges to look at the less significant digits of a VHF signal, it is still necessary to have the switch in the "VHF" position, as the input circuitry must still handle the fill signal frequency.

On the prototype instrument, rather than add a further switch to the front panel, I merely changed the connections to the switch used originally to select either AC or DC input coupling, so that this switch has become the "HF-VHF" switch. The DC input facility had never been used since the instrument had been built, so that it is no great loss. The original coupling capacitor is simply wired permanently in series with the HF input circuitry, as shown in the small diagram.

Because the scaler involves a 10:1 input division instead of the 2:1 division used originally, the appropriate timebase frequencies for correct readings will now be 100kHz and its sub-multiples, not 50kHz and its sub-multiples. Happily these frequencies are already available on the timebase board, so that it is simply a matter of changing over the connections from the range switch wafer S1c to the timebase board. The new frequencies used are as follows:

Range (HF)	Timebase Frequency
0-1999Hz	1Hz
0-19.99kHz	10Hz
0-199.9kHz	100Hz
0-1.999MHz	1kHz
0-19.99MHz	10kHz
0-35MHz or more	100kHz

Strictly it would be necessary to divide these frequencies by ten when the input switch is in the VHF position, to compensate for the 10:1 division introduced by the scaler. However,this would involve either a further wafer on the range switch, or another 10:1 frequency divider IC. Even then it would be necessary to add further provision to reduce the lower sampling rate, as for the lowest rating the gating time would be no less than 10 seconds.

This additional complexity seems to me unwarranted, when one can easily perform a mental x10 multiplication whenever the scaler is switched into circuit. All one has to remember is that readings obtained with the input switch in the VHF position are one-tenth of their correct value; thus the lowest range really reads in units of 10Hz instead of 1Hz, for example, whil the highest range reads directly in HMz and not in units of 100kHz.

Note that the original 2:1 input divider board also included a flip-flop used to divide the lower sampling rate to 0.125Hz. This rate was necessary to allow correct operation with the 0.5Hz timebase frequency used for the lowest frequency range. As the lowest timebase frequency will now be 1Hz, this low sampling rate is no longer required. The 0.25Hz output from the input board may now be taken directly to the sampling switch, giving a lower sampling rate of 1 every four seconds.

After the scaler is completed, there is only one adjustment required to ensure that it is operating correctly. This is exactly the same for either the "long" or "short" version: adjustment of bias for maximum input sensitivity.

The best way to make the adjustment is to feed a VHF signal into the scaler input, with its output connected either to a digital counter or to an oscilloscope. Then the bias preset pot on the scaler board is simply adjusted for reliable operation with the smallest possible input voltage. As viewed on a counter, this will be evident as the bias setting at which one can reduce the amplitude of the VHF input furthest before the reading starts to fall from its correct value and being to vary randomly. On an oscilloscope, it will be the setting where the input can be reduced furthest before the output wave form begins to exhibit "drop-out". Its as simple as that!

BUILD OUR DIGI-METER: A DVM WITHOUT TEARS

Here's a basic DVM which almost anyone should be able to put together with complete success. Despite this its performance is very impressive.

Not very long ago, before integrated circuits came along, digital voltmeters or "DVMs" were large and costly instruments. Because of their cost and complexity they tended to be found only in the rarified atmosphere of the research laboratory. The idea that a DVM would ever be used for everyday measuring jobs seemed a futuristic pipe-dream; as for building a DVM into a piece of equipment as a direct replacement for a moving coil meter movement, that was virtually unthinkable!

Yet, thanks to modern semiconductor technology, and the increasingly complex ICs which it has produced at ever-lower costs, both these dreams have now become a reality. Low cost multi-range DVMs are now available for little more than the cost of a good analog multimeter, and are already being used even in servicing and hobbyist situations. Not only this but more and more original equipment manufacturers ("OEMs") are fitting single-range DVM "panel meters" into equipment in places where once they would have used moving coil movements.

The latest generation of these digital panel meters are truly impressive little devices, a tribute to modern semiconductor devices and advanced circuit design. A particularly outstanding example is the Model AD2010/E recently released by Analog Devices, Inc., of Norwood, Massachussetts.

The size of the AD2010/E is a compact 45 x 76 x 20mm, less than many moving coil movements. It weighs only 113 grams (4 ounces). Yet crammed into this compact package is a complete 3½-digit DVM with a full-scale sensitivity of 199.9mV and an accuracy of 0.05pc plus/minus 1 digit in the least significant position. It also offers such features as bright seven-segment LED readouts with 7mm-high digits, display storage, automatic polarity selection, automatic zero correction, internal overload protection, blanking of leading zeros, BCD outputs for data logging, a DC input resistance of 100 megohms, a normal-mode 50Hz hum rejection of 40dB, and a common-mode rejection of 60dB.

In short, it is a true state-of-the-art single range DVM, compressed into a little black box half the size of many conventional meter movements.

As soon as we saw the AD2010/E a few weeks ago, we wondered whether it might be possible to use it as the heart of a basic and easy to build multi-range DVM for the home constructor. When we approached Parameters with the idea, they were confident that it could be done. And so, with their help and co-operation, the Digi-Meter was born.

As you can see from the photographs and the circuit, it is essentially little more than the AD2010/E fitted into a case, with a power supply and a simple input attenuator circuit to provide four higher voltage ranges. All the real credit must go to Analog Devices! To make the instrument just that more attractive, however, we have added a simple constant-current source circuit, to provide four additional resistance ranges.

The circuit itself must surely be about as simple and as straightforward as one could get with a practical multi-range meter.

As mentioned earlier, the basic DC input resistance of the AD2010/E is 100 megohms, and its sensitivity 199.9mV. To provide the higher voltage ranges we have used an input voltage divider system similar to that in the more complex DVM. Three series-connected 3.3M resistors are switched into circuit in series with the AD2010/E input, with different shunt resistors switched directly across the input for each range.

It would not be sufficient simply to use standard close tolerance fixed resistors for the range divider shunt resistors, because the closest tolerance normally available is 1pc; this would quite seriously degrade the basic 0.05pc accuracy of the AD2010/E. Hence it is necessary to use preset adjustable pots for each range, to allow more accurate calibration. It is still desirable to use high stability resistors, if they are available, but more in the interests of stability than for close tolerance.

The advantage of the particular input attenuator system we have used is that each of the high voltage ranges may be calibrated independently; there is no adjustment interaction (apart from the internal calibration of the AD2010/E, which may be regarded as a reference). The fixed 9.9M resistance in series with the input on all the higher voltage ranges also gives additional overload protection. Note that the input resistance on the higher voltage ranges varies between about 10 and 11 megohms, which is quite suitable for most measurements.

The constant current source used for the resistance range is a simplified version of that used in the more elaborate DVM, and is also designed to operate from the same 5V DC supply used for the AD2010/E. It uses a single forward-biased 1N914 or similar silicon diode as the basic voltage reference, with a second diode-connected transistor to balance the Vbe drop of the actual current source device. Both transistors are high-gain PNP silicon devices such as the 2N3638A. Preset resistors are used again in the emitter feedback circuit, to allow accurate calibration of the four ranges. The currents for the four ranges are 1μA, 10μA, 1mA and 10mA.

The circuit is simplicity itself, thanks to the Analog Devices digital panel meter. Only a handful of other components are required for the power supply and regulator, input attenuator and current source circuit.

Provision of the decimal point selection circuit proved to be a little tricky, because the AD2010/E is designed so that all decimal point LEDs are normally "on". For its normal application as a single-range panel meter, this is no problem as the unwanted points are simply blanked by shorting the appropriate pins to the negative rail. But in the Digi-Meter we had basically only one single-pole 9-position switch section available for decimal point selection – hardly the most appropriate for the job.

After a little head-scratching we came up with the system shown on the circuit, and it seems to work quite well. Essentially we have taken each of the AD2010/E decimal point pins permanently to the negative rail via 1k resistors, and then used the switch to re-apply 5V DC to the pin of the decimal point needed for each range, via a 470-ohm protective resistor. The 1k resistors appear to be quite low enough to reliably blank the undesired LEDs, while at the same time being large enough to allow any one to be unblanked when desired.

Our prototype Digi-Meter was built up in a nominal 7 x 5 x 4 inch vinyl-covered metal instrument case. This produces a neat and professional little unit, yet involves a minimum of work. We mounted the AD2010/E directly on the front panel (it clips into a plain rectangular hole 80 x 45 mm), along with the range switch, the input terminals and a small mains on-off switch.

Most of the rest of the wiring is mounted on the rear panel, which like the front panel is also removable.

The mains cord enters the case at the lower far end of the rear panel, its entry being made via the usual grometted hole. It is clamped in the approved manner with a P-clamp, and the active and neutral wires terminated in a section of "B-B" connector strip. The earth wire is soldered to a lug screwed firmly to the metal panel, so that even when the panel and transformer are removed from the rest of the case, both remain earthed.

The only component not actually mounted on either the front or rear panels of the case is the IC voltage regulator, which is mounted on a simple heatsink bracket bent up from a scrap of 16G aluminium sheet. The bracket measures 65 x 60 x 10mm, and is mounted in the bottom of the case by two of the screws used to attach the rubber feet.

If the usual four mounting holes for a TO-3 device are drilled in the heatsink, this will suit either the LM309K device or the TO-3 to measure a voltage in a low resistance circuit, (say less than about 10k), the effect will be very small, and can generally be neglected.

For measurements in higher resistance circuits, the only way of correcting for the error produced is to first make the measurement, then

simulate the resistance of the circuit by connecting a resistor of similar value across the Digi-Meter input terminals. The residual reading produced is then subtracted from the original reading, algebraically as before, to obtain the corrected reading.

When completed and power is to be applied for the first time, it would be a wise precaution to temporarily detach the 30-pin connector from the AD2010/E until you make sure that the power supply is correctly delivering the nominal 5V. This will prevent any possible damage should a wiring error have been made.

When you have satisifed yourself that the voltage socket between pins J and N on the socket is between the acceptable limits of 4.8V and 5.2V, turn off the power temporarily and refit the 30-pin connector to the AD2010/E. Reapplying the power should then result in normal operation, with digits visible on the readout display.

The only remaining operation is that of calibration. This is a little easier than with the more complex DVM, at least in one respect: the 200mV range is already calibrated. If the full accuracy of the AD2010/E is to be retained for the other ranges, however, it will be necessary to perform a full-scale calibration using a reference instrument and a stable source of adjustable DC.

Probably few readers will be in a position to do this, so that in many cases it will be necessary to do the next best thing: calibrate the 2V and 20V ranges using a source of reasonably known voltage, and then use a few suitable voltages present in an amplifier or other piece of equipment to bring the 200V and 2kV ranges into as close agreement as possible with the lower ranges.

The most convenient source of a reasonably known voltage for most readers will probably be a new mercury cell of the type used in cameras having inbuilt cadmium sulphide exposure meters.

When new, these cells have an open-circuit terminal voltage of 1.3566V, which drops to around 1.3524V after 12 months at an average temperature of about 21 degrees C. It is therefore reasonable to assume that virtually any such cell will have an unloaded voltage of very close to 1.35V, providing it is in reasonably good condition.

Even better, a cell bought as new from a large city store, where it is likely to be fairly fresh, could be reasonably assumed to have an unloaded terminal voltage of 1.355V. Such a cell could therefore be used to calibrate the 2V and 20V ranges to better than 1 per cent.

Calibration of the resistance ranges is best done using a precision decade resistance box, if access to such a device is possible. Some readers may be fortunate enough to gain access to such a decade box at their local technical college. For those unable to do this, probably the only practical alternative is to obtain a few representative close-tolerance resistors, and use these as references.

A final note: when you use the Digi-Meter, you may notice that there will be a very small but non-zero residual reading on the 2V range for open-circuit input. Similarly there will be a more significant residual reading on the 200mV range under the same conditions. Both are normal, and are due to the small bias current drawn by the input circuit of the AD2010/E.

On the 2V range the residual reading should be so small that for most measurements it may be ignored. However, for readings where the maximum possible accuracy is desired, it is only necessary to subtract the residual reading algebraically from the reading produced for the voltage being measured, to obtain the best estimate of the true voltage.

With the 200mV range the situation is not quite so simple, because the effect of the bias current will depend upon the resistance of the circuit in which the measurement is being made. If the Digi-Meter is being used to measure a voltage in a low resistance circuit, (say less than about 10k), the effect will be very small, and can generally be neglected.

For measurements in high resistance circuits, the only way of correcting for the error produced is to first make the measurement, then simulate the resistance of the circuit by connecting a resistor of similar value across the Digi-Meter input terminals. The residual reading produced is then subtracted from the original reading, algebraically as before, to obtain the corrected reading.

BREAKDOWN VOLTAGE TESTER FOR SEMICONDUCTORS

How often have you wanted to select a transistor with especially high breakdown voltage, for a special circuit? Or picked up a zener diode, only to find its identification has rubbed off? If the answer is often, you need this easily built little tester.

Here is a handy, low cost device which should be useful in the laboratory, to servicemen, amateurs and enthusiasts alike. It is designed to make breakdown voltage tests of a non-destructive nature, on bipolar transistors, FETs, diodes (including zener diodes), and other semiconductor devices.

With this tester, such measurements as BVces, BVcer and BVceo may be made directly. If the type of transistor is unknown, PNP or NPN, this may also be determined directly. Unknown diodes may also be checked as to whether they are silicon or germanium, by virtue of the forward voltage drop, together with the reverse breakdown voltage for each device. The zener voltage may be also readily determined for zener diodes. By a little exercise of the imagination, other tests may also be made on specific components. More will be said about testing procedure later on.

Basically, the tester consists of a high voltage supply which is directed across the item to be tested, in series with a limiting resistor. Facilities are included to introduce the item to be tested into the circuit, via suitable switching. Finally, a high resistance voltmeter is provided, which is connected across the device being tested.

Contrary to what was once thought, it is possible to break down the junctions of solid state devices without causing damage, providing the actual power dissipation within the device is kept to a low value. A typical example in practice is the now common zener diode voltage regulator.

In designing a tester of this sort, a number of arbitrary and other decisions have to be made in order to arrive at a practical unit. The extent or value of the high tension voltage to be used must be considered, in the light of the actual maximum voltage breakdown of the more common devices to be tested, against the economics of generating a useful voltage. In this unit, we settled for just a little over 400V. This is easy and economical to generate, and most devices which one could reasonably consider for testing would come within this figure.

While it is essential to have a voltmeter of very high resistance to measure the breakdown voltage of the device, the accuracy of the voltage reading is not all that important, within reasonable limits. This means that the design of the voltmeter part of the circuit may contain some short cuts in order to keep costs down. More will be said about this and similar items as we go along. Meanwhule, let us have a look at the circuit of the complete instrument.

The power supply, including the 400V high tension and the +12V and −12V supplies for the IC are all obtained from one source. A small transformer with a secondary AC voltage of 150, rated at 30mA is fed into a voltage doubler, giving a total output of about 420V DC. A little over 400V of this is applied via 440k to the device to be tested. Under pre-test conditions, this resistor is shorted to ground, thus dissipating within itself just a little under 400mW.

The maximum power which can be dissipated within a device being tested, is when its breakdown voltage is half the supply voltage, and amounts to a bit less than 100mW.

In order to protect the operator against an electric shock, the 440k resistor is normally shorted to ground via a push-button switch. A socket is provided for small transistors and the three connections are duplicated on three banana sockets for large transistors and other devices. A toggle switch reverses the supply voltage to accommodate NPN and PNP devices, while a second three-position toggle switch permits switching for three different test conditions. These are – collector to emitter with base shorted, with 10k in the base and with the base open circuit.

The voltmeter is designed around the ubiquitous 741 IC. This device is itself quite cheap, and it also allows the use of a relatively cheap 0–1mA meter movement.

In order to keep the input resistance to the device high and to restrict the voltage applied to the non-inverting input, a voltage divider consisting of 22M and 22k is used. By varying the negative feedback from the output to the inverting input, the gain, and so the effective voltage read by the meter, is controlled. The meter has 900 ohms in series with its internal 100 ohms, resulting in a 0–1 volt movement. Combined with the negative feedback just mentioned, this gives the requisite voltage ranges of 10V, 100V, and 400V.

Although the amount of current delivered by the 741 IC is restricted, we considered it desirable to add some extra protection to the meter. An ordinary silicon diode, such as an EM401 or BY127 or RS276-1139 has been connected across the movement and this should prevent any overload from exceeding about six times, giving adequate protection. A 10k trimpot is connected between pins 1 and 5, to adjust the zero meter reading.

To provide the positive and negative supply voltages for the 741 IC, we have connected two 12V zener diodes in series. The junction of the diodes becomes the reference point for all measurements involving the IC. The two zener diodes are fed from the 400V supply via 60k.

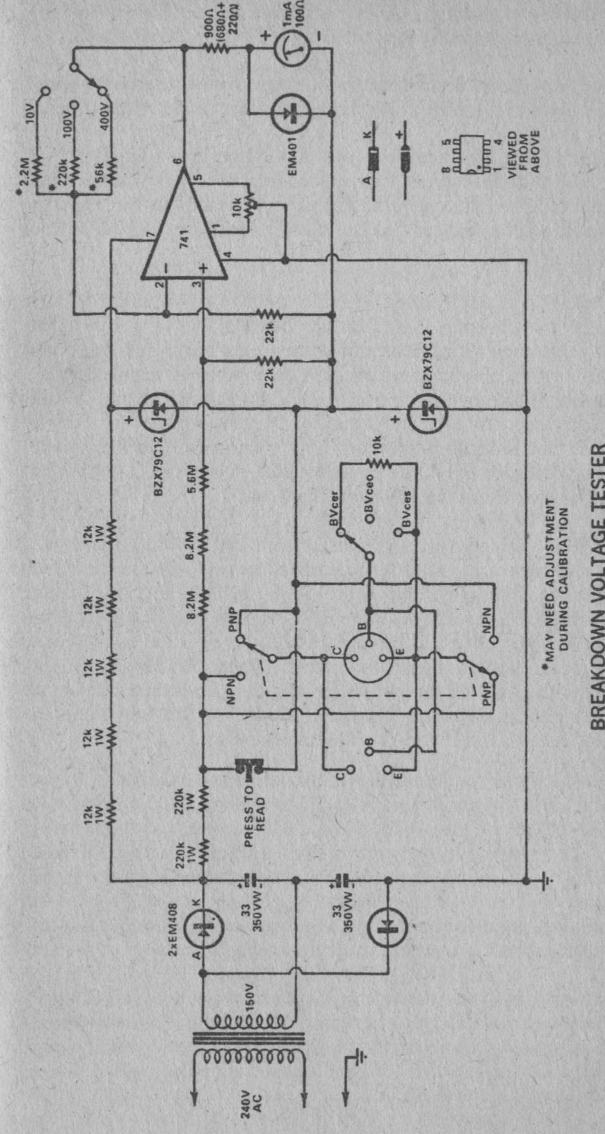
So much for the basic circuit details. A number of components need clarification and so some comments may be helpful. The power transformer which we used is a standard stock item. This transformer has a multitapped secondary but we have ignored the taps and used the full available 150V AC. There is also a 6.3V secondary winding, which we have not used. More will be said about these points under constructional details. If you wish, and another suitable type of transformer is available to you, there is no reason why it should not be used.

The 440k series resistor is made up of two 220k 1W resistors. Although one 470k 1W resistor may do the job satisfactorily, it is not desirable to put too high a voltage across any resistor, notwithstanding its power dissipation capabilities. A somewhat similar situation exists with the 60k resistance in series with the two zener diodes. Not only do we have a high voltage to cope with but the power dissipation of nearly 3 watts must also be considered. Although it is all right to apply high voltages across wire wound resistors, providing the power dissipation is adequate, such resistors are expensive and we settled for five 12k 1W units as an economy measure.

The 22M resistor at the input to the IC should be of low tolerance and perhaps the best way to achieve this end is to make up the value with two 8.2M units and a 5.6M unit, all of low tolerance, in series. Both 22k resistors should also be of low tolerance.

The 900 ohm resistance in series with the meter is made up with a 680 ohm and a 220 ohm resistor in series. These should also be low tolerance types. The 56k resistor should, according to calculations, be 55k. The three resistors involved in the voltage range selection should ideally be tailored to size during calibration of the system against a meter of known accuracy. In point of fact, we fitted a 2.7M resistor in place of the 2.2M and shunted it down until we got the required accuracy. Similarly, we used a 270k resistor, shunted down, instead of the 220k. Also, the 56k must be shunted to give a full scale reading of 400V.

Before leaving the subject of resistors, we have used the term "low tolerance". In our unit, we used 5 percent tolerance resistors where this was required and then did the final calibration with the three resistors in the feedback network, as described in the last paragraph. If you have no means of calibration, then it would be wise to use 2, or even 1 percent tolerance resistors where required and hope that this will lead to a satisfactory level of voltmeter accuracy. Although accuracy is not vital, as suggested earlier, we feel that it should be around the 5 percent mark.



The complete circuit of the breakdown voltage tester. The required range is selected by varying the feedback network.

Although the push-button switch only calls for a single pole, we used a double pole unit as this was available at the time. Also, the single-pole three-position rotary switch, was not available at the time we needed it and we substituted a double pole unit.

The 741 IC is available in a variety of packages but we chose the 8-pin DIL version as this is compact and is easy to fit into the wiring board.

We built the prototype Breakdown Voltage Tester into a plastic moulded case with aluminium front panel, and the result is a neat and compact unit. The actual physical arrangement of the tester is not critical and it may be built into some other type of box if you choose to do so.

Construction is a relatively simple matter but like any other project, it is wise to tackle it in some logical order. The majority of the components are mounted on a length of miniature wiring board and this could be done first. One operation which calls for more than usual care, is the mounting of the socket for the 741 IC. Eight small clearance holes must be accurately drilled in the board so that the socket fits neatly into these holes. The holes should be just large enough to take the pins of the socket. With this done, the pins should then be carefully wired to their terminations as indicated on the diagram.

The rest of the wiring is quite straightforward and should present no difficulties. However, as mentioned earlier, the resistors associated with the calibration of the meter should be given consideration at this stage, according to your approach to this part of the circuit. If you intend to follow our method, then a 2.7M resistors should be fitted instead of the 2.2M and a 270k resistor should replace the 220k. A 56k resistor will be fitted anyway, and all three resistors will then be shunted down after the unit is complete and ready for calibration. For the time being, omit the lead from the 220k resistor to the 8.2M resistor.

Before leaving the wiring board assembly, perhaps we should point out that the two resistors connected in series to make up 900 ohms, share one pair of tags at one end of the board. This means that the resistors are stood off the board at one end, to form a triangle, with a soldered joint at the top. Also, the centre hole in the board at this point is used for screwing the board to the case later on. The equivalent hole at the other end is also used for mounting, which means that the 33μF electrolytic must be moved to one side while mounting is done.

The transformer is then mounted on the back of the box and at an angle. The angle mounting was necessary to fit the transformer into the available space. Before fixing the board which has already been completed, leads for external terminations should be provided. These involve switching, meter leads, etc.

Mounting of the components on the metal panel should present no problems. However, if you have a transistor socket the same as ours,

the question arises how best to fix it. We drilled a hole so that the socket was just a neat fit, set it so that about half of it protruded through the panel and then put a couple of blobs of Araldite between the socket and the back of the panel.

When wiring the components on the panel, some care should be taken with the two toggle switches as these can be a little tricky. The three banana sockets are connected in parallel with the transistor socket. The protective diode is wired directly across the meter terminals. We also ran a lead from the mains earth screw on the terminal strip, to the earth point on the wiring board and continuing onto a solder lug under one of the meter fixing screws.

Having completed your Breakdown Voltage Tester, before proceeding to adjust and calibrate the unit, it is always wise to make a thorough check of the wiring, polarity of components, etc. Satisfied that all is well, set the rotor of the 10k trimpot to its mid-position. Switch on and check for obvious signs of distress.

Measure the voltage from the voltage doubler output, between it and earth. This should be about 420V. Check the voltage between earth and the other end of the two 220k resistors. With the push-button switch operating correctly, this voltage should be about 12V, which is the voltage across one of the zener diodes. A check across both zener diodes in series should give 24V.

At this point, there may be some error in the meter zero reading. This error will be a maximum with the voltage selector set to "10V". Adjust the 10k trimpot for zero reading on the meter, with the selector set to the 10V range.

To calibrate the meter, it will be necessary to have a source of variable voltages around 10V, 100V and 400V. A good multimeter is also needed to calibrate against. It does not matter in which order the voltage ranges are calibrated. Connect the negative lead of the multimeter and the negative lead of the voltage source to the junction of the two zener diodes. With the 8.2M voltmeter input resistor still isolated from the rest of the circuit, this is connected to the positive pole of the voltage source and the positive lead of the multimeter.

Set the appropriate range on the voltage selector switch, adjust the input voltage from the source, for the correct reading on the multimeter. Now proceed to shunt the appropriate resistor in the feedback network until the meter on the tester reads correctly. Solder this new resistor permanently in place. Repeat this procedure for the other two ranges and calibration is complete. Having removed the multimeter and voltage source leads from the unit, connect the 8.2M resistor to the push-button switch side of the 220k resistor. This done and with the voltage switch set to 400V, pressing the push-button should give a meter reading just exceeding full scale.

Although the use of the Breakdown Voltage Tester is more or less self-explanatory, some comments and suggestions may be helpful. The simplest devices to test are diodes in their various forms. Bipolar transistors, whether small or large, NPN or PNP, silicon or germanium, can also be tested simply and easily. Junction FETs may also be tested for BVgso.

Before making a test, always start with the voltmeter set to 400V and then if the subsequent reading is low, the range may be changed to 100V or 10V as required. After taking a reading, always reset the voltmeter to 400V.

To test any diode for its reverse breakdown voltage, or to find the operating voltage of a zener diode, connect the cathode of the diode to the collector point on the transistor socket, or the equivalent banana socket point via an alligator clip and banana plug. The anode of the diode is connected to the emitter point. Set the switch to "NPN" and press the button for the reverse breakdown voltage reading. Setting the switch to "PNP" will give the forward voltage drop, which will be about 0.6V for a silicon device and about 0.2V for a germanium device.

To test small bipolar transistors in TO18, TO5 packages, etc., they are plugged directly into the small socket provided. However, in some cases, the connections are such that they may not be plugged in directly, without bending the leads so that the right connections are made between the socket and the device. The popular BF115 is a case in point. The shield lead will be ignored, but the base and emitter leads must be reversed. Whenever there is a doubt, the appropriate manufacturers reference should be consulted.

With the device connected, the polarity switch should be set to NPN or PNP as required. Pressing the button will give the breakdown voltage readings for BVces, BVceo and BVcer, according to the position selected on the switch. In most cases, there will be little difference in readings between BVcer and BVceo. BVces will generally be somewhat higher.

If the bipolar transistor is of the larger variety and cannot be plugged into the small socket, then it may be literally hung on the three alligator clips, clipped to the appropriate connections on the transistor. Testing is then carried out as previously described.

If you wish to test any bipolar transistor for BVcbo, then this may be done by using the alligator clips, or by plugging the appropriate leads into the socket. In this case, the collector will be connected as before but the base will be connected to the emitter point and the emitter will be left open. The reading will then be taken by pressing the button and with the switch set for polarity. The three-position switch has no effect on this reading. It may be of interest to mention that this test gives virtually the same reading as BVces.

There are many occasions when the type and particularly the polarity of a transistor are unknown. If the transistor is a good one, with the polarity switch the wrong way only a very low reading will be observed. With the polarity switch correctly set, the normal voltage reading will be obtained. If the transistor is short circuited, no reading will be obtained in either polarity. If the transistor is open circuited, the full voltage reading will be obtained in both directions. By thoughtful use of the polarity and the three-position condition switches, the state of a transistor can be determined with reasonable certainty.

To test a junction FET for BVgso, connect the gate to the collector point and the source to the emitter point, with the source left open. Set the polarity switch to PNP for N-channel devices and to NPN for P-channel devices. Pressing the button gives the breakdown voltage reading.

The foregoing is just a brief run down on testing solid state devices for breakdown voltage effects. For a more in-depth treatment, readers may wish to refer to Transistor and Diode Testing in our Bernard's Book No.206 "Practical Transistor Circuits for Modern Test Equipment" on pages 80 to 96.

LOW RANGE OHMMETER

This ohmmeter fulfils a need for measurement of resistors from 0.01 ohm to over 100 ohms by comparing a resistor of unknown value with the selected 1% tolerance reference resistor. In operation the meter is zeroed by means of RV1 with the range switch set at position 2. In positions 3, 4 and 5 a voltage of almost 15mV across the reference resistor, coupled with an IC gain of 101 produces an output of about 1.5V and by adjusting RV2. the meter is set to FSD.

When connected, an unknown resistor forms a parallel circuit across the reference resistor lowering the voltage across it, thereby reducing the meter reading. Accuracy is better than 1% + or – the reference resistor tolerance. A meter having a mid-scale reading of 10 is necessary. Any VOM having this type of ohms scale could be used as the read-out by connecting the lower end of the 680 ohm resistor to 0V and connecting the VOM set at the 1V range between points X and Y.

A low range ohmmeter

EXPERIMENTAL BRIDGE TYPE OHMMETER

Here is an interesting experimental project which should appeal to beginners and advanced workers alike; a simple bridge type ohmmeter using a novel form of null indicator. The circuit would also lend itself to a wide range of other applications.

Following the description of our most recent RC Bridge there was some discussion in our laboratory concerning bridge circuits in general and the manner in which they can be modified to perform specific functions. The discussion considered in particular the various forms of null indicator available and their suitability for unskilled operators who, ideally, need an unambiguous "high" or "low" indication or, in some cases a simple "go" or "no go" indication.

Arising out of this was the circuit we are about to describe; a null indicator based on an operational amplifier IC (uA741) and a pair of light emitting diodes. Not only is it a novel circuit but, as far as we know, also an original one. More importantly, it would seem to have considerable potential in many applications, particularly those involving unskilled operators, as already mentioned.

Fig. 1 is a simplified explanatory circuit, in which the operational amplifier is being used as a comparator. If the voltage at the non-inverting input is higher than that at the inverting input, the op amp will saturate, and the output voltage will rise to a value close to that of the positive supply rail, Vcc. This will forward bias one of the light emitting diodes, which will give a visible indication, and reverse bias the other diode, which will not emit.

When this situation is reversed, and the voltage at the inverting input is higher than that at the non-inverting input, the op amp will saturate in the reverse direction, and the output voltage will fall to a value close to that of the negative supply rail, – Vcc. This will forward bias the other light emitting diode, and reverse bias the first one.

Since the op amp has a very high gain, the change-over between the two conditions will occur very rapidly and over a very small range of differential input voltages. Thus the null of the bridge will be indicated by the point at which the two LED's change from off to on and vice-versa.

To prove the circuit, we made up a simple bridge network similar to that shown on the left hand side of Fig. 1.

It consists of a 1k linear pot, a set of three standard (close tolerance) resistors, a battery, and provision to connect the unknown resistor (Rx). The 1k pot forms a pair of resistors whose ratio is variable over a wide range although, in practice, we limit this range so as to provide a practical scale. From the mid position of the moving arm, which represents a 1 to 1 ratio, we provide for an extremity of 100 to 1 in either direction.

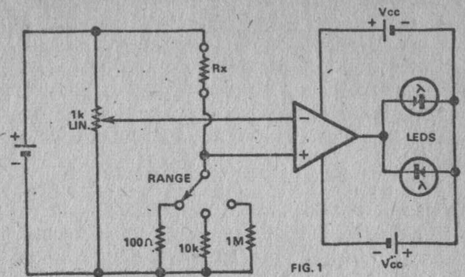

FIG. 1

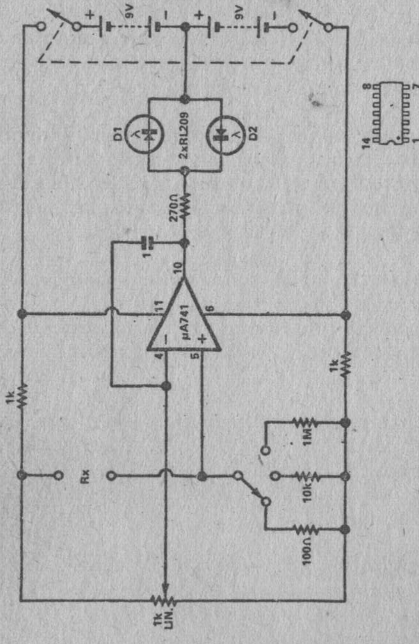
Fig. 1. Simplified diagram showing the basic bridge configuration. Note that the 1k linear pot provides two of the four resistors making up the bridge. The other two are the unknown resistor and one of the standard resistors selected by the range switch.



EXPERIMENTAL OP. AMP. BRIDGE

FIG. 2

Fig. 2. The circuit as finally developed. The bridge circuit remains essentially the same, except for the addition of two 1k current limiting resistors. The one battery pack, supplying 9V each side of a centre tap, serves both the bridge and the IC.

The three standard resistors are 100 ohms, 10k and 1M. In conjunction with the pot movement just discussed, this gives a range of measurement from at least 10 ohms to 10M, beyond this with some limitations, and with useful overlap between ranges.

After ironing out a few minor problems we came up with a circuit which we feel is worth passing on to readers. As presented it is a simple battery operated bridge, using relatively few low cost components, but capable of quite useful accuracy. It would seem to be an ideal project for YRCS groups or similar organisations.

Alternatively, by using closer tolerance components, it can be upgraded to provide a much higher order of accuracy, but at some increase in cost. And for the really keen experimental types there is an almost unlimited scope for its exploitation in automatic control circuits.

The practical circuit is shown in Fig. 2, and is worth discussing in some detail. The 741 op amp requires nominal voltages of plus and minus 15, but it will work quite satisfactorily for our purpose from voltages as low as plus and minus six. Since 9V batteries are readily available in convenient sizes, we elected to use two of these.

This gives us a total of 18V, which also becomes the power supply for the bridge. The latter should be as high as possible when high value resistors are being measured, otherwise current due to thermal noise in the resistors may be comparable with the current due to the supply.

On the other hand, a high supply voltage causes problems when low values of resistance are being measured, as the battery drain increases enormously. To avoid this, limiting resistors are connected in series with the bridge. To keep the input voltages to the op amp centered about zero, equal value resistors are fitted at the top and bottom of the bridge.

These resistors also limit the current to the op amp inputs, so that it is not necessary to provide separate input resistors. A protective resistor is required for the LEDs, to keep the forward current within the maximum allowable. Because the two diodes are back to back it is not possible to exceed their reverse voltage rating.

When the prototype was constructed, some trouble was experienced with oscillation at the null point. This took the form of cycling between the LEDs, which made both LEDs appear to be on at the same time. This was prevented by using a 1uF capacitor to provide negative feedback from the output to the inverting input.

In order to prevent oscillation if the wiper arm of the pot should become dirty and go open circuit, it is necessary that the wiper arm be connected to the inverting input, and not the non-inverting input.

The circuit does have one minor disadvantage. Because the null indicator operates from the same supply as the bridge, and because there will be some leakage between the op amp input terminals and the supply rails, there will be some error introduced into the null indication at higher resistance values. In practice this is insignificant up to about 10M, which should be regarded as the upper limit for accurate measurement.

The only close tolerance components are the three standard resistors. We used 1% types but, if these are not available, it may be possible to trim 5 or even 10% types to the correct values. To ensure stability with respect to temperature, only good quality components should be used.

We constructed our unit on a panel measuring 111mm x 161mm, which happened to suit a box we had on hand, Since the size of the panel and the type of box is not critical, we suggest that the reader make his own choice in this regard, possibly using something which is on hand.

A good idea of the panel layout and general assembly can be obtained from the photographs. The pot is in the top centre of the panel and the two switches and the unknown resistor terminals at the bottom. The LEDs we used fit neatly into a 1/8in hole and we mounted them at the top of the panel, about 20mm apart, where they are easily seen.

The only other piece of metal work is a simple battery clamp made from a scrap of aluminium. It is roughly "U" shape, but with wings extending outwards from the uprights of the "U". One 9V cell is held under each of these wings, but they also support a piece of veroboard on which is mounted the IC and other minor components. The bracket and the veroboard are clearly visible in the photograph. The bracket is fastened to the front panel by the pot, avoiding the need for unsightly screws.

We mounted the three standard resistors on the back of the single pole three position range switch. It was necessary to add a dummy terminal to the switch, to provide the common point for the resistors, by attaching a solder lug to a spare hole fortunately provided. Alternatively, there is ample room to mount the resistors on the veroboard with the remainder of the components, although this will entail running more wires to the switch.

The 741IC we used was in a 14 pin dual-in-line package. These devices are also available in an 8 pin dual-in-line package and in an 8 lead metal can. All are suitable for use in the bridge. We used veroboard with the correct hole spacing to suit the dual-in-line package.

In order to reduce the height needed for the op amp, we mounted it directly on the veroboard. As only pins 4, 5, 6, 10 and 11 are used, we did not solder the remaining pins to the veroboard. This makes it easier to remove the op amp if necessary. Take care not to damage the IC while it is being soldered, due to excess heat. It is a good idea to leave it to the last to solder in.

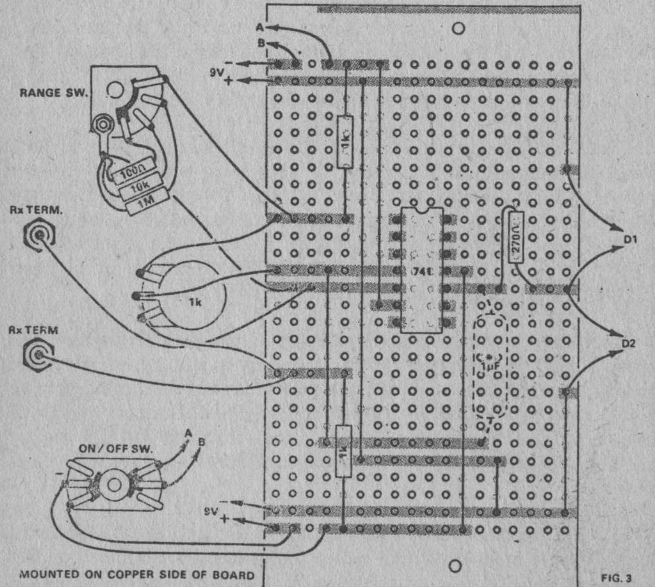


FIG. 3

Fig. 3. Wiring diagram showing the general layout of components and the pattern of the Veroboard. Layout is not critical and almost any other physical arrangement would be acceptable. All components mount on the panel, simplifying the choice of a box.

As shown in the photographs, the IC and the remaining three resistors are mounted on top of the veroboard. The LED's and the 1uF capacitor are mounted underneath. This saves space, in the case of the capacitor, and enables the LED's to fit into their mounting holes in the front panel. The veroboard is attached to the battery mounting clamp using two self-tapping screws and some washers for spacers. Leave sufficient clearance under the board to avoid shorts to the battery case.

We chose to polarise the unknown resistor terminals by selecting one red and one black. While resistors are not normally polarised, the bridge may be used in other applications, such as checking the forward and reverse leakage of a diode. The red terminal should indicate positive.

We used pointer knobs for the two rotary switches and a larger round knob for the potentiometer. To this we added a clear plastic pointer, fastened to the bottom of the knob with a strong epoxy glue. Make sure that the line on the pointer is truly radial and in line with any lines or arrows already on the knob.

Finally, there is the matter of a scale. In the case of previous bridge projects we have been able to publish a calibrated scale and supply details to any firms wishing to supply etched labels. We are deliberately avoiding this approach on this occasion for a number of reasons.

Such a scale is valid only if the pot used by the builder is identical with that used in the prototype. This means, in practice, nothing less than a wire wound type of the same make and model. Unfortunately, wire wound pots are quite expensive and, to keep the cost down in what is, after all, mainly an experimental project, we used a linear carbon pot, which is a good deal cheaper.

Unfortunately, carbon pots, as a class, introduce two unwanted variables. They are not necessarily as linear as the wire wound type, even from unit to unit of the same model, and the angle of rotation varies from make to make. Thus, a scale prepared for brand "A" will not necessarily suit brand "B". But the linearity is another matter.

Because of these variables, the best approach is to make one's own scale; an interesting exercise in its own right. There are two approaches. One is direct calibration against a large number of close tolerance resistors, ideally one for each calibration mark.

The other is direct calibration of only two points, one at each extremity of the scale, and all other points by calculation on the assumption that the pot is linear.

Obviously the first would be the more accurate, but is seldom practical. The second is more practical, but leaves the accuracy at the mercy of the pot linearity. We used the second method.

For this method we require three close tolerance resistors, 1k, 10k and 100k, a protractor, and ordinary drawing instruments. The first job is to determine the angle between two selected values near the extremities of the pot rotation. Place a scrap of paper on the panel where the scale will finally fit and secure it with sticky tape. Fit the pointer so that it swings approximately evenly each side of centre. This setting is not critical at this stage.

Set the range switch to 10k and note the positions at which the 1k and 100k resistors are nulled. The 1k should null near the furthest anti-clockwise position, and the 100k near the furthest clockwise position. If these positions are reversed, reverse the outside connections to the pot.

Remove the pointer and the piece of paper and, with the protractor, measure the angle between the two marked points. This will be easier if the centre of the pot can be marked, using lines at right angles, before the paper is removed from under the pointer. The angle should be about 200 degrees.

Let us call this angle W. Then, if s is the fraction or multiple of 1 by which the standard has to be multiplied, and p is the angle in degrees that actually corresponds to this value of s, we can say $p = 0.611 \times W \times (s-1) / (s+1)$. This formula enables the values of p to be calculated from the values of s. The angle p is measured from the vertical, which corresponds to the position $s = 1$, $p = 0$. The angles are measured positive clockwise and negative anti-clockwise.

As an example, we have calculated the angle at which the scale marking "0.5" would be placed. We have taken the measured value W as 200.

$p = 0.611 \times 200 \times (0.5-1) / (0.5 + 1)$

$p = 122.2 \times (0.5-1) / (0.5 + 1)$

$p = 122.2 \times (-0.5) / (1.5)$

$p = 122.2 \times (-0.333)$

$p = -40.74$ degrees

This means that the scale point marked "0.5" should be positioned 40.74 degrees anti-clockwise from the centre of the scale.

These calculations will be much easier if a slide-rule or a calculator can be used, as well as being much less prone to error.

Once the values for the scale have been obtained, the scale can be drawn on a suitable piece of white card. We made the scale with a diameter of 80mm, the major graduations 6mm long, and the minor graduations 3mm long, using India ink. Black ball point pen would provide an acceptable substitute for ink. We used rub-on lettering to mark the major points on the scale and also to label the functions of the rotary switches.

When the scale is finished, suitable cutouts must be made for the pot and switch shafts, the LED's and the terminals. With the scale fitted, the pointer can be attached to the pot shaft, and correctly aligned with the scale. This is done using the 10k close tolerance resistor, with the range switch on the 10k range. The pointer should be attached to the shaft so that when the bridge is balanced, the pointer reads 1.0. Provided there are no serious linearity errors in the pot, the scale should then be accurately calibrated for all ranges.

Care should be exercised in regard to battery life. The current consumption is highest on the lowest resistance range, and unlike an ohm-meter, current is consumed even when the unknown terminals are open circuit. Fortunately, the LED's give a visible indication that the power has been left on. Otherwise, due to the intermittent nature of the current drain, battery life should be quite long.

A SYNCHRONOUS GATING UNIT FOR AF TONE-BURST TESTING

A fully solid-state instrument which produces synchronously grated AF tone bursts suitable for a wide variety of audio measurements. The use of integrated microcircuits gives the instrument a standard of performance comparable with quite costly commercial units, despite the fact that it is easily constructed at low cost.

Although at first sight the instrument described in this article might appear to be suitable only for a few specialised and somewhat esoteric applications, this is not the case. In fact it has many uses, of which probably the most practical and straightforward is the measurement of short-term or "dynamic" power output capability of audio power amplifiers.

Other direct uses include testing of amplifier stability, measurement of loudspeaker system response and damping, measurement of room and auditorium acoustics, measurement of the performance of filters and automatic gain and level control circuits, sonar equipment testing, and psychometric research and testing. The instrument may also be used to produce sound effects for live theatre and motion pictures, and in the production of electronic music.

In addition it may be used directly or indirectly as a signal shaper-squarer, a wide-range binary scaler-frequency divider, or a synchronous digital gate controller suitable for counting, frequency and time measurement, or clock word generation.

In view of the likely interest in the use of tone-bursts to measure the short-term power output capability of audio amplifiers, a brief discussion of this application will now be presented by way of a preamble to the description of the instrument itself. It is hoped that the discussion will be found of value not only to those who may contemplate construction of the instrument but also to those who wish solely to gain a theoretical knowledge of this relatively recently evolved technique.

It is commonly found that the maximum power output which may be obtained from an audio power amplifier, before discernible waveform clipping or other distortion is incurred, depends significantly upon the period of time over which the power is to be delivered. Generally, the shorter the period involved the higher the power which may be delivered —althouth this simple relationship will naturally be limited by transformer losses and other effects influencing the power frequency response.

Thus the maximum power output delivered by a power amplifier when tested under continuous sinewave conditions may often be significantly less than that which it is capable of delivering during the short and relatively infrequent amplitude peaks present in typical musical programme material. Hence for the many audio amplifiers

Specification

A synchronous analog gating unit which may be used to derive pedestal-free bursts of input signals between 10Hz and 60KHz. The integral number of cycles in each burst and the burst repetition rate may be adjusted independently, or locked if desired. The instrument is fully solid-state and employs low-cost RTL digital microcircuits. It may also be used as a signal shaper-squarer, a scaler frequency-divider or a synchronous digital gate controller.

ANALOG INPUT:
Frequency Response: 10Hz—60KHz.
Minimum Input: Less than 150mV RMS.
Maximum Input: Greater than 600mV RMS.
Switching Ratio: Better than 40dB.
Insertion Loss (gate open): Less than 6dB minimum.
Switching Transients: Less than 30mV P-P.
Input Impedance: Approximately 33K.
Output Impedance: Maximum 6K, minimum 500 ohms.
T.H. Distortion (gate open): Less than 0.2% at 250mV RMS input.
Gate offset or pedestal: Negligible.

BURST LENGTH: Adjustable to 1, 2, 4, 8, 16 or 32 cycles; also continuous.

BURST REPETITION RATE: Internal trigger generator provides a range of approx. 3Hz—500Hz. Single bursts triggered manually by panel push-button. External triggering by +3V pulse, duration less than 20uS. Inter-burst interval may also be locked to equal the burst length.

SYNC OUTPUT: Rectangular waveform with level 0V when gate is closed and +3V when gate is open.

intended to handle musical signals rather than sinewaves, a conventional power output rating based upon continuous sinewave measurement may be both unduly conservative and of only incidental relevance, despite the relative ease and high order of objectivity with which the measurement may be made.

Aware of the limitations of a continuous sinewave power rating when used alone as a performance criterion applied to their products, manufacturers of high fidelity amplifiers some time ago adopted other rating methods which have been employed either as supplements to the basic continuous sinewave rating, or as substitutes for it.

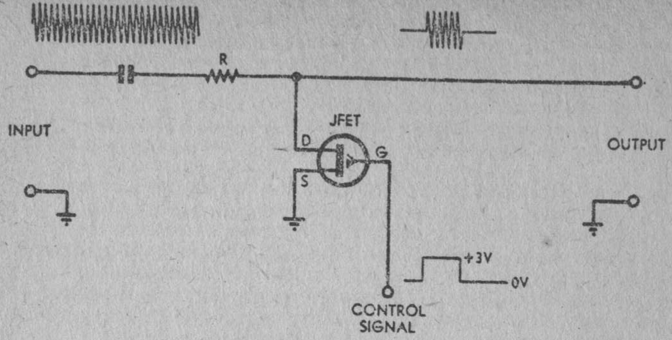
It is undoubtedly true that academic purism was by no means the sole motivation behind the adoption of these other–usually more flattering–rating methods. It is also true that some of the rating methods adopted were and still are, of dubious technical value. However, it is neither appropriate not possible in the present article either to discuss in detail the various rating systems or to examine the motivation behind their introduction. Sufficient to say that one of these ratings, the so-called "music power" rating, was introduced in an effort to provide a measure of the actual power output capability of an amplifier when reproducing a musical programme.

Unfortunately while such a rating is easily proposed and validly justified, the measurement ideally required is not at all simple or straightforward in execution. The basically statistical nature of musical signals itself produces both theoretical and practical problems when one attempts to measure the power level involved, quite apart from the perhaps more obvious difficulty in selecting the "typical" musical programme to be used as a basis for inter-amplifier comparison.

The method originally adopted for "music power" measurements bypassed these problems altogether, by making a convenient and usually fairly valid assumption regarding the cause of the diminished power output capability of an amplifier when tested under sinewave conditions. The assumption was that the diminished power output was due solely to imperfect power supply voltage regulation under the steady drain of continuous operation at maximum power output.

The converse corollary of the assumption was that under the transient conditions of a musical programme the power supply was sufficient to cope with the relatively infrequent demands for full power, and was therefore able to maintain supply voltages at their full amplitude. Hence in order to measure the "music power" output capability of an amplifier, it was reasoned, it was not necessary to attempt to take measurements under actual musical conditions but simply necessary to take a "normal" continuous sinewave measurement with the amplifier supply voltages maintained at their full amplitude to duplicate the situation prevailing during brief musical peaks.

Consequently an established technique for the measurement of amplifier "music power" is to substitute for the internal amplifier power supply an external heavy-duty regulated supply–delivering the same voltages–and to measure the maximum continuous sinewave output under these artificial conditions.



(a) BASIC JFET SHUNT ANALOG GATE

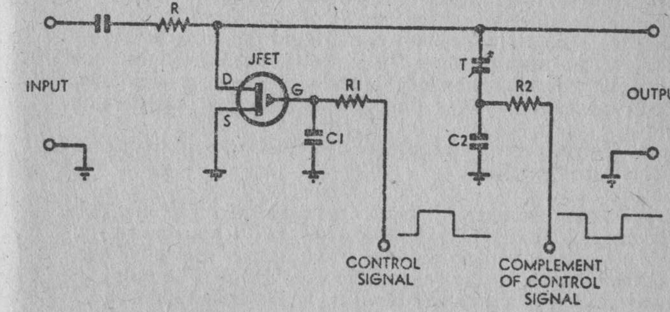


Fig. 2 (b) MODIFIED ANALOG GATE WITH TRANSIENT SUPPRESSION

Although this technique is widely used it is not without its critics. Many are not happy about the assumptions involved, and are dubious about the validity of simply equating sinewave conditions with a substitute power supply to transient conditions with an amplifier's actual power supply. Quite apart from such criticisms there is the practical inconvenience involved in matching a substitute regulated supply to an amplifier and connecting it in circuit for the testing.

Fortunately an alternative approach exists, and one which is not only more valid theoretically but also more convenient in practice. The method involves testing using short bursts of sinewaves delivered to the amplifier from an instrument such as that to be described, with the amplifier itself unaltered and powered from its own internal supply. The "tone bursts" used are quite easily arranged to have a duration and repetition rate which effectively duplicates infrequent musical programme peaks, while their relatively simple and basic nature makes them both easily reproduceable and also more readily measured than a musical signal.

It should be noted that a tone burst power output measurement does not really give the information originally signified by the term "music power"–nor, for that matter, does a measurement made using the "substitute power supply" method. Both methods give essentially the absolute maximum power output capability of an amplifier, under short-term conditions; and this is not strictly equivalent to the somewhat vague notion of "music power output".

Probably the most accurate way of visualising the situation is to regard the "music power" capability of an amplifier as a dynamic or variable parameter which depends at any instant upon the immediately preceding amplifier conditions, and which accordingly varies over a range defined at its lower limit by the normal continuous sinewave output rating and at its upper limit by the normal continuous sinewave output rating and at its upper limit by the rating provided by a tone-burst or "substitute supply" measurement.

Late in 1965 the American Institute of High Fidelity published a revised version of their earlier "IHF Amplifier Standard" rating system, in which they advocated the use of the term "dynamic power rating" to signify the short-term output power capability of an amplifier, replacing the term "music power rating". The method suggested for the measurement of dynamic power rating was the tone-burst method, using bursts of 10mS suration at a low reception rate.

Let us now turn to the instrument to be described, considering first its principle of operation.

The input signal to be gated is fed to both an analog gate and to a shaper-squarer. The latter derives from the signal a squarewave equivalent having extremely fast rise- and fall-times corresponding to the zero crossings of the original signal waveform. The output of the squarer is fed to a group of flip-flops which are arranged in "toggling" mode and connected in cascade to form a binary scaler or frequency divider.

A six-position switch (S1) is arranged to select either the direct output from the squarer or the scaled-down signal from a chosen scaler stage. The selected signal from the switch is then passed to an AND logic gate whose second input is controlled by a simple set-reset state and thus holds the AND gate closed; thus the signal selected by the switch cannot progress further.

The "set" (S) input of the control flip-flop is connected to a second switch (S2) which may be used to select the desired source of burst triggering signals. There are two triggering sources internal to the instrument, one a free-running "sampling oscillator" of adjustable frequency–for repetitive operation–and the other a manual on-off circuit operated by a front-panel push-button. A third position of the switch allows the use of external triggering sources.

On the arrival of a triggering pulse at its S input, the control flip-flop switches to its set state and accordingly opens the control AND gate. This excursion from the signal selected by S1 to pass through the gate and reach the "toggle" (T) input of a second flip-flop, which is a J-K type whose output controls the analog gate.

Under quiescent conditions this "main gate" flip-flop is in the reset state, and accordingly the analog gate is closed. The analog (tone) input signal is therefore prevented from reaching the output terminal. However, the arrival of the first toggling edge from the control gate switches the main gate flip-flop into the set state, and the gate is immediately opened to pass the tone signal.

The period of time for which the gate remains open depends upon the setting of switch S1, because the second toggling edge to reach the main gate flip-flop via the control gate will cause the former to be reset once more–closing the analog gate with it. And depending upon the setting of switch S1, this turn-off edge will correspond to the end of a single tone cycle, or two cycles, or four, eight, sixteen, or thirty-two. Hence the analog gate will have been open for a period which accurately corresponds to an integral number of tone cycles, and a "burst" of the desired number of tone cycles will have been passed to the output terminal.

In order to prevent further opening and closing of the analog gate due to the arrival of further toggling edges at the main flip-flop (from S1), a pulse derived from the main gate output is used to reset the control gate flip-flop immediately following the resetting of the main gate flip-flop. This closes the control gate and prevents further signals from reaching the main gate flip-flop from S1. Both flip-flops thus remain reset, and the analog gate remains closed, until the arrival of another triggering pulse from S2.

From the foregoing it should be apparent that it is the triggering pulses, supplied to the control gate flip-flop from S2, which initiate each tone burst; while the duration of each burst is governed by the tone-derived signal selected by S1. The burst repetition rate and the burst duration may therefore be adjusted independently.

Before turning to consider the full circuit diagram of the new instrument it may be worthwhile to look briefly at the operation of the analog gate circuit employed.

A number of circuits have been developed for this purpose; however, the circuit which has been selected in the present instance employs a p-channel junction field-effect transistor (JFET) as a voltage-controlled shunt switch. Its basic operation is shown in the diagram of figure 2(a).

As may be seen the gate circuit proper consists simply of a series input isolating resistor R and the JFET, whose drain-source channel is connected between the output terminal and ground. The effective drain-source resistance of the JFET is controlled by means of a control signal applied to the gate electrode.

When the control voltage is at zero, there is no applied transverse electric field in the JFET channel. Accordingly the drain-source is low–a few hundred ohms–and the input signal suffers heavy attenuation as a result of the divider action produced by resistor R. Under these conditions the gate is effectively "closed".

AF TONE BURST GATE

When the gate is taken positive, however, the reverse bias applied to the gate-channel junctions of the JFET produces a transverse field which "pinches off" the channel. The drain-source resistance rises to a very high value, and the input signal therefore appears at the output terminal suffering only slight attenuation. The gate under these conditions is effectively "open".

The switching action of this type of analog gate is free from many of the problems associated with other circuits. Because the drain-source channel requires no DC bias, and furthermore acts over a fairly wide signal amplitude range as an almost perfectly linear resistor (of controllable value), there is virtually no DC offset component or "pedestal" associated with resultant tone bursts.

The available channel resistance range is quite wide, even with moderate control voltages, giving the gate a high "on" to "off" ratio combined with a low insertion loss in the "on" state. Hence the gate circuit used in the final instrument exhibits an on-off switching ratio of more than 40dB, with an insertion loss of only about 5dB.

The shunt JFET gate is also capable of switching at a high speed although the operation at high speeds is complicated by inter-electrode capacitances. Drain-source capacitance tends to increase the insertion loss and reduce the switching ratio at high signal frequencies, while gate-source capacitance tends to slow down the rise and fall of the gate control voltage. However, more troublesome than both of these is gate-drain capacitance, which tends to feed control signal energy into the signal circuit.

The effect of the latter is that sharply differentiated switching "spikes" tend to appear across the analog output terminals. A large positive spike appears as the gate opens, and a smaller and narrower negative spike as the gate closes. The differences in amplitude and duration arise as a result of the differing dynamic R and C situations present in the JFET for turn-off and turn-on. As the spikes represent spurious gate output or "noise", it is important that they be suppressed.

A number of suppression techniques may be used. However, the method which has been adopted in the present instrument is shown in the diagram of figure 2(b). A two-step process, it works partly by slowing down the attack and decay of the JFET gate control signal by means of the low-pass filter formed by resistor R1 and capacitor C1. This reduces the charge stored in the JFET gate-drain capacitance, by reducing the rate of change of voltage. (The reduced switching speed is still high relative to the analogue signals being switched, so that the gate operation is not impaired.)

The second step involves cancellation or nulling the remaining spikes, in effect by injecting into the analog circuit spikes of opposite polarity. This is performed by an adjustable trimmer capacitor T which is connected to a source of signal complementary to the JFET control signal. A second low-pass filter comprising R2 and C2 is used to adjust the attack and decay of the nulling signal to correspond with the JFET gate signal.

At a critical adjustment of the trimmer the net charge transfer to or from the analog circuit during gate opening and closure is reduced to a very low level. The tone bursts produced by the gate are then quite "clean".

Reference to the main circuit diagram of the complete instrument will show that many of the logical functions are performed by integrated digital microcircuits. Six such devices are used, five of which are in the "dual in-line" encapsulation while the remaining device is of the TO-5 eight-lead type. All six devices are of the economy plastic RTL type, the dual in-line devices being from the Motorola Semiconductors' MC700P range and the TO-5 device from the Fairchild Semiconductor FuL900 range.

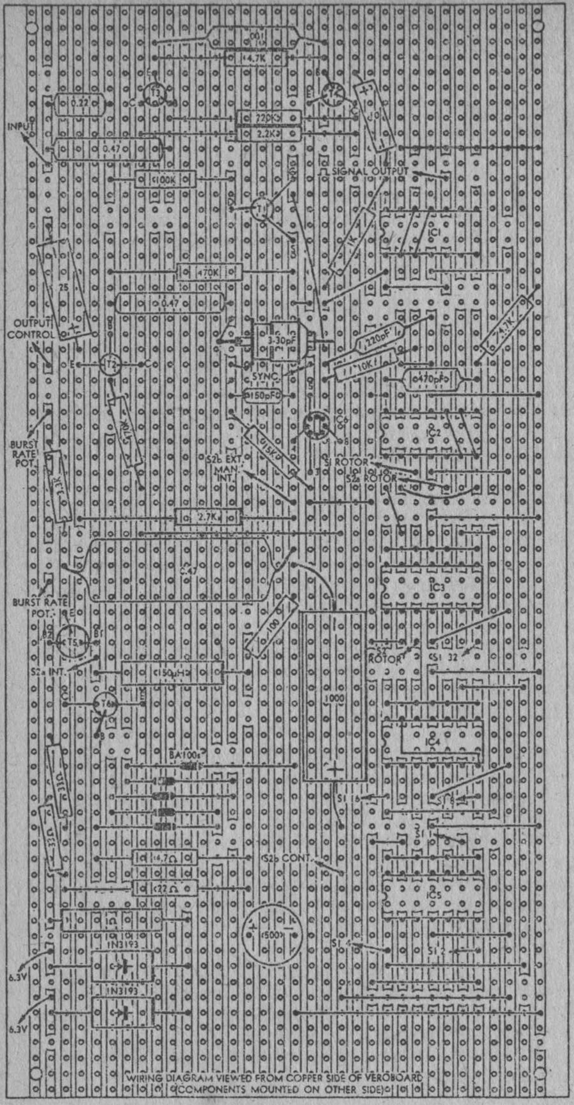
The cost of these devices is quite modest when one considers the number of discrete components which would be required to perform the same functions—if one includes the functionally identifiable devices within the microcircuits, for example, the total transistor count for the complete tone-burst gate is greater than 90! From this figure it may also be deduced that, quite apart from the cost advantage, the use of microcircuits simplifies quite drastically the construction of the instrument.

The shaping-squaring function of the instrument is performed by transistors T3 and T4 together with IC1, which is an MC724P quadruple 2-input gate. The transistors are employed in a simple input preamplifier circuit having a moderately high input impedance. Output from T4 is coupled to gate A of IC1, and the output of this gate in turn feeds to gate B. Both gates are used simply as squarer/inverters, with a small amount of positive feedback from B's output back to A's input via a 1K resistor to improve input sensitivity. The two remaining gates of IC1 are connected in cascade from the output of B, to give additional squaring; the output from gate D accordingly has quite short rise–and fall–times.

Although in the simplified instrument block diagram of figure 1 the output of the shaper-squarer block is taken directly to the scaler and selector switch, in the instrument itself this connection is made by means of a small slider switch mounted on the rear of the case. In addition both the shaper output and the scaler-selector input are made available at adjacent coaxial connectors. This allows the internal connection between the two to be broken at will, and external arrangements made either for use of the squared signal and/or for use of substitute gating signals.

As a result of this simple and inexpensive refinement not only is the instrument made more flexible in terms of its main function, but it is also rendered capable of performing additional functions. Thus the squarer section becomes available for external use, as does the scaler section. Use of the latter section as an external scaler/frequency divider will be discussed further shortly.

The scaler section itself consists of five binary J-K flip-flops, each of which is half an MC790P microcircuit. Devices IC4 and IC5 provide four of the flip-flops, while the fifth is the element in IC3, remote



This diagram of the wiring board for the tone-burst gate shows the interconnections and most of the minor components.

from the indexing notch (pins 5-10). Each flip-flop has both J and K gating inputs taken to "1" (ground) to ensure simple toggling mode operation. As before switch S1 is used to select the desired gating signal, the switch being labelled "burst length".

The control gate function is performed by gate B of IC2, which is a second MC724P quadruple gate device. Gates C and D of this device form the control gate flip-flop, being interconnected in the usual manner to form a simple S-R flip-flop. Switch S2a forms the triggering selector as before, with positions for internal, manual and external triggering modes. Note, however, that the switch has an additional fourth position, in which no triggering input is admitted; the position is a "gate continuously open" mode, provided for setting-up purposes, and will be discussed further in a moment.

The internal triggering generator is a simple relaxation oscillator circuit, employing an economy unijunction transistor type 2N2646, or similar and whose frequency may be adjested over the approximate range 3-500Hz. A small inductor is employed in the unijunction B1 circuit to sharpen the output pulse waveform, as a sharp pulse of less than 20uS duration is necessary to preclude the appearance of spurious secondary bursts at high signal frequencies.

The "Manual" triggering circuit consists simply of a panel push-button together with a low-value differentiating capacitor and discharging resistor. The design of the triggering circuitry is such that contact bounce has virtually negligible effect upon instrument operation; however, it is wise to employ a high quality push-button, preferably one with a rapid-acting "micro-switch" movement.

The external triggering input will accept signals varying between OV and +3V relative to groond, with the +3V level corresponding to logical "1". For normal operation, in which the burst length gating is synchronous but the repetition rate is not, the triggering signal should consist of sharp pulses with a duration of less than 20uS.

If it is desired, locked burst operation may be obtained quite simply by merely connecting a source of +3V DC to the external triggering input—with S2 in the appropriate position, of course. When this is done the control gate flip-flop is clamped in the set position and prevented from resetting on the arrival of the "lock-off" pulse from the main gate flip-flop at the end of each burst. The instrument thus produces a continuous series of bursts spaced such that the inter-burst interval is automatically equal to the burst duration.

A +3V DC signal connected to the external triggering input is also used when it is required to use the scaler section of the instrument for external scaling or frequency division.

The main gate flip-flop function is performed by the second element of IC3, again a J-K element connected for simple toggling mode operation. As the output voltage swing from this element is inadequate for direct operation of the analog gate, it is passed through gate A of IC2 for amplification and incidental inversion. The direct flip-flop output is also differentiated to produce the control gate flip-flop "lock-off" signal. Additionally it is used to derive the analog gate transient suppression signal, and also to provide an oscilloscope synchronising signal via IC6. The latter device is employed as an isolating buffer-inverter, and accordingly delivers a +3V rectangular signal corresponding to the "open" state of the analog gate.

It is the IC6 "sync" output connector which may be used as the output of the scale section of the instrument when the latter is required for external use. With the signal to be scaled or divided applied to the "Ext T.B." input connector, the slider switch in the "Ext" position, and +3V DC applied to the external triggering input, the selector switch S1 may be used to adjust the scaling ratio over the binary range from 1:2 to 1:64. Note that when the instrument is used in this way the main gate control flip-flop is used as a sixth scaler stage.

As mentioned earlier there is a fourth position of the "mode" switch S2, in which the analog gate is kept "open" continuously to permit setting-up of auxiliary equipment. To provide this mode of operation a second pole of S2 is used to apply +3.6V to the "reset" input of the main gate flip-flop, holding the latter locked in the reset state. As output is taken from the Y-complement output of the flip-flop rather than from the Y output, this results in the analog gate being locked in the "open" condition.

The analog gate of the instrument is of identical form to that already discussed and illustrated in figure 2. It employs a P-channel economy silicon JFET type 2N4360 or similar, and as a result of the relatively modest demands made by this mode of operation, most such devices should work satisfactorily despite the wide spread in parameters. A small proportion of devices may prove unsuitable by virtue of unduly low gain or channel resistance, but these should be sufficiently rare to make replacement an economic proposition.

In order to achieve maximum switching ratio combined with minimum insertion loss, an emitter follower stage is employed following the analog gate as an impedance transformer and buffer. As the dynamic range of the gate itself is but modest, the emitter follower functions quite satisfactorily from the +3.6V microcircuit supply line.

For optimum performance the analog gate and emitter follower should be operated at a signal input level of between 250 and 500mV RMS, as this provides the best noise/distortion compromise. In view of this, and because in most applications a burst signal of adjustable amplitude will be required, the output of the emitter follower is controlled by a simple potentiometer attenuator.

The power supply of the instrument is a relatively simple circuit supplying approximately 7V unregulated for the unijunction trigger oscillator and a regulated 3.6V + or - 10% for the remaining circuits. The unregulated supply is a simple full-wave rectifier employing two silicon diodes type OA605, 1N3193 or similar, and a miniature centre-tapped 12.6V step-down transformer.

The regulator is a simple series type employing either a germanium type AC127 or a silicon type 2N3566 medium-power NPN transistor. The base reference voltage is well filtered and regulated, the latter being performed by a string of forward-biased silicon diodes in view of the relative scarcity of low-voltage zener diodes. The number of diodes is arranged so that the regulated output voltage at the transistor emitter is within + or - 10% of its nominal 3.6V value.

As may be seen from the photographs the instrument is housed in the small flanged front panel instrument case used for most of our recent instrument designs, measuring 7½in x 5in x 4in. There are only four main front-panel controls, comprising the "burst length" and "mode" switches together with the "burst rate" and "output" potentiometers. The remaining fittings consist of the push-button for manual operation and the four main coaxial connectors.

At the rear of the case are the squared-signal output and external timebase input connectors, the "Int-Ext" slider switch and the mains cord entry.

Inside the case, most of the components are mounted on a "Veroboard" perforated printed-strip conductor panel measuring 7in x 3¾in; the panel is a section of stock Veroboard strip. The position of components and interconnection of copper conductors should be fairly clear from the board diagram provided, and also from the internal photographs.

The Veroboard wiring panel is supported by two small sheetmetal brackets which are attached to the rear of the front panel by the input connector mounting screws and the "burst length" switch mounting bush respectively. The brackets mount the panel at a distance of 2in behind the front panel, and close to the top of the case.

Wiring of the components on the board is a fairly straightforward operation, and should present few problems. However, care should be taken to ensure that components are not damaged either by mechanical strain during the lead bending and insertion, or by overheating during the soldering operation. The soldering itself should be done quickly and carefully with a low to medium power iron having a small bit; a steady and sure hand is required to ensure that the copper conductors are not overheated nor accidentally shorted by tiny solder links.

The microcircuit connection leads should not be cut, but simply passed through the board holes, bent over carefully and soldered. It will be found that the "dual in-line" devices have small moulded projections which automatically space the device from the board. The TO-5 device should be spaced approximately 3/8in from the board, which spacing may also be used for the transistors.

To prevent strain on the Veroboard panel the power transformer is mounted in the lower rear of the case, with the mains cord, primary and secondary leads terminated on a 5-lug tagstrip alongside. The mains cord is clamped inside the case to prevent strain on the tagstrip.

Three minor components are supported by convenient switch and potentiometer lugs behind the front panel rather than on the Veroboard panel. These components are the 2.7K resistor and 390pF capacitor associated with the manual triggering button, and the 1000uF 10VW power supply input reservoir electrolytic capacitor. The first of these connects between the puch-button and the input connector earth bus, while the second connects between the appropriate lug on S2 and an unused lug on S1. The 1000uF electrolytic connects between the +7V lug on the "burst rate" pot and an earth lug on the "mode switch".

When wiring the unit it is wise to connect only four BA100 diodes into the power supply reference circuit. This will ensure that when the unit is first switched on the regulated output will not be excessively high. Upon switch-on the voltage should be checked, and an additional diode or diodes added as necessary to bring the supply within the required range.

The only other adjustment to be made to the completed instrument is that concerning the switching transient suppressor trimmer. This adjustment is most easily made with a sensitive wide-band oscilloscope connected to the AF output, and in the absence of AF signal input. To permit gate operation under these conditions an external square-wave gating signal must be connected to the "Ext T.B." socket, with the slider switch set appropriately.

It will be found that at a critical setting of the trimmer, switching transients are reduced to a minimum. The trimmer should be locked in position at this setting with a small dab of nail lacquer or similar cement, to prevent vibration disturbance. If difficulty is experienced in obtaining a null balance, or if the null is insufficiently accurate to reduce the transients below 30mV P-P, it may be necessary to modify the R-C filter values in either the JFET gate circuit, or the trimmer feed circuit, or both.

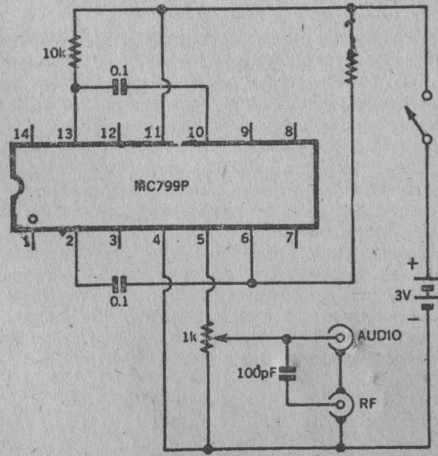
SIGNAL INJECTOR USES IC

I decided to make up an injector using a Motorola IC type MC799/P and the circuit shows what I came up with. It is basically a battery powered 1000Hz multivibrator that generates square waves. The amplitude of the square wave output is fully variable and sufficient to test a loudspeaker.

The injector also provides a wide bandwidth RF signal suitable for testing RF and IF stages. Current drain is of the order of 80mA which allows a reasonably long battery life. The resistors used were ¼W types and the 1K potentiometer is a carbon type with switch. The two 0.1uF capacitors are 10V disc type, the 100pF capacitor is also a disc type.

Construction may be left to the individual ideas and requirements of the builder. Many ideas will no doubt suggest themselves, possibly dictated by what materials and facilities happen to be available at the time.



SIMPLIFIED VERSION OF SQUARE WAVE GENERATOR

After experimenting and consulting the Fairchild data sheets, which gave the output of the FuL914 as 16 units and the input of the FuL900 as 6 units, I decided that the FuL914 would not be overloaded by the FuL900. Tests showed that the circuit operated satisfactorily in this mode, so I built up the complete unit as illustrated. In addition, I left the No. 2 lead of the FuL914 floating in order to use it as a sync. input, should this be necessary. AC and DC outputs were also made separate.

The performance seems to be unchanged by the modifications, since my generator has a frequency range of 4Hz to 2MHz. You may be interested in my experience with the modified circuit.

In addition, I would draw attention to the method of construction adopted, which is much less messy and time consuming than etching your own boards. Basically, it involves the removal of thin strips of copper from the board with a suitable scribing tool, to provide the necessary pattern. The method, incidentally, leaves intact a maximum amount of copper and, with it, the ability to make the circuit changes which are often necessary in '1 off' designs.

The approach is first to collect all the components required for the project, since physical placement is most importants. Then draw the circuit on the copper side of the board in pencil, which can be rubbed out, if necessary, with an ordinary eraser. Leave room for the actual size of the components involved and, for preference, arrange them in a neat and orderly fashion. After a certain amount of planning and possible rearrangement, it will become apparent where lines have to be scribed to separate the components.

Fine parallel lines are scribed to cut through the copper and a tool, made from a specially ground section of hacksaw blade, can be used to roll the copper out from between the scribed lines. A little practice is required to get the knack; too steep an angle will cause the tool to dig in; too shallow an angle will cause the blade to skip out of the groove.

Having drilled the holes for the component pigtails, the board can be viewed against the light from both sides to pick out any copper which has been missed or copper feathers which might short across the grooves. The components can then be soldered in, taking care to use a heat shunt when soldering leads to delicate components. If the planning has been done well, the need for jumpers will have been minimised but, if desired, these can often be hidden under components. We use a standard knife devised for scribing Laminex and similar sheeting. During development of the original square-wave generator, we passed through the simpler form suggested but decided on the additional stages: (a) to render the device less dependent for its operation on a degree of unbalance in the basic multivibrator sections and (b) to preserve a near-unity mark-space ratio irrespective of output load conditions. However, if "1-off" units constructed to the simpler design work satisfactorily, a worthwhile economy will have been effected. If particular units fail to operate, it may be necessary to try another FuL914

Electrons in Motion

We can make a picture of an atom as simple or as complicated as we like. We can show a hydrogen atom as a central nucleus or proton, circled by a single electron [1]. The proton has a positive charge, and is 1,840 times the mass of the electron, which has a negative charge.

The electron circles the nucleus millions of times in a millionth of a second, and hundreds of millions of atoms side by side would be needed to occupy an inch of space. Positive and negative charges (proton and electron) neutralize each other.

Helium has two electrons and two protons. The heavier elements have more electrons [2]. Uranium has 92.

There are other particles besides protons and electrons. The neutron is also found in some atoms. It has no charge; however, it is the 'glue' that holds the proton mass together. Other transitory particles arise, change their state, or apparently disappear in energy.

A hydrogen atom electron can absorb a photon or light particle, and take energy from it, moving to an orbit at a higher energy level. Or electrons may collapse to lower energy levels, emitting photons.

Ions

We have seen that, normally, the negative electron charge equals the positive nucleus charge: hence the atom is in equilibrium. However, sometimes an atom may gain an electron and then it becomes a negative ion. If an atom loses an electron, it becomes a positive ion. With semiconductors, we may speak of positive 'holes' or hole carriers. These can be imagined as spaces which could be occupied by electrons.

A body with a considerable excess of electrons has a strong negative charge; one with a relative lack of electrons has a strong positive charge [3]. Thus there is a difference of potential, which exists so long as there is no means of electrons escaping, or nuclei gaining the electrons they lack.

Electrons, being negative, repel one another when they are close together, but are attracted by positive nuclei. A force draws the one to the other. If they are supplied to a *conductor* that allows electrons to move, the force draws them along the conductor to a positive ion region lacking electrons [4]. The force is electromotive force (e.m.f.) and the movement is current.

The Electric Current

If the flow of electrons is to be maintained, a supply must be generated or produced to replace those traveling away from the supply along the conductor. In a circuit, current will flow from the negative battery terminal (supply), along the conductor to a lamp or other apparatus (the load). The electrons that have not been dropped across the load will return along another conductor back to the positive battery terminal.

A supply of electrons can be produced chemically by a

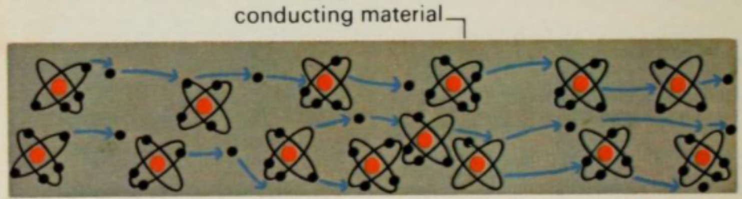
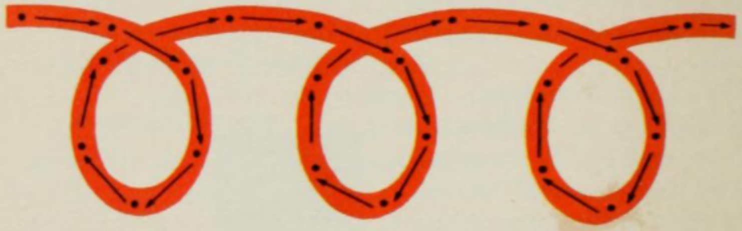
battery, electromagnetically by a generator or by several other methods.

Conductors

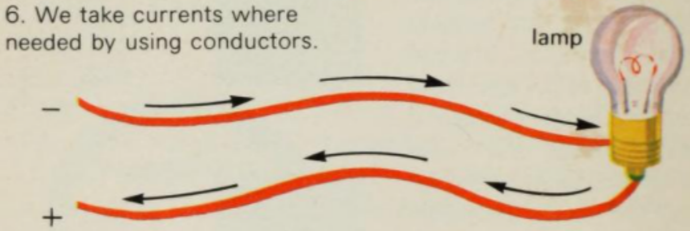
We use conductors to take current to the point where it is wanted. A conductor readily allows the exchange of free orbital electrons, so electrons forming the electric current can move from atom to atom in the material [5]. Silver and copper are good conductors, for they allow current to flow freely. Copper is drawn into wires, or wound into coils or used to carry current [6].



5. Easy exchange of electrons forms current.



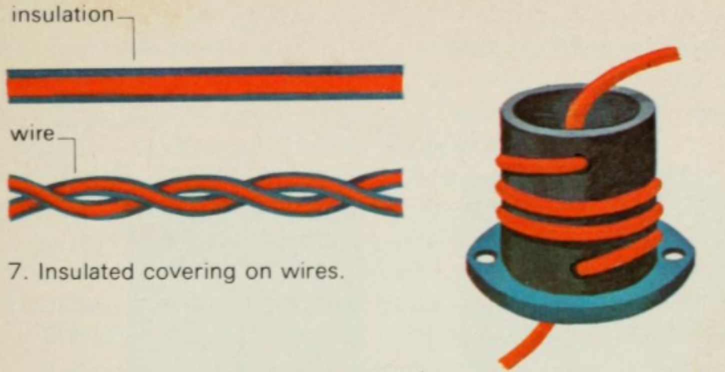
6. We take currents where needed by using conductors.



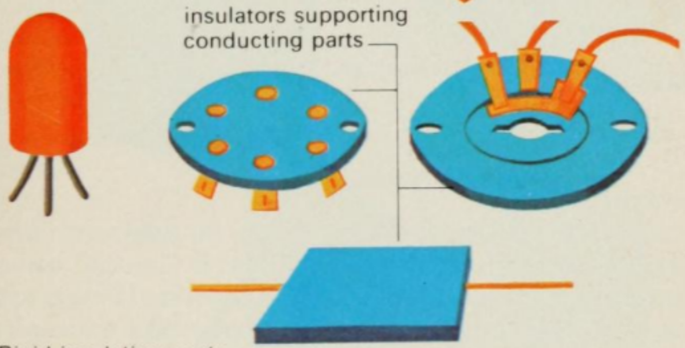
To find resistance of a conductor:

$$R = \frac{kl}{A}$$

where R = Resistance
k = Material constant
l = Length of wire
A = Cross-sectional area (usually in circular mils)



7. Insulated covering on wires.



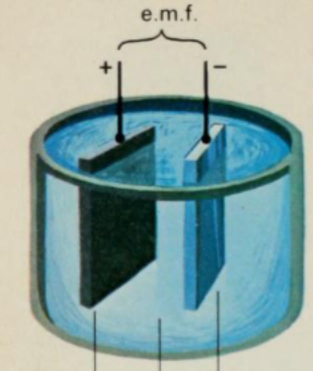
8. Rigid insulating parts.

Insulators

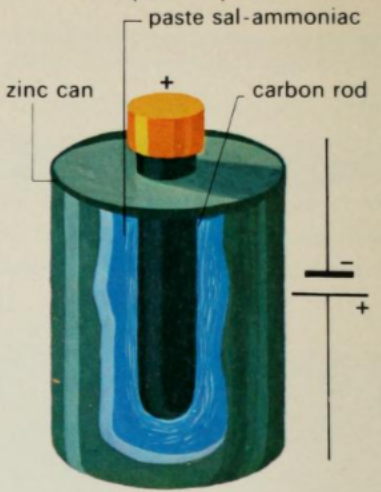
Some materials are poor conductors. This fact makes them good insulators. A perfect insulator would allow no exchange of electrons. Hence there would be no movement from atom to atom, and no current would flow. Pyrex, micalex and steatite are good insulators, but so are many other substances. Rubber, polyvinyl chloride (pvc), cotton, silk, enamel or other insulating material on wires prevents the wires touching each other or nearby metal parts where current is not wanted [7].

Glass, mica, ceramic, phenolic plastic and other rigid insulating parts support conducting items in switches, tube sockets, transistors, capacitors and many other electronic components [8].

What is the best kind of insulator depends on the work it must do. Insulators on wires may need to be thin and flexible. Insulating parts may have to be very strong or may have to withstand high voltages or high temperatures.



9. Simple cell generates electromotive force chemically.



10. Popular dry cell

Primary Cells

We said that a potential difference can be produced chemically. Primary cells or batteries do this. If zinc and carbon plates are placed in a solution of sal-ammoniac [9] this happens. Chlorine atoms in the sal-ammoniac take incomplete atoms from the zinc, but each atom removed leaves two electrons. An available supply of electrons, or negative charge, distributes evenly on the zinc plate.

The removed zinc atoms enter the solution as positive ions, or atoms lacking some electrons, until the solution can accept no more. The solution then has a positive charge and so has the carbon plate immersed in contact with it.

A potential difference or electromotive force (e.m.f.) now exists between the zinc and carbon plates. If a wire is connected from zinc to carbon, electrons flow through it. Chemical action maintains surplus electrons at the zinc until the cell is discharged.

The popular 'dry' Leclanché cell has a zinc canister as negative electrode and central carbon rod as the positive electrode [10]. The rod is surrounded by powdered carbon and manganese dioxide, whose molecules can combine with hydrogen molecules to produce water and prevent hydrogen accumulating. The e.m.f. is about 1.5 volts.

Batteries

If the cell is large, there is more area for chemical action, and a more powerful current is available. If cells have the carbon rods and also the zinc cases joined [11], this is electrically like a larger cell. Voltage is that of a single cell.

If cells are joined positive to negative, the cells are in series [12]. The battery voltage is that of the cells added together—3 volts for two 1.5 volt cells, and so on. A layer battery [12] has flat units placed one upon another. Miniature mercury cells are made for small apparatus.

Secondary cells or lead acid cells are re-charged by passing direct current through them from a generator or other supply. A car battery usually has spongy lead and lead peroxide plates in dilute sulphuric acid, and each cell has an e.m.f. of 2 volts. Six cells form a 12 volt battery.

12. Cells in series provide a higher voltage.

Free Electrons

Negative electrons move toward a positive charge [13]. If a free electron is moving near a positive charge, its path is curved, because of this attraction.

Repulsion exists between charges of the same polarity [4]. The path of a free electron or stream of electrons curves away from a negative charge. These effects are used to direct the electron stream in various electronic devices, such as the cathode ray tube used in oscilloscopes. The path of a free electron is also changed by a magnetic field. Television tubes and magnetrons utilize this effect.

Electron Gun

A stream of electrons is obtained from an electron gun having a cathode heated by an internal filament [15]. The high temperature causes thermionic emission of electrons. The beam passes through a hole in a cylinder, its intensity controlled by potential applied. Making the cylinder negative repels electrons and reduces the beam.

Focusing

A convex optical lens will focus light rays to a point. An electron lens has a similar effect on the cathode ray beam, the electric field curvature acting in much the same way as the glass lens on light rays [16]. Cylinders having different potentials have a similar effect.

By controlling the potential on one or more electrodes, the intensity of the field and its curvature can be adjusted to focus the stream of electrons into a narrow beam.

The cathode ray tube has an electron gun, grid or aperture to control beam intensity, and accelerator and focusing electrodes. The beam strikes a fluorescent coating, producing a spot of light visible on the tube. Stray electrons are absorbed by the aquadag coating.

Circuit Laws and Units

A volt (V) is the unit of *pressure* from a battery or from some other source. A dry cell has a pressure of 1.5 volts. Two cells in series provide 1.5 + 1.5 = 3 volts. A vessel half full has a depth of water H1 [17]. The depth H2 is twice H1. A pipe from the bottom of the second vessel delivers water at twice the pressure of the first vessel. Similarly, raising the voltage increases electrical pressure.

Some circuits operate at low voltage. Others require hundreds or thousands of volts. 1,000 volts = 1 kilovolt, or 1kV. On the other hand, very low voltages are in millivolts or mV. 1,000mV = 1V. Extremely low voltages are in microvolts, or μV. 1,000μV = 1mV.

The ampere (A) is the unit of current flow. For example, a bulb could take 1A [18a]. Two such bulbs take 1 ampere each, or 2 amperes, or twice as much current [18b].

Small currents are given in milliamperes, or mA. 1,000 mA = 1 ampere. Extremely small currents are in microamperes, or μA. 1,000μA = 1mA.

The ohm (Ω) is the unit of *resistance*. A thick wire has little resistance and lets current pass readily [19]. In the same way a large pipe lets water flow easily. A thin wire resists the ready flow of current, just as the small pipe offers resistance to the flow of water. The greater the electrical resistance of a component or circuit, the more the passage of current is hindered.

Copper wires have little resistance, so they let current pass readily. But we may want resistance in many circuits. Iron and alloy wires can provide this. Making the wire thinner or increasing its length raises the resistance. Carbon compounds resist the ready flow of current, and can be formed into rods having any resistance needed. They are widely used. A component having resistance is a *resistor* [20]. A variable resistor has a sliding contact, bringing into circuit as much of the resistance element as is wanted. A potentiometer has a connection at each end and sliding contact.

For high values we use kΩ, k, or kilo-ohm. 1k = 1,000 ohms. Very high values are in MΩ (megohms). 1 MΩ = 1,000k. Resistors are usually color-coded. Each color shows a figure, or a number of zeros.

Ohm's Law

If we increase the voltage applied to a circuit, the electron flow becomes stronger [21]. Reducing the voltage makes the current weaker.

If we leave the voltage the same, increasing the resistance will make the current weaker [22]. Reducing the resistance naturally allows more current to flow.

These facts are the basis of Ohm's Law. We say:

Current in Amperes × *Resistance in Ohms* = e.m.f. As I is used for current, and R for ohms, this is $I \times R = E$, or $IR = E$. In the same way, $\frac{E}{I} = R$ and $\frac{E}{R} = I$.

Always remember that the basic units are amperes, volts and ohms. As an example, 1mA flows through 100k. What voltage is dropped? 1mA = 0.001 ampere, and 100k = 100,000 ohms. So 0.001 × 100,000 = 100 volts.

The *power* that is usefully employed or perhaps wasted or dissipated as heat in a circuit is given in watts. Useful power could raise the temperature of tube heaters, or operate a loudspeaker or other device. Wasted power might be that lost in a resistor which is used to drop the voltage.

24. Voltage, resistance, current and wattage.

We could give the useful output of an amplifier or other device in watts. Small powers are given in milliwatts. 1,000 mW = 1 watt. Power in watts = voltage × current.

Voltage in Volts × *Current in Amperes* = *Power in Watts*

Or we can say $\frac{\textit{Watts}}{\textit{Volts}} = \textit{Amperes}$ or $\frac{\textit{Watts}}{\textit{Amperes}} = \textit{Volts}$

A 36 watt car bulb is run from a 12 volt battery [23]. So it draws $\frac{36}{12} = 3$ amperes current.

Imagine that a potential of 10 volts is present across a 400 ohm resistor [24a].

From $I = \frac{\textit{Volts}}{\textit{Resistance}} = \frac{10}{400} = 0.025$ ampere.

With resistors in series, 8,000 ohms + 2,000 ohms = 10,000 ohms [24b]. From $I = \frac{E}{R}$ or $\frac{100}{10{,}000}$ we find that 10mA (0.01A) flows.

The Inductor

The inductor is a wire wound as a coil. When current is applied, a magnetic field swells around the coil. When the coil is disconnected, a spark appears between the disconnected lead and the source, and the magnetic field collapses. These events indicate that energy had been stored in the coil field.

Both the building and collapsing fields resist changes in current flow (show *reactance*). With a current alternately changing back and forth, or *alternating current* (AC), the inductor assumes an inductive reactance that acts much like a resistance [25a]. The more turns on the coil, the more its inductance and the more its reactance [25b].

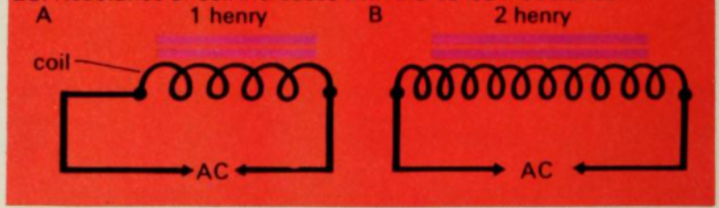
The formula $X_L = 2\pi fL$ gives reactance where:

$X_L =$ Reactance in ohms
$2\pi =$ Constant for one cycle
$f =$ Frequency in Hertz (Hz)
$L =$ Inductance in henrys

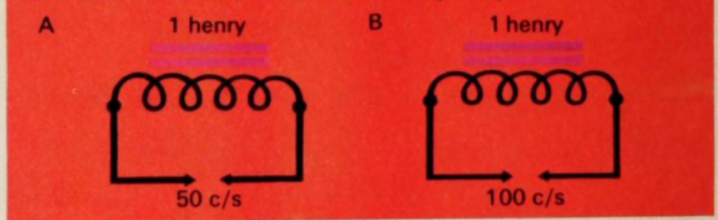
In Figure 26A the supply has a frequency of 50 cycles per second, or 50 Hz. It changes direction 50 times a second. At [26b] the frequency is 100 Hz. The reactance of the inductor B is twice that of A (Hertz (Hz) can be written as cps).

Millihenrys (mH) and microhenrys (μH) are smaller values of henry (H) for inductance.

25. Reactance of coil increases with increased inductance.



26. Reactance of coil increases with frequency.



Reactance of Capacitor

A capacitor has two closely spaced plates insulated from each other. If we connect an e.m.f., there will be only a brief surge of current as the capacitor charges to the applied voltage. If we remove the e.m.f. and place a wire across the capacitor, current will surge briefly as it loses its charge. Current flows only with a changing e.m.f. (see page 28).

In Figure 27a, AC is connected to the capacitor and a certain current flows. If we make the capacitor larger (27b), the current is larger too, because the reactance is lower. Reactance falls with an increase in capacity or frequency. In Figure 28a we apply 50 c/s AC to the capacitor. At (28b), we apply 100 c/s. The reactance of the capacitor falls with increased frequency.

$$X_C = \frac{1}{2\pi fC}$$

Where:

$X_c =$ Capacitive reactance in ohms
$2\pi =$ Angular constant
$f =$ Frequency in cycles per second
$C =$ Capacity in farads

Does it Matter?

Figure 29 shows a transformer (see page 40). Primary P takes audio signals from amplifier; secondary S supplies loudspeaker. Capacitor C is across the primary. Higher frequen-

cies more readily pass through C and do not flow through the primary. This acts as a treble tone control.

In Figure 30 capacitor C1 is from an audio amplifier tube plate, and by-passes or loses higher frequencies to ground.

The effect is changed by placing part of the variable resistor VR1 in circuit. VR1 is a variable tone control.

The switch S1 selects a small capacitor C2, a medium value capacitor C3, or a large capacitor C4. C2 lets high frequencies pass easily. C3 lets some lower frequencies pass. C4 allows low frequencies to pass readily. Tone controls are often found in receivers and amplifiers. Most make use of the fact that capacitive reactance falls with increased frequency.

Inductive reactance also has many uses. In Figure 31 a rectifier supplies a power filter. Output from the rectifier

has pronouned ripple. L is a choke with high inductance. It hinders fluctuations in current. Capacitor C1 acts as a reservoir. The inductor L refuses to let ripples pass, and capacitor C2 provides almost pure direct current. This is called 'smoothing' (see page 45).

In Figure 32a radio frequency (RF) signals and audio frequency (AF) signals arise at collector C. The radio frequency choke hinders RF, so this goes through the small capacitor C1. The choke reactance is low at low frequency, so AF passes through it and is taken off by the larger capacitor C2.

At [32b], a high frequency noise filter choke is placed in an audio circuit. It does not let high frequencies pass, and so reduces surface noise when playing records.

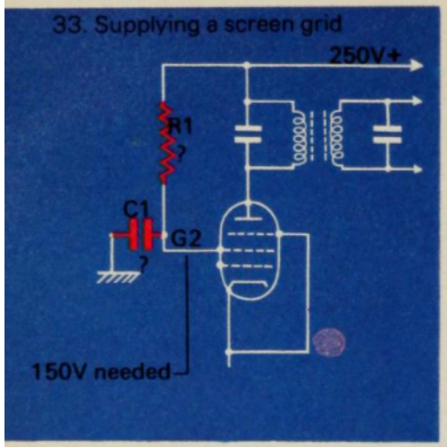
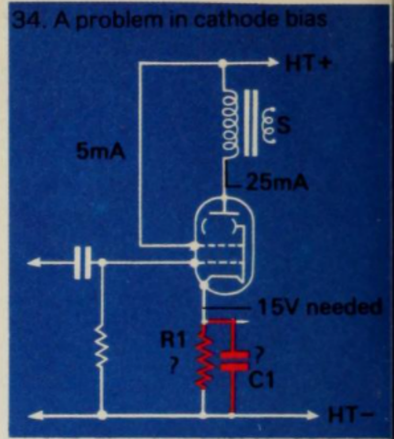
33. Supplying a screen grid



34. A problem in cathode bias



A pentode as amplifier is shown in Figure 33. The supply is 250 volts, but the screen grid G2 should have only 150 volts. Since 250–150 = 100, resistor R1 should drop 100 volts.

The current flowing through R1 is measured or found from a tube manual. It is 5mA. Recalling

that $\frac{E}{I} = R$, we can say that $\frac{100}{0.005} = 20{,}000$ ohms for R1.

What power is dissipated in R1?

$Watts = E \times I = 100 \times 0.005 = 0.5$ watt. So we use a 20K ½-watt resistor. G2 needs to be grounded at operating frequency. So C1 is a 0.05 μF 250 volt capacitor.

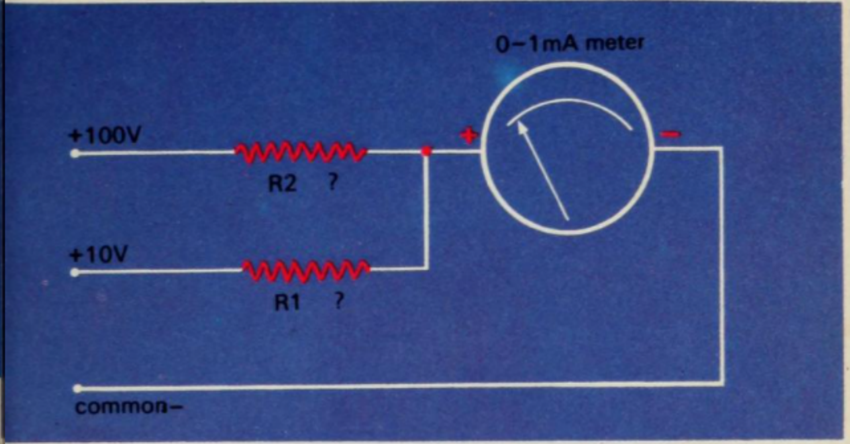
At the output stage of the receiver, 15 volts should be present at the cathode [34]. Cathode current is 25 + 5mA = 30mA or 0.03A.

$$\text{So R1 is } \frac{15}{0.03} = 500 \text{ ohms.}$$

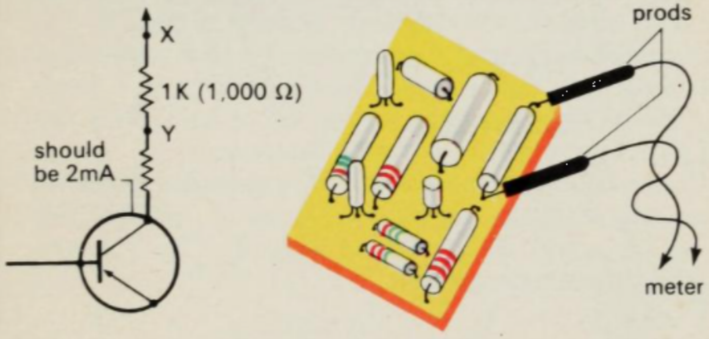
For audio frequencies and 15 volts, C1 can be 25 μF 25 working volts.

A test instrument for two voltage ranges—0 to 10 volts and 0 to 100 volts—is shown in Figure 35. For a full-scale reading, 1mA must flow (.001A). This is to show 10 volts with R1. R1 = $\frac{10}{0.001}$ = 10,000 ohms. Similarly, R2 = 100,000 ohms.

35. Resistor values for a voltmeter



36. DC working conditions of a transistor amplifier.



A transistor circuit where we suspect the transistor is not drawing the correct collector current, though all resistors and the supply voltage are correct, is shown in Figure 36. The collector current should be 2mA. The simplest test is to measure the voltage across the resistor, from X to Y. From $E = I \times R$, the voltage should be $0.002 \times 1{,}000 = 2$ volts.

A meter reads only 0.5 volt.

$$\text{From } I = \frac{E}{R} = \frac{0.5}{1{,}000}$$

we see that the transistor collector current is actually 0.5mA.

Electronic Circuit Diagrams

For some electronic equipment, components could be shown in outline, with connections, in a scale drawing just as in the apparatus.

But it is usually better to have a circuit diagram where simple symbols represent various components. Symbols are often simplified representations of the components. By comparing components and their symbols, you will become familiar with them.

Lines represent wires. These may be joined as in Figure 37a. They may cross without contact [37b]. Dots [37c] show connecting points such as sockets, which could be for plugs connected to a loudspeaker, or could be used for some other purpose.

A fixed resistor symbol is shown in Figure 38, together with three resistors in a small part of a circuit. In Figures 39a and 39b is shown a variable resistor. If connections are taken to X and Y, moving the sliding contact (arrow) to the right increases the resistance actually in circuit.

The resistance element may be wire for low values, but carbon is used for high values. The track can be in a semicircle, and rotating a spindle moves the contact along the track [39c]. Figure 39d is a typical component.

B, C and D are potentiometers. If a potential—such as an audio signal voltage—is taken to X and Z, any required level can be tapped off by moving slider Y. This happens with an audio volume control.

Switches

In Figure 40 is shown an on/off switch. It could be a supply voltage toggle switch, low voltage rotary switch, or any other component.

A volume control often has a switch. It can be a single on/off type (single pole), or it can be two on/off switches (double pole) which work together to interrupt two circuits.

The rotary switch in Figure 40 has a contact X, which can transfer a circuit to 1, 2 or 3, the switch having three positions. It is '1-pole 3-way'. It could have more contacts and more ways, as required.

Inductors and Coils

Insulated wire wound upon an insulated tube forms a coil or inductor [41]. We can increase the inductance by using more turns, or having a larger coil. Or we can place a core in the winding to concentrate the magnetic field and raise its inductance.

The inductor might be of very small inductance and have few turns [42a]. Larger inductance coils have more turns [42b]. The coil could have a tapped winding—or two or more windings on the same insulated tube [42c]. If there are very many turns they may be in sections [42d]. This is a 'high frequency choke'—an inductor which prevents the passage of high frequencies.

Special materials have to be used for cores for radio frequency coils (those that work at radio frequencies). A core of ferrite or iron dust material placed in the coil winding intensifies the magnetic field and raises the inductance, so if we want to adjust the inductance, we can use a threaded core, and screw it in or out [43]. In the symbol, the dotted line is the core, and the sloping line shows it is adjustable. To simplify large circuit diagrams, cores are often not shown.

41. Radio frequency (RF) chokes

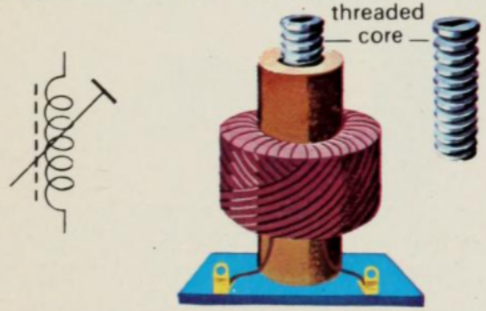
LF Cores

At low frequencies, cores can be made from various alloys [44]. Thin sheet iron was once used.

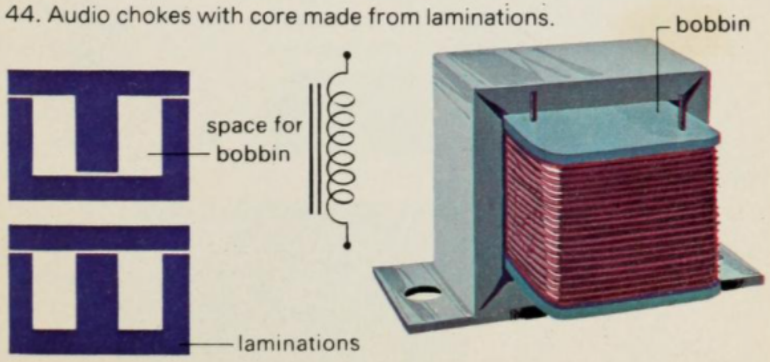
The winding is often on a bobbin, entirely surrounded by the core. One limb fits inside the winding. This core is often of thin metal 'stampings' or laminations, and enough are used to make up the thickness wanted.

Since this inductor prevents the ready flow of low frequencies it is a 'low frequency choke'. Such a choke is often employed to help remove ripple in a supply from a power circuit, and is then called a 'smoothing choke'. In order to be used for this purpose, it would normally have an inductance of several henrys.

43. Adjustable core allows inductance to be changed.



44. Audio chokes with core made from laminations.



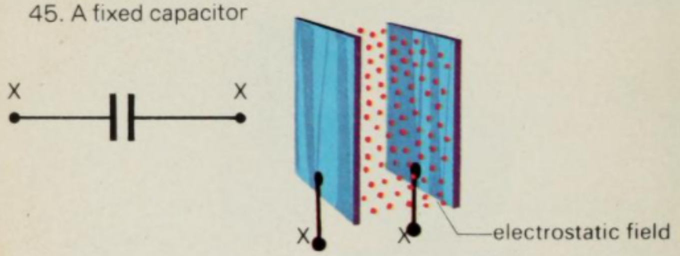
Capacitors

Two metal plates near each other but not in contact form a capacitor and can store a charge [45]. If we connect a voltage to X-X a deficiency of electrons arises at one plate, and a surplus at the other. Electrostatic stress arises in the insulating space between plates. The capacitor is 'charged' with a power depending on 'capacity' or charge-storing ability. Unit of capacitance = farad (F).

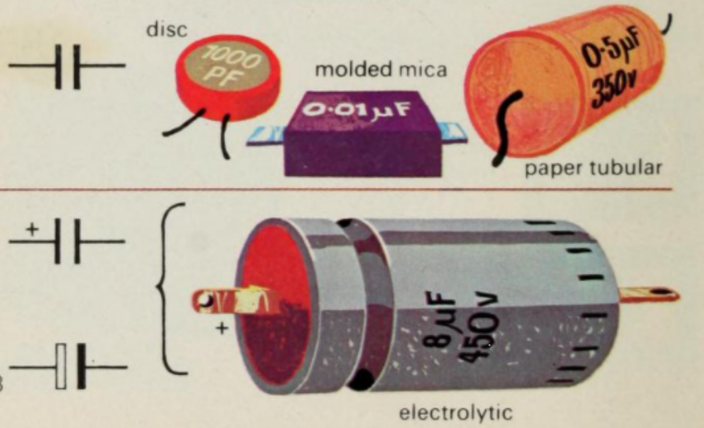
If X-X are joined together, the capacitor gives up its charge. We can increase the capacity to hold a charge by placing the plates nearer each other, and in other ways. The insulation between plates is the 'dielectric'. Capacitors are made with mica and ceramic insulation, or foil rolled up with insulating paper and in a tube [46]. Or metallic conductors may be deposited on an insulator.

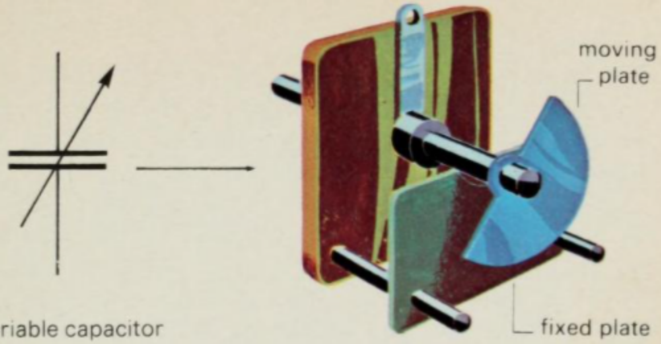
'Electrolytic' capacitors are so made that an applied voltage must be of the correct polarity. These capacitors are of some set value and are called 'fixed capacitors'.

45. A fixed capacitor



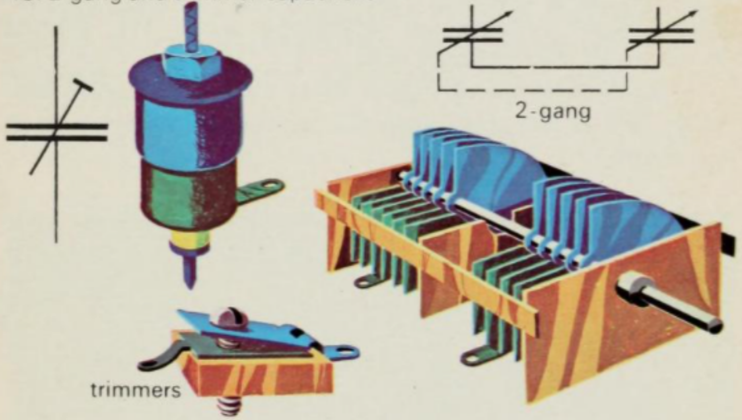
46. Some capacitors for electronic equipment





47. Variable capacitor

48. 2-gang and trimmer capacitors



We may need to change the capacitance at any time and for this we want a 'variable capacitor'. A small variable capacitor can have one fixed plate, and one moving plate attached to a spindle [47]. Rotating the spindle changes the extent to which moving and fixed plates overlap each other, and thus alters the capacity. Capacitance is least with the plates not overlapping at all.

We may wish to tune two circuits simultaneously in a radio receiver and can then use a 2-gang capacitor [48]. By having many fixed and many moving plates, the total capacity of each section can be increased. Sometimes the capacity has to be adjusted when first putting a circuit into proper working condition. A 'trimmer' is then used. It is adjusted with a screwdriver or other tool, and brings moving and fixed plates closer to increase the capacitance.

A Voltage Amplifier

The circuit in Figure 49 is the first audio amplifier stage of a receiver or large audio amplifier. It increases the voltage of audio signals obtained from a pick-up employed to play records, or from a receiver detector.

Capacitor C1 isolates earlier direct current circuits from the base B of the transistor, supplied by the resistors R1 and R2. Resistor R3 applies a small negative bias to the emitter E. Bias increases when emitter current rises. This helps to make working conditions stable. C2 grounds the emitter E at audio frequencies.

Current from collector C flows through resistor R4. Amplified signal voltages are developed across R4. Signals are taken off by capacitor C3.

A practical layout of Figure 49 is shown in Figure 50a. Figure 50b is the same amplifier assembled in more compact form.

Block Diagrams

We may show the essential parts of a circuit without going into detail. Block diagrams do this. Figure 51 is a block diagram of a large amplifier. Each 'box' represents one section—Section 1 is an audio frequency amplifier like Figure 49. So is Section 2. Section 3 is an output stage, or amplifier which supplies appreciable power. Signals reach it from Section 2, and its output goes to the loudspeaker.

Figure 52a is for playing stereo records. The stereo pick-up produces left and right channel signals. These go to the balancing section, where the relative volume is adjusted. Amplifiers supply outputs for right and left speakers.

Figure 52b is a block diagram showing a photoelectric counter. An item interrupts light falling on the cell, causing electrical output to work a counter.

Other Symbols

The symbol for a PNP transistor is shown in Figure 53a; that for the NPN transistor at 53b. Figure 53c is the symbol for a triode tube. The tube might be of any type.

Remember, most symbols are simplified representations of the component or its function! The relay [54] illustrates this. Tags X-X take current to an electromagnet winding. The spring-actuated contact Y normally rests against the fixed contact 1. When current flows in the winding, the armature Y moves and switches the circuit to 2.

Sometimes items in a circuit can be omitted, to obtain a diagram which is easier to follow, or to ignore repeated details. In Figure 55 the switch allows inductor L1, L2, L3 or L4 to be selected. This is shown in full at [55a]. At [55b] the actual way in which inductor L1 is connected is shown and inductors L2, L3, and L4 are omitted.

Simplifications of this kind are very useful when there are several switch positions and sections, and possibly quite a large number of inductors or other parts.

Theoretical circuits do not usually take into account the actual way in which the equipment is assembled. For example, an amplifier circuit could be assembled on a panel and occupy quite a large space. Or it could be arranged on a smaller panel, with components close together, or made with miniature components to the smallest possible size. But in all these cases it might be the same circuit.

Magnetism is Important

An unmagnetized bar has all its particles at random [57a]. Magnetizing it draws them into similar polarity [57b]. The bar magnet [57c] has a north pole at one end, and south pole at the other end. Other shapes are the horses shoe [57d] and ring magnets [57e].

If the north pole of one magnet is near the south pole of another magnet, an attractive force arises. But if a north pole is placed by a north pole, or a south pole by a south pole, a repulsive force pushes the magnets apart. Both poles attract ferrous or iron objects.

Various specially shaped magnet assemblies are used [58]. That at Figure 58a has curved ends to accommodate the rotating coil of a meter; [58b] is for a similar purpose. Figure 58c is for a moving-coil speaker or microphone.

If we connect a coil to a battery or other direct current supply, a magnetic field is created [59a]. It has north and south poles, and exists so long as current flows. The magnetic field arises when the switch is closed and current begins [59b]. When the switch is opened, the field collapses [59c]. This generates an electromotive force or e.m.f. in the coil, of opposite polarity to that from the battery. If the supply polarity is reversed, the magnetic poles are also reversed. If we connect the coil to an alternating current supply [60] current flows back and forth through the coil. At each reversal of direction, the magnetic field collapses and arises with opposite polarity. Most electromagnets have cores allowing concentration of magnetic force. Current in a winding creates a magnetic field.

The reverse arises. If a magnet is moved in or out of a coil, an e.m.f. is produced [61]. Relative motion must exist between the field and conductor. The magnetic field can be from a permanent magnet, or from another electromagnet. These effects are used in generators and other devices where the rapid motion of magnetic fields produces strong currents.

In Figure 62, a strong field exists in the circular space between the shaped pole pieces. A coil is pivoted to rotate in this gap. Current is fed to it by hairsprings, and a pointer is attached.

When current flows in the coil, the magnetic field surrounding the conductors interacts with the permanent magnet field, and the coil rotates slightly. This can show current, voltage, or other things we wish to know. When current ceases, the coil returns to its original position.

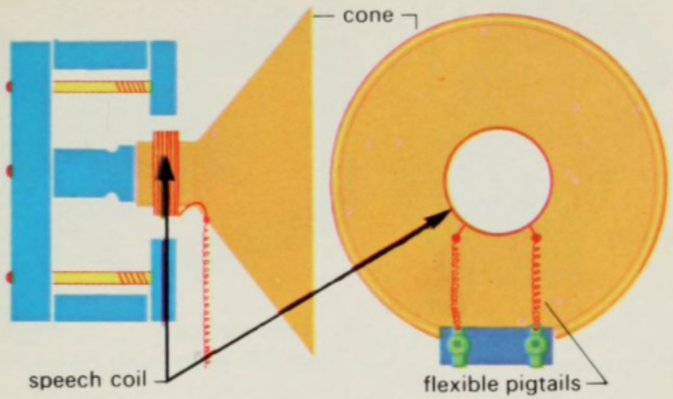
This embodies a cone carrying a very light coil, which receives current by flexible leads [63]. The coil occupies a narrow gap in a magnet assembly, and can move in and out in line with the cone axis.

Audio signals taken to the coil generate a fluctuating magnetic field. Interaction between this field and the fixed magnet field causes the coil and cone to move in and out. This is transmitted to the air, producing sound waves.



63. Moving-coil loudspeaker

The winding is often called the 'speech coil'. 'Permanent magnet' moving-coil speakers have a permanent magnet assembly. 'Energized' speakers have an electromagnet, or winding, on the center limb of the assembly, and current in this produces the magnetic field.

In a moving-coil microphone, vibrations of the cone and coil produce an e.m.f. in the coil.

65. Solenoids

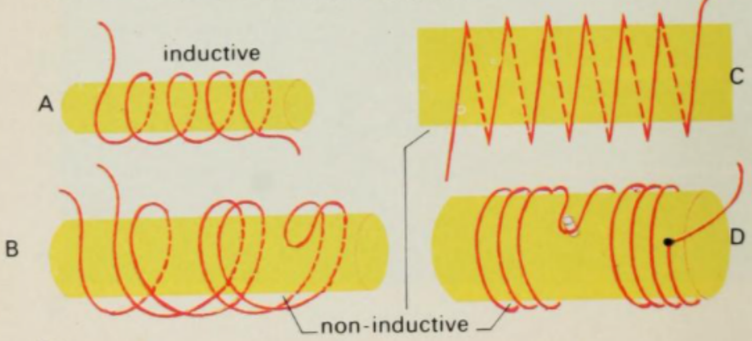
Solenoid and Magnetic Field

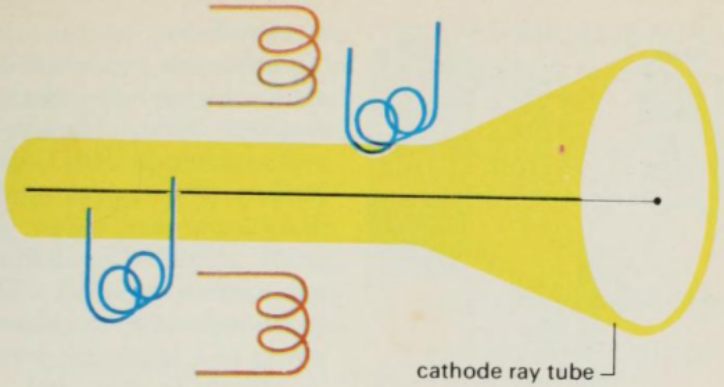
When current flows in a winding, a core becomes magnetized. If the core is out of the winding, magnetic forces pull it in [65]. The limbs of the plunger and the fixed portion of the assembly can be shaped to assist this action by concentrating the magnetic field. A solenoid may control fuel or liquid flow valves, mechanical step-by-step counters, and many other devices.

Sometimes we wish to avoid magnetic fields, as in 'non-inductive' wire-wound resistors. Then we try to make one part of the field cancel another part [66]. Here, A is a wire-wound resistor, resembling an electromagnet. B has a loop: current reverses and flows back. C uses thin flat mica. One-half of each turn lies flat under the other half. D reverses the winding direction half-way.

Electrons are influenced by the presence of magnetic fields. This is useful with television picture tubes, and with magnetrons, and so on.

66. Non-inductive wire-wound resistors





67. Magnetic deflection of cathode ray

A stream of electrons is emitted by the electron gun of a cathode ray tube [67]. The beam passes between coils on the tube. When no current flows in these coils, the beam travels straight to the screen, and produces a central bright spot on the face of the tube.

Current flowing in the coils produces a field which curves the electron path up or down, or from side to side. In this way the beam is made to strike the screen at any point we want.

By altering the strength and polarity of current in the coils, the beam can be made to travel over any part of the picture-tube face. The coils are specially shaped to lie around the tube [68]. Electromagnetic deflection of the electron beam is used in television receivers.

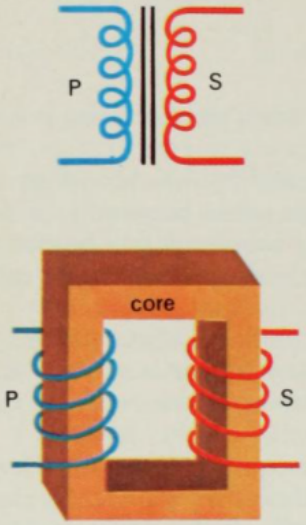
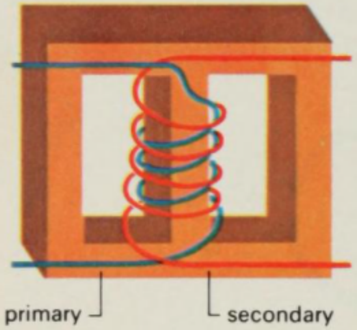
69. An air-core transformer

70. Transformer with core





Transformers

Transformers are useful devices relying on electromagnetic effects. They have two windings [69]. The primary (P) receives power from some source (an antenna, amplifier, or alternating current supply). The secondary (S) delivers power to a following device or circuit (a transistor or tube, a loudspeaker, a motor, an electric lamp, etc.).

The transformer may be 'air core' for high frequencies [69]—that is, it may have no solid core material. Currents in the primary develop a fluctuating electromagnetic field, rising and falling rapidly according to the current. This field cuts the turns of the secondary, and induces an e.m.f. in the winding.

For lower frequencies, audio circuits, or alternating current supply, solid cores are placed in the windings. These concentrate the magnetic field, and are generally made up from thin laminations. (See also page 27).

Primary and secondary may be on separate limbs of the core [70] or a bobbin fitted on the center limb.

The transformer changes or transforms one voltage to another, according to the 'turns ratio', or relationship between primary turns and secondary turns [71], given by: Transformer formulas:

$$\frac{N_p}{N_s}=\frac{e_p}{e_s}=\frac{i_s}{i_p}=\sqrt{\frac{Z_p}{Z_s}}$$

The subscripts denote primary and secondary where:

N = Number of turns
e = Voltage
i = Current
Z = Impedance

These relationships presuppose 100% transformer efficiency. Suppose the secondary has one-third the number of primary turns. The ratio is 3:1. If the primary received 240 volts AC, the secondary would deliver 80 volts. But if the secondary had twice as many turns as the primary, the ratio would be 1:2. If the primary received 240 volts, the secondary would receive 480 volts.

Transformers produce the voltages we want, or couple circuits together. A transformer may have several windings [72]. The primary here is tapped for 210/230/250 volt. One secondary supplies 5 volts, another 6.3 volts, and a third 500 volts center tapped, or 250/0/250 volts. That is, 250 volts each side of the tapping.

The Magnetron

A small 2-plate magnetron—a device which can produce radio frequency energy—is shown in Figure 73. If no magnetic field were present, negative electrons would flow from cathode to positive plates. When the magnetic field intensity is raised the electrons take curved paths and tend to circle the cathode.

An alternating potential is obtained on the plates from a resonant circuit. Electrons approaching the higher potential accelerate. Those approaching the lower potential lose velocity, so that clusters of electrons tend to revolve around the cathode, maintaining the oscillation.

Operation is in brief duty periods (less than one per cent) with high power at high frequency. Large radar magnetrons deliver many thousands of watts, at centimeter wave lengths. For very high frequencies, the plates are formed with cavities which act as the resonant circuit. Plates and cavities are arranged in a ring [74].

Cyclotron

The cyclotron [75] can supply high-energy particles and has two D-shaped members. They are supplied with high frequency alternating current at many kilovolts. The whole is in a vacuum and placed between magnetic poles. Particles travel in a curved path because of the magnetic field. Particles approach each of the D-shaped members as the potential is rising, and this accelerates them. They travel around and around, gaining velocity until ejected through the opening. They bombard other particles, and facts are learned about the nucleus. The synchrotron, with magnets around a circular track, has accelerated particles up to nearly the speed of light. Particles generated include protons, deuterons and alpha particles.

Magnetohydrodynamics, or Gas Flow Electricity

If a conductor is moved across the lines of force of a magnetic field, an electromotive force is generated [76]. When a flow of ionized gas is directed between the poles of a magnet, an e.m.f. is also produced. Current can be taken away by conducting plates.

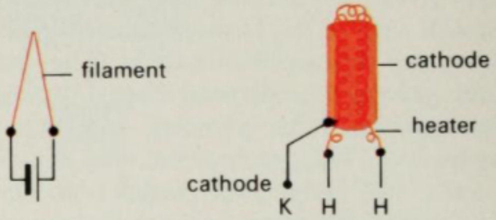
Electron Tubes

A directly heated filament is a thin wire heated by an electric current. It then emits electrons.

Often we have the surface which emits electrons separated electrically from the filament [77]. The filament is electrically insulated from the tube or cathode, which reaches working temperature after an interval. The filament is the heater; the tubes are 'indirectly heated'.

77. Directly heated filament and indirectly heated cathode

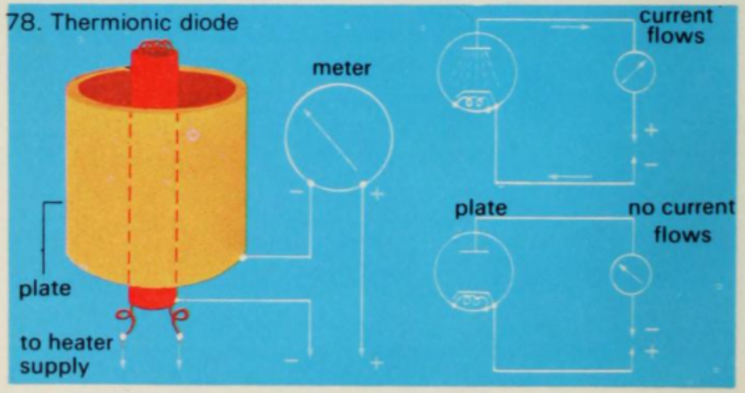


Diode

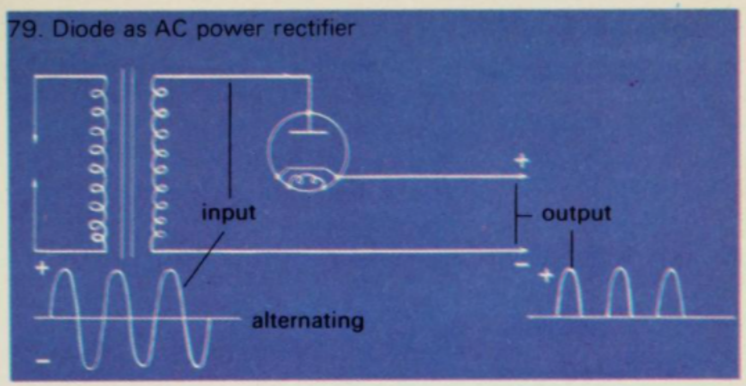
A thermionic diode has two essential electrodes, and it lets current pass one way only. The diode has a metal plate by the cathode [78]. In working circuits we assume that current will be applied to the heater: so these connections are often omitted in diagrams.

If the plate has a positive potential, electrons emitted by the cathode flow to the plate. If the plate is negative, electrons emitted by the cathode are not attracted. No current flows. The diode allows electrons to flow from cathode to plate, but not from plate to cathode.

78. Thermionic diode



79. Diode as AC power rectifier

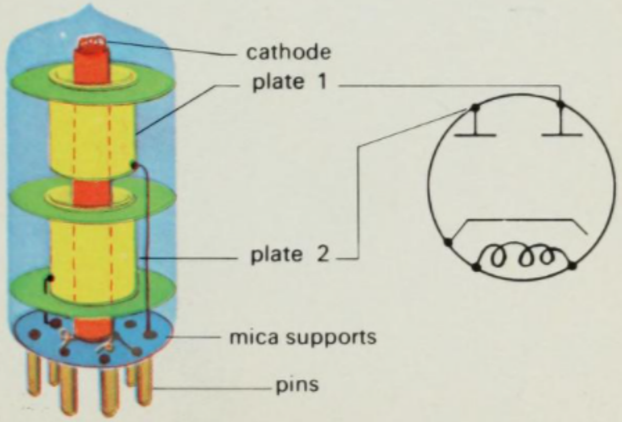


Diode Rectifier

Direct current flows steadily in one direction. Alternating current flows first one way, then the other. With 60 cycle per second supplies there are 60 cycles each second [79]. If we apply this to a diode, current passes only during those intervals when the diode plate is positive. Half-cycles of opposite polarity are suppressed, so we obtain pulsating direct current.

A single diode has cathode and plate. This is also a 'half wave rectifier'. A 'full-wave rectifier' [80] has two plates, and can be connected to make use of both half-waves of the AC supply cycles.

80. A full-wave rectifier



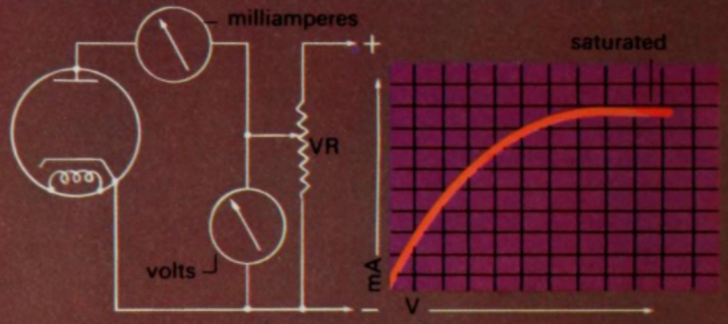
Diode Current

Suppose we provide any chosen voltage by moving the Wiper of a potentiometer VR [81]. A milliammeter indicates the diode current. As the voltage increases, more electrons are attracted to the plate, and current rises. When practically all the electrons are attracted, the current levels off, and scarcely increases at all, even with a much higher plate voltage. This is the maximum, or saturation current.

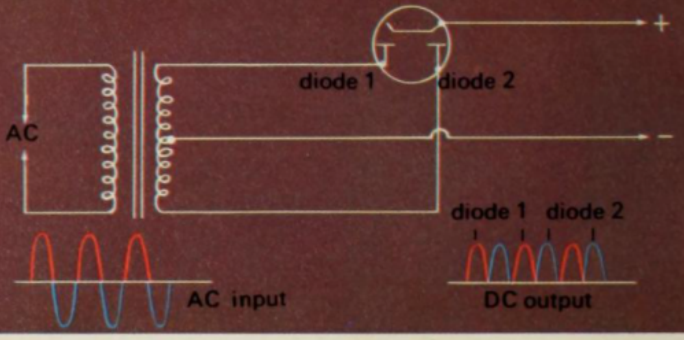
Full-Wave Rectification

A single diode in a half-wave rectification circuit allowed half-cycles of an alternating supply to flow, so we obtained pulsating direct current. Full-wave rectification is possible with two plates or two separate single diodes [82]. The transformer secondary is center-tapped. For one half-cycle one diode is positive, and for the other half-cycle the other diode is positive. So both half-cycles are utilized.

81. Current flowing through a diode



82. Full-wave rectification

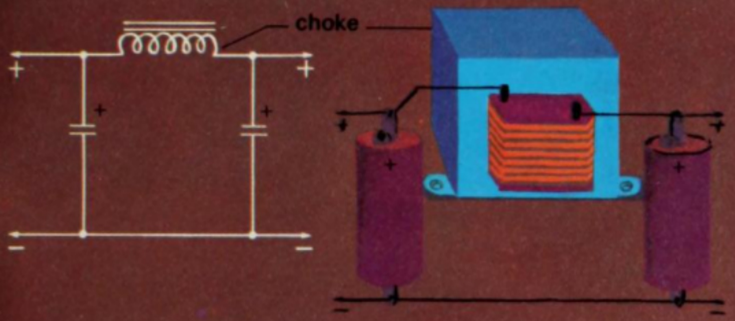


Much AC equipment has a rectifier which supplies direct current for other tubes. The pulsating DC has to be made steady and continuous. 'Smoothing capacitors' across the supply, and a 'smoothing choke' in series do this [83]. The capacitors store energy and give out current. The choke opposes changes in current. Thus a smooth supply, almost like that from a battery, is available. Plate voltages are called the 'B' supply.

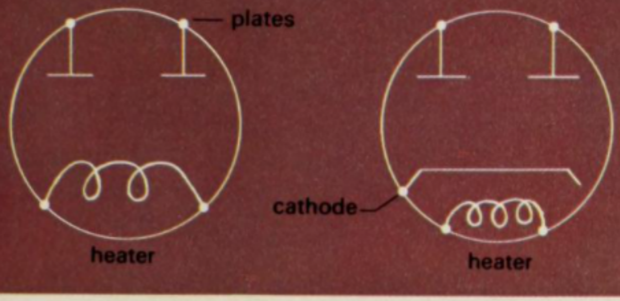
Uses for Diodes

Thermionic diode power rectifiers [84] can supply large currents at high voltage. Smaller diodes provide detection or demodulation, or rectify signals for automatic volume control bias. With an indirectly heated cathode, heater and cathode can be connected to different circuits. But if it has a directly heated cathode or filament, there is no separate cathode connection. This can be important with power rectifiers.

83. Power supply smoothing circuit



84. Thermionic rectifiers with directly heated and indirectly heated cathodes



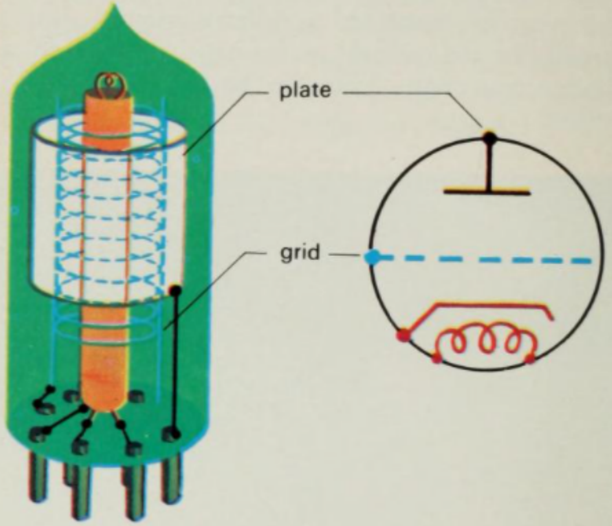
The Triode

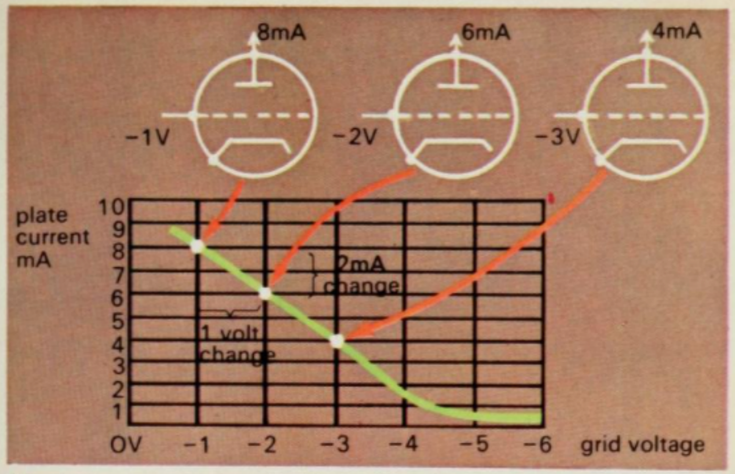
A diode has two important electrodes: cathode and plate. The triode has a third electrode, a grid of thin wires, between cathode and plate [85]. Electrons emitted from cathode to plate pass between the meshes of the grid. The triode can 'amplify' signals, or increase their strength. If the grid is at or near zero potential it has little effect on the flow of electrons.

Suppose a meter placed between the plate and supply shows 8mA with−1 volt [86]. If we make the grid more negative, electrons are repelled from its vicinity, so that plate current is reduced. With−2 volts at the grid, plate current has fallen to about 6mA. At−3 volts current is 4mA. If the grid is made very negative, virtually all the electrons emitted by the cathode are repelled by the negative charge on it, and do not reach the plate.

Changes in grid voltage cause changes in plate current. This grid is called the 'control grid'. A steady D-C voltage is called 'grid bias'. Changing the grid potential by 1 volt causes plate current to change by 2mA. The tube has a mutual conductance of 2mA per volt, or 2mA/V.

85. A triode has control grid between cathode and plate



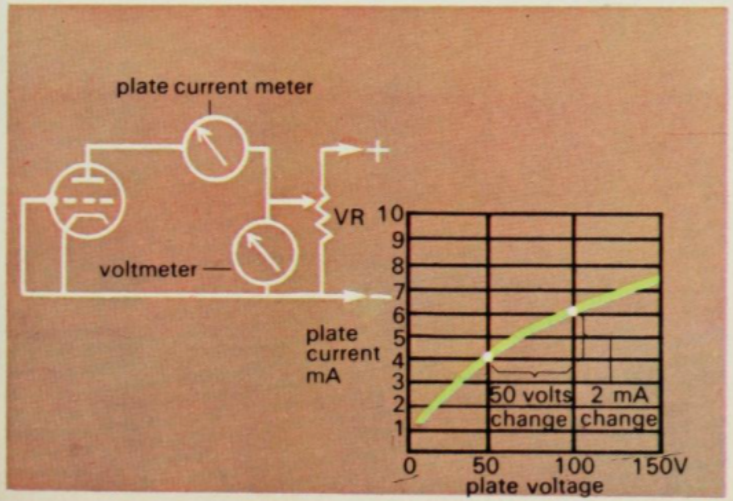


86. Plate current controlled by grid voltage

We can apply various voltages, and read current with a meter [87]. As we raise the voltage, current increases. At 50 volts it is 4mA, but it has risen to 6mA at 100 volts. If the bias voltage is unchanged, altering the plate potential by 50 volts changes the plate current by 2mA [88]. In Figure 86 changing the grid potential by 1 volt changed the plate current by 2mA. So altering grid potential by 1 volt has the same result on plate current as changing the plate potential by 50 volts.

87. Changing plate voltage also changes plate current

88. Plate voltage and current



Triode Amplifier

An audio signal is applied to X in Figure 89. Resistor R1 completes the tube grid circuit. Cathode current flows through R2. We need the control grid to be −2 volts relative to the cathode K. So R2 drops 2 volts. C1 by-passes R2 at frequencies to be amplified.

With no signal at X, bias is −2 volts and plate current is 6mA. The audio signal is 2 volts from peak to peak, so swings the grid from 1 volt to 3 volts. Plate current swings from 8mA to 4mA. The voltage dropped in resistor R3 depends on plate current. So the plate voltage also swings up and down. An amplified signal is taken off by capacitor C2. Such capacitors isolate other circuits [90].

More Electrodes

A screen grid G2 betweeen control grid G1 and plate [91] has a positive potential. Plate current depends less on the plate voltage, and amplification is increased. Electrons may be knocked off the plate and return to the positively charged screen grid. The suppressor grid G3 hinders this. This tube is a pentode. Shaped plates between screen grid and plate in a 'beam tetrode' also hinder the flow of electrons from plate to screen grid.

We control the electron stream from two circuits by using a tube with more grids, such as a heptode [92]. Signals applied to grids G1 and G3 control the electron flow. Grids 2 and 4 form a screen each side of G3. G5 is the suppressor grid.

A duo-triode has two triodes in a single bulb. A duo-diode triode has two diodes together with a triode assembly. In the same way, there are other tubes, such as triode-hexodes, triode pentodes, pentodes with diodes, and duo-pentodes.

Variable-Mu Pentodes or Remote Cut-off Pentodes

Amplification can be controlled by using a grid having irregular spacing [93]. By increasing the negative bias, the amplification can be reduced to a very small fraction. The tube might have a mutual conductance of 5mA/V with zero bias, falling to 0.005mA/V and 20 volt bias.

Negative Resistance Condition

If a screen grid tube has certain screen grid and plate potentials, electrons strike the plate at a velocity causing other electrons to be liberated. These 'secondary emission' electrons return to the screen grid. When potentials are suitable, and the screen grid potential is higher than the plate, secondary emission is considerable. If the plate voltage is increased, electrons strike it with added velocity, and liberate more secondary electrons. So over a certain part of the operating curve plate current *falls* for an increase in plate voltage [94]. This is 'negative resistance'. It can cancel the actual or positive resistance of a circuit, sustaining oscillation.

Semiconductors

The electrons of an atom have various energy levels so that they can be thought of as occupying different bands or positions. Free electrons in the outer position, or shell, can move from atom to atom, forming an electric current.

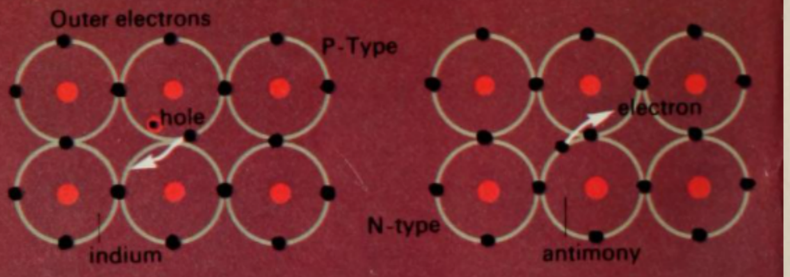
Germanium has 32 electrons, with four in the outer shell. By adding impurities, an excess or lack of electrons is arranged. Indium has 49 electrons, with three in the outer shell. This is one less than the germanium outer shell, so an electron from a germanium atom can move in to occupy the space, leaving a germanium atom with a deficiency of one electron. This, a positive 'hole', can accept an electron from another germanium atom [97].

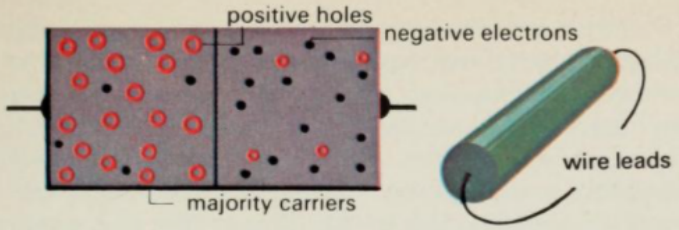
Antimony has 51 electrons, with five in the outer shell. This extra electron can displace an adjoining electron, which in turn can move elsewhere.

Lack of an electron leaves a positive charge, so the crystal is termed 'P-type'. Excess of electrons constitutes a negative charge and gives 'N-type' material. Movement of the electrons or hole carriers forms an electric current.

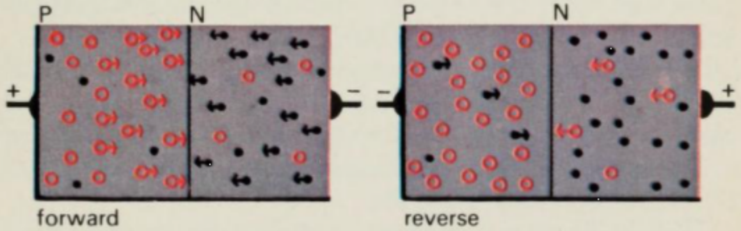
A semiconductor junction diode is a junction of N-type and P-type regions, and is often called a PN diode. Current in N-type germanium is conveyed mostly by electrons, but in the P-type mostly by holes [98].

97 Germanium with positive and negative carriers





98. PN junction diode

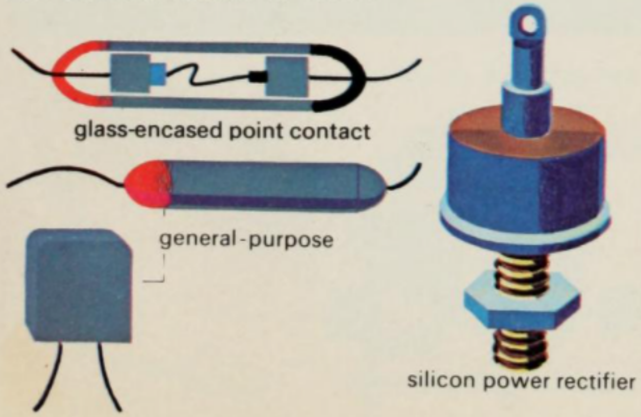


99. Junction with forward and reverse voltage

The diode allows current to pass readily in the 'forward' direction. There are many positive holes to move across to the N-region, and numerous negative electrons to travel to the P-region [99]. This represents a large flow of current across the junction. With the voltage reversed, there are few negative electrons in the P-region, and few positive holes in the N-region, so that the current is small. Semiconductor diodes are made to suit the voltage, current and frequency [100]. Point contact diodes pass small currents, but can operate at very high frequencies.

Germanium rectifiers tend to fail around 75° C, while silicon can withstand up to about 200° C. Thus a silicon rectifier is less affected by rises in temperature, and can operate with currents of many amperes.

100. Some semiconductor diodes



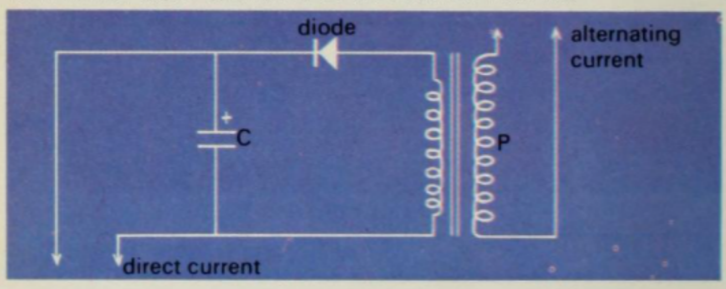
Semiconductor diodes are now much used in power supply circuits for rectification. They are small in size, have low forward resistance, can handle high voltages and current, and need no separate heater supply.

Many electronic circuits, including those of receivers and amplifiers, require direct current. The alternating current supply is usually taken to the primary (P) of a power transformer [101]. This isolates equipment from any actual connection with the supply. Voltage can be reduced or increased by a suitable turns ratio.

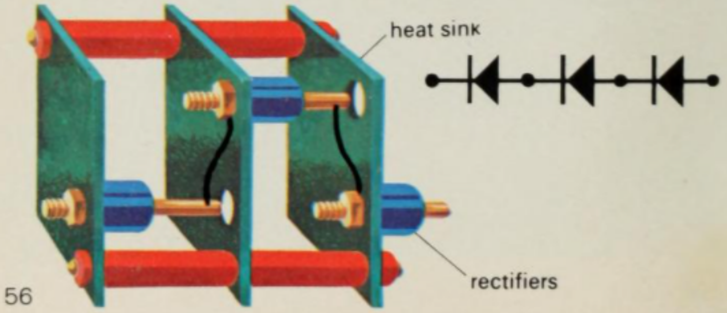
The diode allows current to pass readily one way and so can charge a reservoir capacitor. Compare this with the half-wave tube circuit. Semiconductor diodes can also be used in full-wave circuits, to make use of both half-cycles of the AC supply, as with tubes.

When rectifiers are working at maximum current, heat is produced. This is carried away by a metal plate or heat sink. Rectifiers may be connected in series or parallel, to obtain a higher voltage or current rating, or they can be stacked in special assemblies [102].

101. Power diode allows DC to be obtained from AC



102. Rectifier stack with convection cooling



Compensating Diode

In transistor receivers and amplifiers, working conditions of the output transistors which supply the loudspeaker are quite critical. Wrong bias will increase battery drain, or cause distortion.

Base bias which is suitable for a new battery may be unsatisfactory with one that is partly discharged. The temperature at which they are operating affects somewhat the working of transistors.

A compensating diode [103] helps overcome this. The diode's resistance (and transistor operation) varies with the temperature. When battery voltage falls, current through the diode is less. Its resistance rises, helping to shift the base supply more negative and restore satisfactory operation.

RF Probe

The point contact diode has extremely small internal capacity, and can operate at very high frequencies. It is suitable for a radio frequency probe [104]. The probe can be taken to any circuit point where RF is present.

Transistors

A transistor has a central region, or base, of one kind of semiconductor material, with junctions of an opposite kind of material on each side. A PNP transistor has positive-negative-positive material, with a negative central base [105]. The NPN transistor has negative-positive-negative material—a positive central region or base.

For the PNP transistor, pellets of indium are fused on by heating, and diffuse into the base to form P-type regions. The whole is fitted with leads and sealed in a protective case.

Such a transistor becomes less efficient at high frequencies. An alloy junction transistor has a base region only a small fraction of a millimeter wide. Planar transistors [106] made by alloy diffusion have an extremely thin active base region, and construction which reduces the time required for the movement of the current carriers.

The PNP emitter is connected to a positive supply, and the collector to a negative [107]. If the base is appreciably negative, relative to the emitter, the emitter-base junction acts as a diode junction with forward bias. Holes pass into the base, and are drawn by the negative charge of the collector, so that they usually flow to the collector. Current passing through the transistor is large.

If the forward bias is reduced, fewer holes travel to the collector. The current flow is quite small [108]. In a PNP transistor, there is a small movement of 'minority' or negative electron carriers, the 'majority' or most numerous carriers being positive holes—a positive charge equal to an electron. Base and collector currents added together form approximately the emitter current. Almost all the emitter current passes to the collector.

Note the important difference between PNP and NPN transistors [109]. The PNP transistor base is negative-type material, and majority current carriers are positive holes, caused by a deficiency of negative electrons. Emitter goes to *positive*. With the NPN transistor, the base is positive-type material, and electrons are majority carriers. Emitter goes to *negative*.

Note that the arrow symbol is always the emitter, and agrees with the motion of positive hole carriers. We can regard this as the conventional electrical current flow from positive to negative, encountered in some text books. The flow of electron current is from negative to positive. A heavy current may flow if a supply is connected in the wrong polarity to a transistor. If resistors and so on do not impede this current, transistor junction may be damaged.

Internal Feedback

The electrodes of a transistor are very close together and this and other effects cause unwanted feedback from the collector. In Figure 110, an imaginary capacitor connection from collector to base stands for the unwanted feedback. This is usually unimportant at low frequencies, but troublesome at high frequencies, where special precautions have to be taken to avoid oscillation or other effects.

Transistors for high frequencies may have a fourth lead, or shield, between base and collector [110]. It helps to reduce unwanted feedback.

Receiver transistors [11] are usually quite small, with insulated or metal cases.

They are made for radio frequency amplification, audio amplification, etc. They are also produced in small sizes for miniature equipment.

Power transistors [112] for RF and audio amplification are larger; usually they can be clamped to a metal plate or heat sink, to help avoid overheating. Some transistors are made in similar or matched pairs, in a single case. Other transistors are intended for computer ‘logic’ and various special applications.

Some Circuit Points

We use transistors in various ways. Some are shown in Figure 113. Here A has input to emitter and base, with output from collector and base. R is a load resistor across which power is developed, or a tuning coil or other device. Both input and output circuits use the base, so A is a *common and grounded base* arrangement.

B has input between base and emitter, and output developed across collector and emitter circuits. It is a *common and grounded emitter*. In the same way C is a *common emitter grounded collector* arrangement.

A, B and C are NPN transistors. D is a PNP transistor with input to base and emitter, and output developed across collector and emitter circuits. It is a *common emitter grounded emitter* circuit.

Some methods provide best power gain. Others operate better at high frequency. Some have high impedance input and low impedance output, or the reverse. The 'impedance' is the 'resistance' at operating frequency. Figure 114 shows the transistor as a current generator, with input impedance R1 and output impedance R2. Maximum useful power results when input and output circuits match R1 and R2.

Dynamic Operation

Figure 115 is a PNP common emitter amplifier, with base bias set by R1 and R2 and output developed across R3. C1 and C2 isolate the stage from other direct current points. R4 provides emitter bias to stabilize operation, and has a by-pass capacitor, C3.

Base current Ib is at some small steady value. Collector current Ic is also at a steady value, and emitter current Ie approximately equals Ib plus Ic. Currents are indicated without regard to polarity. When a signal to be amplified arrives through C1, base current swings up and down with each cycle, as shown in [116-Ib]. Slight increases in base current cause large increases in emitter-collector current. So collector current Ic swings up and down in value, developing an output voltage across R3.

A moving-coil meter would show the average currents [115], an oscilloscope dynamic conditions.

Audio Amplifiers

A signal is 'amplified' to make it stronger. An audio amplifier deals with frequencies from about 15 c/s to 15,000 c/s. Musical items mostly lie in the 50 c/s to 2,000 c/s range, but 'harmonics' must be reproduced for good results. The electrical output of a record-player pick-up may be a few millivolts. A loudspeaker needs much more power, so signals are amplified [117].

Figure 118 is a triode tube audio amplifier. There is 2 volts negative bias through R1 for the control grid. The tube passes 1mA from its cathode to its plate. Plate current flows through R2. From Ohm's Law ($E = I \times R$) the voltage dropped at R2 is 100 volts. Suppose a positive signal peak of 1 volt reaches the grid [119a]. The grid voltage is now —1 volt. Plate current rises to 1.5mA. So 1.5mA flows through R2. The voltage drop is now 150 volts, leaving 50 volts at the plate. Imagine that a 1 volt negative peak reaches the grid, B. This adds to the—2 volts present, giving—3 volts. Suppose plate current falls to 0.5mA. The voltage lost in R2 is now 50 volts, so the plate potential is 200–50 = 150 volts.

Hence by applying a signal which swings 1 volt above and below zero we have obtained an output or plate voltage which swings from 150 volts to 50 volts.

C1 is the usual coupling capacitor [120]. It interrupts any direct current path, but it has little reactance at audio frequency, and therefore lets signals pass. In the same way, C2 feeds another stage.

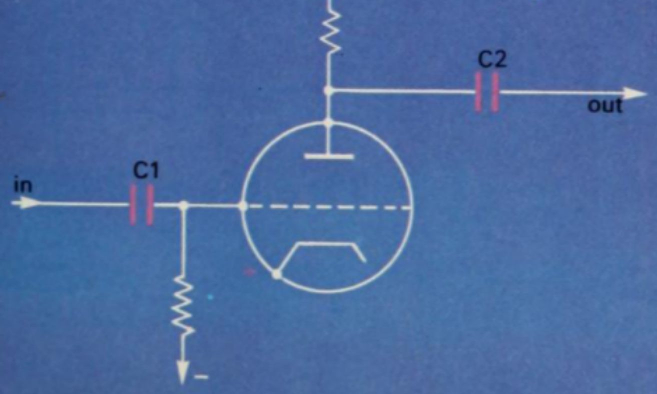
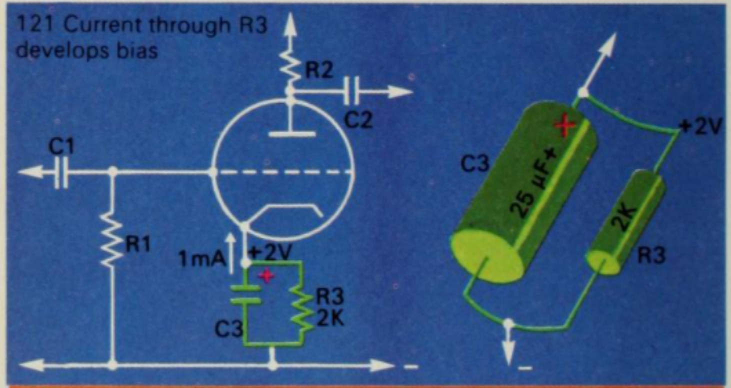
120. Coupling capacitors block DC

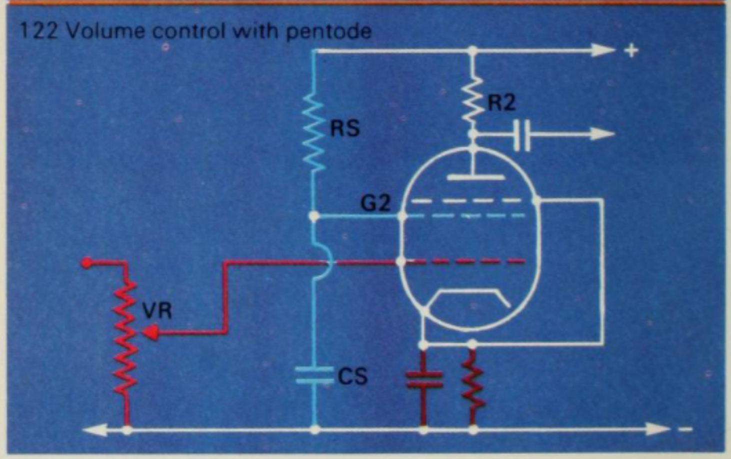


We need the control grid to receive a small negative bias voltage. Figure 121 has cathode bias resistor R3, which must drop 2 volts with 1mA passing. $\frac{E}{I} = R$. So R3 is 2,000 ohms.

C3 across R3 'by-passes' the cathode to ground at operating frequency. We often use a pentode and get higher 'gain' or amplification than from a triode [122]. VR is a potentiometer which allows any portion of the signal voltage to be taken, and so acts as volume control. RS supplies the screen grid G2, and CS is the screen grid by-pass capacitor. The suppressor grid is at the same potential as the cathode.



121 Current through R3 develops bias

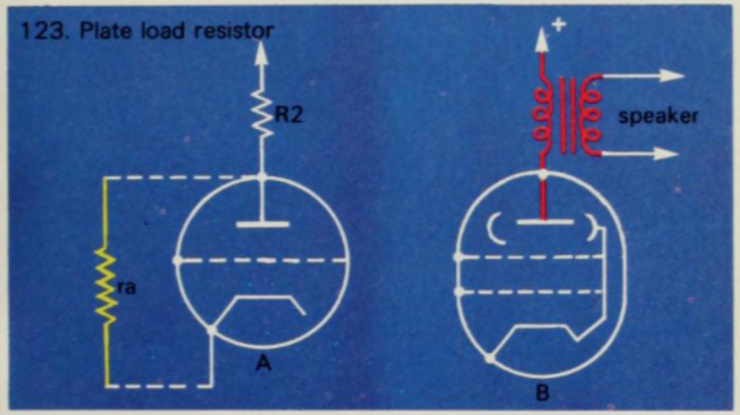


122 Volume control with pentode

Useful work is done by the plate load resistor R2—a signal voltage is developed across it. The tube, with resistors and other components, is termed a 'stage'. The 'stage gain' or amplification achieved is less than the amplification factor of the tube.

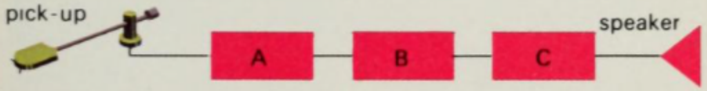
Imaginary resistor Ra [123a] represents the tube internal impedance and the plate load resistor R2 is chosen to suit this. With output tubes this is termed the 'optimum' (best) load. In Figure 123b it is furnished by the transformer and speaker. By choosing a suitable transformer ratio, we can provide any optimum load we choose.

Loudspeaker impedance will often be about 2 to 15 ohms. Transformer ratio is usually from about 15:1 to 60:1.



123. Plate load resistor

124 Three-stage amplifier



Cascaded Stages

We usually need more amplification than is provided by one stage, so use two or more stages [124]. Here A could be an initial voltage amplifier [122], B a further amplifier stage [121], and C an output stage working a loudspeaker.

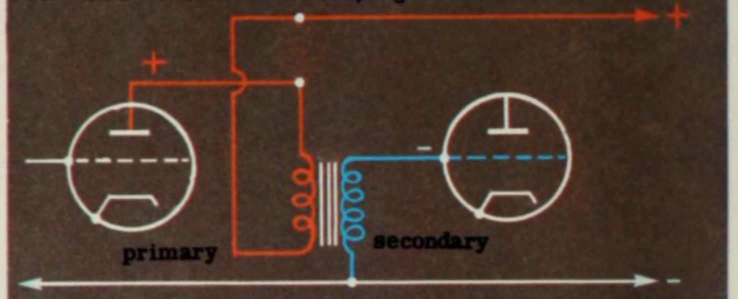
Transformer Coupling

In Figure 125 the transformer primary winding receives audio signals from an earlier stage. The secondary delivers signals to the next grid. This system is little used today, but the diagram will help to explain circuits given later. When one end of the secondary swings negative, the other end is positive. For the next half-cycle, this is reversed.

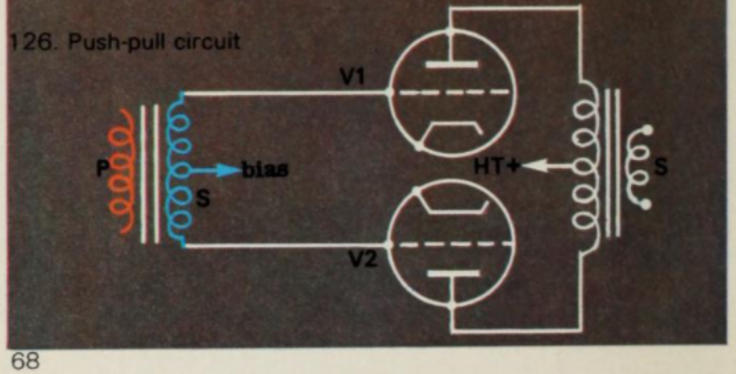
Figure 126 has a center-tapped secondary. For one half-cycle V1 receives a negative signal, but V2 a positive signal. So V1 passes less plate current, and V2 more plate current. During the next half-cycle the opposite occurs so that V1 current increases and V2 current falls.

The 'half outputs' from V1 and V2 go to the output transformer primary. They are combined and work the speaker, connected to secondary S. This is called 'push-pull'. We can also provide so much bias that plate current is nearly cut off except when a tube grid receives a positive signal voltage. This is called 'Class B' operation, and is less drain on the supply.

125. Audio transformer for coupling



126. Push-pull circuit

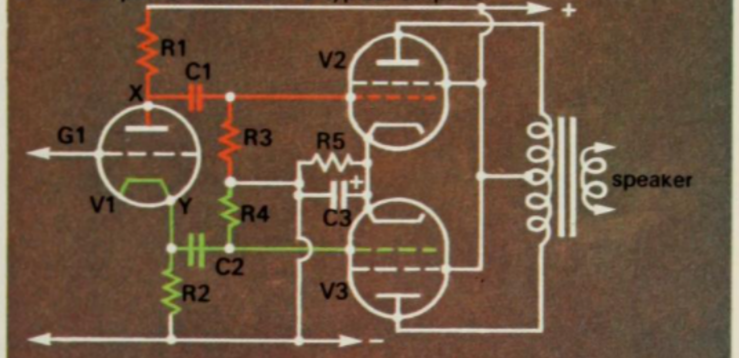


Resistance Capacity Coupling can be employed instead. In Figure 127, V1 receives audio signals at G1. When its plate current rises, the voltage drop in R1 and R2 increases. So point X swings negative, and Y swings positive. The result is like using a center-tapped transformer to supply V2 and V3. Signals go via C1 and C2. R3 and R4 are grid resistors. R5 supplies cathode bias.

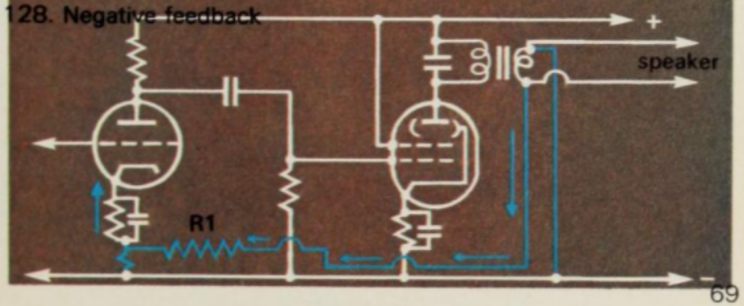
Negative Feedback

We can take part of the output signal and return it to *oppose* the original signal. This reduces distortion. Components such as capacitors have varying effects as frequency changes. Suppose the amplifier gives most amplification to high tones, or has too much treble. If we feed back signals to oppose the input, these top frequencies will be most strongly present. This will reduce high frequencies more than lower frequencies. The overall result is better 'fidelity', or faithfulness of amplification. In Figure 128, feedback is through R1 to the tube cathode.

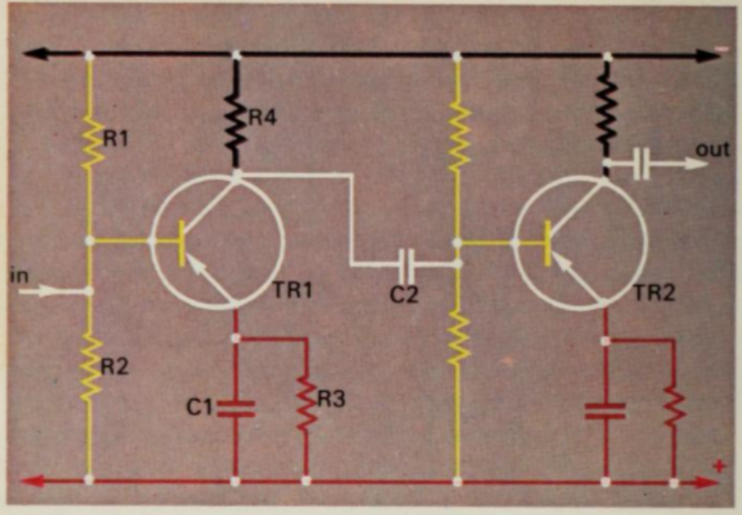
127. Push-pull circuit from a typical amplifier



128. Negative feedback



129 Two stages of transistor amplifier



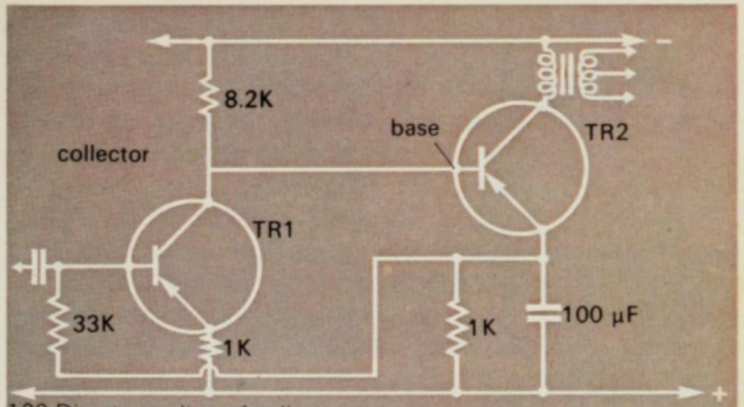
Transistor Audio Amplifier

Figure 129 has TR1 as audio amplifier. R1 and R2 are chosen so that a small base current flows and the PNP transistor base is slightly more negative than the emitter. R3 stabilizes the working conditions by emitter bias. If current rises, more voltage is lost in R3. So the emitter is more negative. This lowers the base-to-emitter voltage and reduces current. C1 by-passes R3 at working frequency.

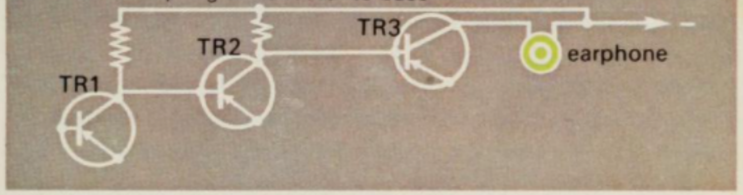
Changes in base current from the signal source cause changes in collector current. These develop a signal voltage across the load resistor R4. C2 has low reactance at audio frequencies, so signals arrive at the base of the second transistor TR2. Because of C2 the circuit is called 'capacitor coupled'. TR2 gives further amplification.

In Figure 130, potentials on TR1 collector and TR2 base are arranged to be the same, so that they can be directly connected. This is 'direct coupling'.

Figure 131 has three stages of amplification, all directly coupled. The collector voltages on TR1 and TR2 will be low, but can be sufficient for good results.



130 Direct coupling of collector to base



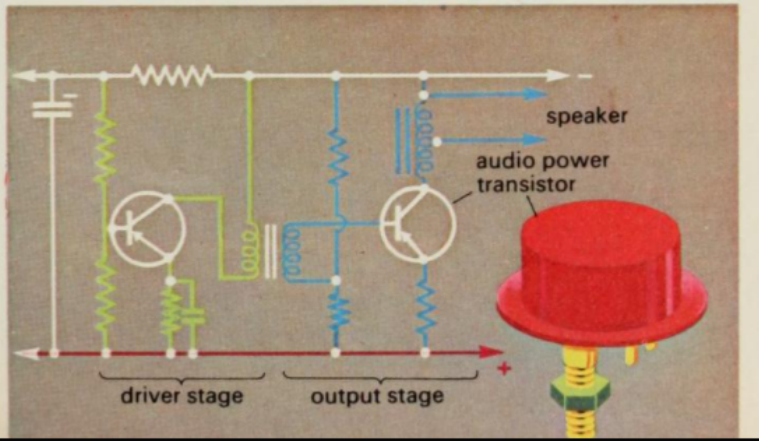
131. Direct coupling for miniature hearing aid

Car Radio

Figure 132 is a typical car radio amplifier. The output transistor needs a large current, but can work directly from a 12 volt battery. Only one transistor is present. It must amplify the whole audio cycle. This is termed Class A operation.

Speaker matching is by a tapped winding, instead of a transformer with separate primary and secondary. Such a tapped component is an 'auto-transformer'.

132. Car radio Class A output stage



Push-Pull Too

'Class B' working with transistors uses base bias which causes collector current to be lower than with 'Class A'. Figure 133 has resistors R1 and R2 to supply the bases of TR1 and TR2 through the transformer secondary. When audio signals drive TR1 into the conducting region for one half-cycle, collector current rises. For the other half-cycle TR2 is made to conduct [134]. This is the same as using electron tubes in push-pull. Battery drain is small at low volume, or when no signal is present, but rises to allow adequate loudspeaker volume when required.

Figure 135 shows an arrangement often found in miniature transistor receivers. The transformer has two secondaries, each driving one transistor. The transistors conduct on alternate halves of the signal cycle. No output transformer is needed, and a miniature 8 ohm or other speaker can be fed directly.

Stereophonic Amplifier

A stereo amplifier [136] has two channels. Volume control VR1 takes off the required signal level from a stereo pick-up, which supplies right and left outputs. Signals pass through R1 and R2 to V1A. V1A and V1B are assemblies of a triode-tetrode. R4 is the plate load, and C3 couples to the control grid of V1B. R5 and R8 with by-pass capacitors C2 and C5 provide cathode bias. R7 and C4 drop and smooth the supply for V1A. Transformer T couples to the speaker. Higher frequencies pass back through C6 and R9 to the junction of R2 and R3, to provide selective feedback controlled by VR2, for adjusting treble.

The left channel output of the pick-up goes to a second identical amplifier, and to the left speaker. A common power pack supplies both amplifiers, and the equipment is generally assembled on a single chassis.

During the recording, right and left channels depend on strength according to the position of the musical instruments or performers, and so a person listening to the speakers in Figure 136 obtains a sensation of depth. (See also page 104). A similar effect is obtained when listening to stereo broadcasts. Special means are used to provide right and left channels.

How a Radio Receiver Works

Radio waves travel 300 million meters a second, with the electromagnetic field and the electrostatic field at right angles. We speak of 'wave length' or 'frequency'. If the wave changes from positive to negative and back 300,000 times a second, there will be 1,000 meters from the crest of one wave to the next. So a wave length of 1,000 meters equals a frequency of 300,000 cycles per second (c/s).

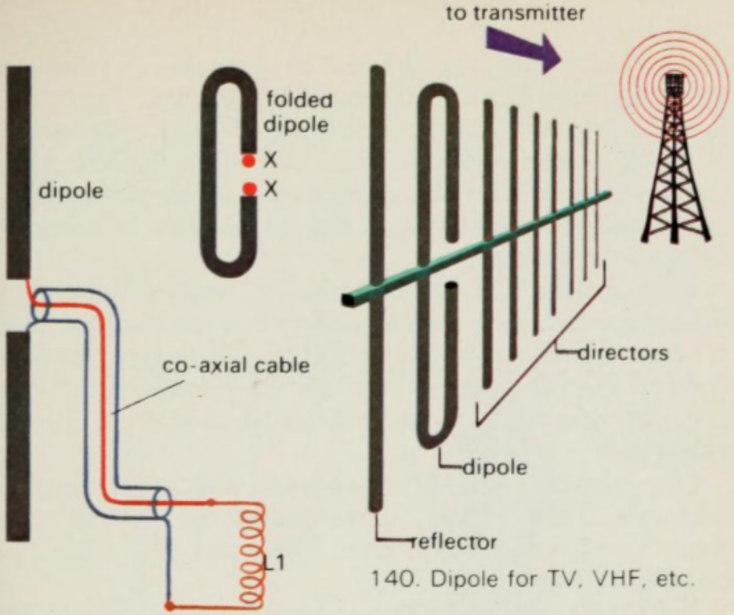
1,000c/s = 1 kilocycle, 1kc/s, or 1 kilo Hertz

1,000m = 300kc/s

1,000kc/s = 1 megacycle, 1Mc/s, or 1MHz.

A long wire can intercept part of the radio wave [37]. A signal voltage across the coil L1 induces a voltage in the coil L2, which is tuned by the variable capacitor VC1 to select the desired frequency.

Portable receivers may use a frame antenna [138]. The wave induces a signal voltage in the winding, which is tuned to the desired station by VC1. Small portables generally have a loop-stick antenna [139]. A winding is tuned by VC1. A smaller coupling winding X-X supplies a transistor.



140. Dipole for TV, VHF, etc.

Frame and loop-stick antennas are directive. They pick up signals best when an imaginary axis through the windings is at right angles to the direction of the transmitter. Pick-up is least when the axis points to the transmitter. This is used in direction-finding equipment. (See also page 122).

Television and Very High Frequency

Television and very high frequency (VHF) transmissions are of very short wave length, and so a dipole can be used [140]. It is about the same length as a half-wave. It is cut at the center and a 75 ohm co-axial or twin feeder connected. This carries signal currents to the coil L1.

A slightly longer element or 'reflector' can be put behind the dipole. This increases signal strength. Shorter elements or 'directors' may be positioned in front of the dipole. The elements may be arranged like an H, or an X.

Adding a reflector and directors changes the center impedance of the dipole, making it low. Therefore it is folded and the feeder is attached to X-X. The antenna has its elements placed vertically and horizontally to match the 'polarization' of the television or VHF signal.

Resonance

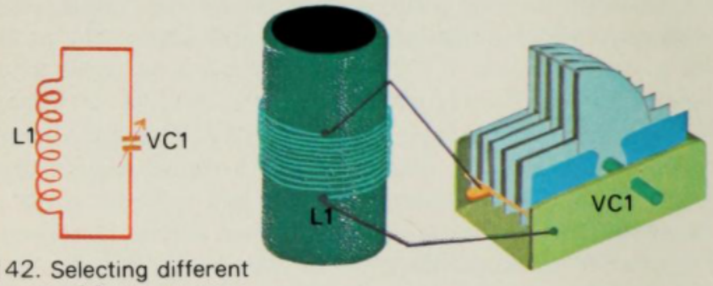
Radio transmitters use different frequencies. To choose a signal we tune a circuit to 'resonance' with it. Figure 141 is a parallel-tuned circuit. The 'resonant frequency' is that at which a signal voltage is developed across the coil. Altering the capacity VC1 changes the resonant frequency. VC1 is operated by a drive having a dial marked with frequencies, stations, or wavelengths.

With a fixed coil L1, moving VC1 from minimum to maximum capacity covers a band of frequencies. One band is about 1,500kc to 600kc, or 200 to 500 meters (medium waves). For other wavebands, we select coils of different size and inductance. Figure 142 has S1 to select L1 or L2. Other coils can be present.

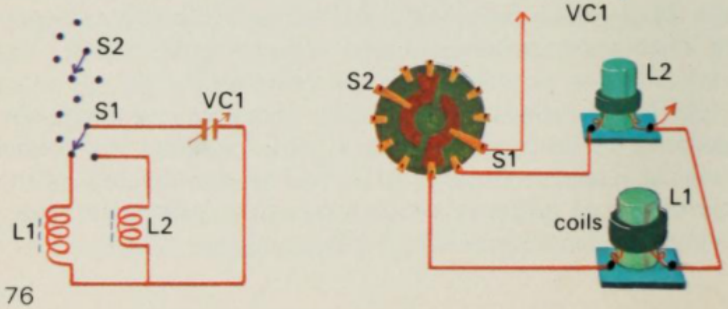
Often the coils have other windings, such as the coupling primaries. Then section S2 can choose these at the same time. A receiver may have several coils and a switch with a number of sections.

We may tune two or more circuits at once. Figure 143 has the antenna coil with primary P1 and secondary S1, tuned by VC1. Amplified signals go to Y and to the primary P2. The secondary S2 is tuned by VC2. The ganged capacitor VC1—VC2 has two sets of plates with a single shank. In some receivers, VC1 and VC2 both tune the same frequency—that of the transmission wanted. Two tuned circuits make the receiver more 'selective': we can better choose or select one station from others on near frequencies.

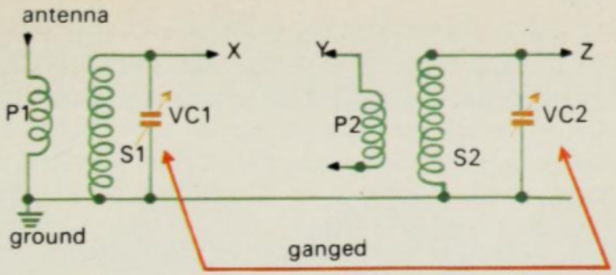
141. Parallel tuned current



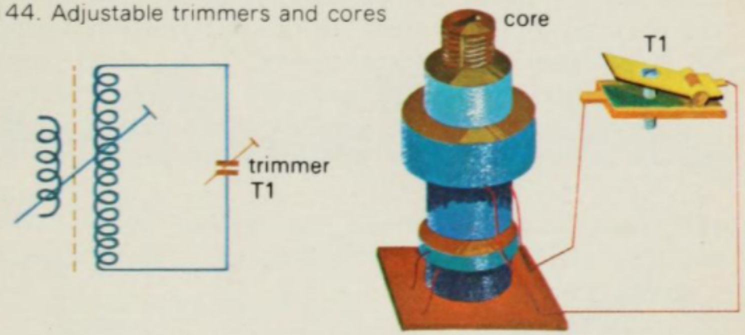
142. Selecting different bands of frequency



143 Ganged tuning

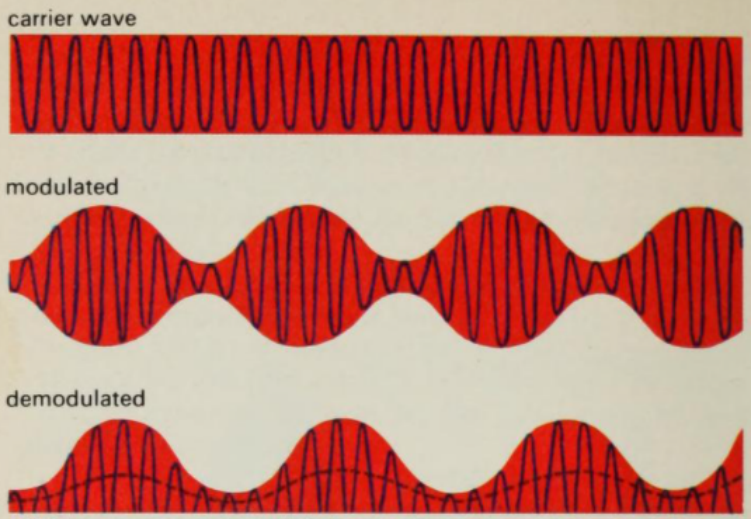


144. Adjustable trimmers and cores

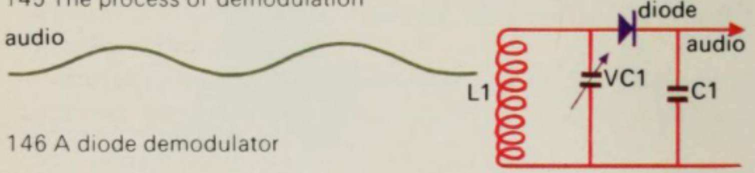


In superhet receivers, VC2 tunes to a different frequency. By a process called heterodyning or beating all stations produce a signal of the same frequency. Later circuits can be permanently tuned to this new frequency.

Often each coil has an adjustable core [144]. Its inductance can be matched with other coils. Coils generally have a trimmer T1. This compensates for stray circuit capacity in wiring, tubes, transistors, etc. The technician adjusts cores and trimmers so that the circuits 'gang' as exactly as possible together.



145 The process of demodulation



146 A diode demodulator

Demodulation

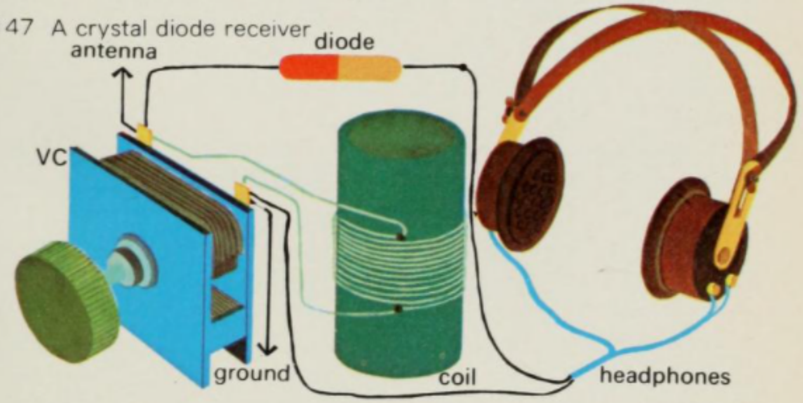
Putting the audible program into the radio wave is called 'modulation'. Recovering the sound from the signal is 'demodulation' or 'detection'. A radio wave with no modulation is of uniform strength [145]. Many broadcasts use 'amplitude' modulation. A radio wave modulated with a single tone is represented, but for speech and music the shape is very complicated. The modulated wave reaches a diode in the receiver. This lets current pass one way only, and so removes one-half of the modulated waves, as shown in the diagram.

The peaks of the radio signals are smoothed by later circuits, leaving a copy of the audio signal used to modulate the transmitted signal. In Figure 146, L1 is tuned to the desired station by VC1. Signal voltages resemble the 'modulated' wave. The diode produces the 'demodulated' wave. Capacitor C1 helps smooth the radio frequency peaks to produce the audio output. This could be heard with headphones, but as a rule will pass to an amplifier. When the signals are strong, enough output is obtained from the diode to work headphones [147]. This is the simple crystal radio receiver, similar in performance to the crystal sets so popular in the early days of radio. Semiconductor diodes were not then made, but an efficient detector consisted of a crystal, and cat's-whisker of thin wire. This resembled the point contact diode.

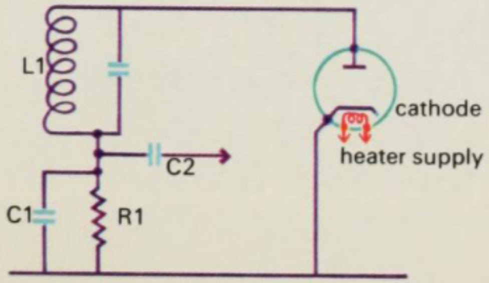
In tube receivers, a thermionic diode often provides demodulation. The heated cathode emits electrons, and the diode conducts from cathode to plate only [148]. The audio signal is developed across R1, and taken from C2 to an amplifier. L1 is usually the secondary of an 'intermediate frequency transformer'. The diode is generally part of a diode-triode or duo-diode-triode tube. The triode section is used for audio amplification. C1 is a radio frequency by-pass capacitor.

Nearly all receivers are 'superhets'—abbreviated from 'super-heterodyne'. In a superhet, an oscillator generates

147 A crystal diode receiver



148. Thermionic tube diode as demodulator



a signal which is made to beat with, or heterodyne received signals. This beating produces a fixed intermediate frequency, which passes to an amplifier with fixed tuned circuits. The frequencies are above audibility.

In Figure 149 the station desired is tuned in by L1 and VC1. L2 is an oscillator coil, tuned by VC2. If two frequencies are mixed, another frequency produced is equal to the difference. Suppose L1 is tuned to 200kc/s and L2 to 670kc/s. The difference is 470kc/s. Should L1 be adjusted to 1,400kc/s, and L2 to 1,870kc/s, the difference is still 470kc/s. By arranging that the *difference* between L1 and L2 frequencies remains unchanged, the same frequency output is obtained.

Figure 150 is a transistor mixer. L1 is tuned to the desired transmission. L2 transfers the signals to the base B. L3 is the oscillator coil, with windings connected to collector C and emitter E. R3 is for emitter bias.

If L1 tunes from 500kc/s to 1,500kc/s for medium waves, and the later stages are to operate at 470kc/s, then L3 tunes from 970kc/s to 1,970kc/s. The *ratio* of frequencies covered by L3 (970:1,970) is smaller than frequencies covered by L1 (500: 1,500) so VC2 is smaller, or has a capacitor C in series.

The desired frequency from the mixer is the 'intermediate frequency'. It is often around 455kc/s to 470kc/s, but much higher in receivers for high frequencies.

Switching can select other coils, for more wavebands [151]. Each coil can have its own trimmer and adjustable core.

Some receivers have a radio frequency amplifier before the mixer [152]. This is tuned to the desired station frequency ('signal frequency'). Tube receivers operate in a similar way, with the circuit arranged for tubes.

When signals have been converted to a chosen fixed frequency, they pass to the 'intermediate frequency' amplifier. Signals have been converted from radio frequency to this intermediate frequency. Later they will become a lower, audio frequency.

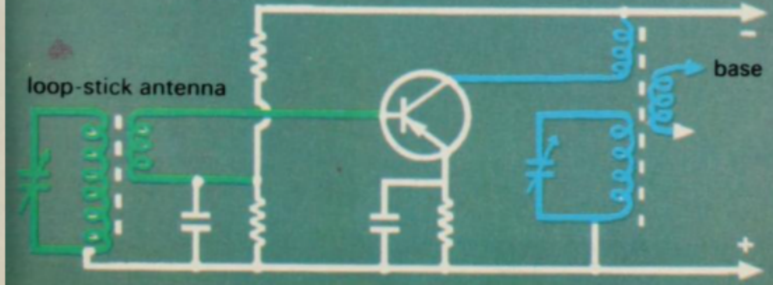
152. Radio frequency amplifier



IF Amplifier

The intermediate frequency transformer IFT1 [153] is permanently tuned to the intermediate frequency. After amplification by transistor TR1, signals pass to IFT2, then to transistor TR2. Each transistor has base supplies at X and Y. IFT3 feeds the demodulator diode D1. Audio signals are obtained across the volume control VR1. The sliding contact takes off audio signals as required.

Transformers, used to couple tubes, transistors, or other circuits, generally have two windings [154]. Each is permanently tuned by a fixed capacitor C. The cores are screwed in or out, allowing changes in inductance and precise adjustment to the correct frequency. Often the diode winding is not tuned [IFT3, Figure 153]. In some receivers, none of the secondaries is tuned.

A transistor can provide demodulation [155]. Audio signals are taken off through capacitor C. Thermionic diodes, triodes, and other tubes can be used as detectors. A semiconductor diode is very popular.

Figure 156 shows the stages of a receiver. The mixer converts all incoming signals to one frequency. The intermediate frequency amplifier tuned circuits help eliminate possible interference from other transmissions, and also raise the signal strength. The detector recovers the audio signal. But this signal is not yet strong enough to operate a loudspeaker and must be raised in level by the audio amplifier. The output stage or last amplifier increases the power even more, and signal strength becomes great enough to drive the loudspeaker. The same sequence of stages is often used in a tube receiver.

How a Television Receiver Works

The television station transmits two signals—one for audio and one for video. It would be possible to use separate receivers and antennas, one for audio and the other for picture reception [157].

But sound and picture frequencies are near each other, so we may employ the same antenna. We can also build the equipment as a single receiver, and employ some sections for both audio and video [158]. A radio frequency amplifier increases the strength of both audio and video signals, which are then separated. A common power pack provides current for both sound and picture sections.

TV Sound

The sound program may be provided by amplitude modulation of the carrier wave. The apparent strength of the wave changes with the audio signals—speech or music, etc. A detector recovers the sound, as with radio.

Sound can also be provided by frequency modulation. The amplitude of the wave remains the same, but its frequency is changed to carry audio signals. The sound is recovered by a 'ratio detector' or other frequency modulation detector. FM is used for television sound.

Frequencies

The frequency or wavelength determines the channel, just as in sound broadcasting [159]. As already mentioned, each station has two adjacent frequencies—one for sound, and one for video. We usually select the station by some form of rotary or other preset tuning arrangement, to which a variable fine tuner may be added.

The antenna is arranged to suit the channel we want, or we may have a combined antenna for two or more frequencies. The receiver antenna elements must be vertical or horizontal, in order to suit the 'polarization' of the signals [160], depending on the transmitter.

Color Television

Colors other than black can be made up by mixing three chosen colors. The additive combination of light differs from results obtained with pigments. Absence of all colors forms black. Red and green together provide yellow. Blue and red give purple, and blue and green provide blue-green [177]. When red, blue and green are present in an intensity of 40 percent, 26 percent and 34 percent, combining them provides white.

To transmit a color picture, the scene is scanned by cameras sensitive to three colors, which are reproduced in the receiver. Other colors are reproduced by changing the intensity of the red, blue and green channels.

Figure 178 is a color camera system. Mirror A lets red pass, but reflects blue and green. B reflects green but transmits blue, which is reflected by C. In this way the scene scanned is separated into the three colors, each providing its own signal. Other arrangements of selective mirrors may be used in order to obtain the desired result. The picture could be reproduced by three projection tubes, one each for red, green and blue, and each receiving the red, green or blue signal [179].

A shadow mask color tube has three separate cathode assemblies [180]. Each emits a ray controlled by the red, green or blue channels. A mask with many small holes is fitted inside the tube. The cathode rays come from slightly different directions, and after passing through the same hole strike different spots on the screen. The screen is coated so that rays from the blue channel gun strike areas producing blue. The cathode ray responsible for green strikes areas which produce green, and in the same way the red-producing ray strikes areas which cause red. The different color spots are so small that the eye blends them together into the various desired shades. Deflection coils move the three cathode rays over the tube face together.

Recording on Tape, and Disc Stereo

Tape recordings are much used for video or television picture recording, input and storage of computer information, and other purposes.

For sound recording, the signal level is raised with an audio amplifier [181], and taken to a recording head that has a winding and magnetic core with a narrow gap. Signals in the winding cause a fluctuating magnetic field across this gap.

The tape is polyvinyl chloride or other insulating material, coated on one side with tiny particles of iron oxide. It is often ¼ in. wide for sound, and 2 ins. for video.

181. Amplification and recording head

The unused tape has magnetic particles lying at random [182]. A mechanism draws the tape smoothly by the head gap. The particles are brought into magnetic alignment, and the tape has magnetized areas corresponding to the audio currents in the head winding.

For longer playing time, about half the track is used with the tape passing one way, and the remaining half with the tape reversed. Quarter-track recording is also used.

Frequency Response

Suppose the tape moves 15 ins. per second and a 15 cycle per second audio tone is recorded. There will be 1 in. tape length from one cycle peak to the next. If the tape moves at 7½ ips the distance would fall to ½ in. For slower tape speeds, the distance between peaks becomes smaller [183]. Raising the audio frequency also brings the magnetized sections closer to each other.

182. Magnetic recording on tape

A limit arises when the magnetic 'domain' length from one cycle to the next is smaller than the gap of the head. Then results soon fall off. To help avoid this limit, head gaps are very small—as small as 0.00025 in.

For music, or when a response up to 10,000cps or so will be wanted, the tape may move at 15 ips, while 7½ ips and 3¾ in. per second speeds suit less exacting needs, and 1⅞ ins. per second or slower movement allows satisfactory recording of speech, and gives long playing time with small reels. Two or more tracks also give longer time.

The tape is drawn by a 'capstan', a revolving roller. It may have a heavy flywheel and belt drive [184].

Playback

To hear the recording, the tape is wound on its original reel, then drawn past a playback head at the same speed as when recorded [185]. The magnetized tape causes a small magnetic field in the head core, thus generating an electrical output. When recording, audio currents produce a varying magnetic field; during playback, the varying of the magnetic field causes audio currents.

In many spheres, such as broadcasting, news gathering and so on, signals may be recorded from sources other than a microphone (e.g., from other tape recordings, from discs or from radio programs). Signals can also be recorded from television so that playback supplies a picture. Equipment for this is complicated.

For house current use, recorders can employ about four stages, resistance capacity coupled [186]. For better volume and fidelity, push-pull output may be provided.

Record/Playback

The same head may be used to record on the tape, and obtain signals when playing the recording. Switching of input and output circuits allows the same amplifier to be employed for both purposes [187]. With the switch at R (Record) the microphone provides the amplifier input.

For playback (P) the head is switched to the amplifier input, and the output to a loudspeaker. There are two 'outputs', because that for the head is taken from an earlier stage—the full power of a large amplifier is not used while recording.

Recording Level Indicator

An indicator shows us that recording is at a suitable level. In Figure 188, X goes to an audio amplifier. The diode rectifies audio signals, building up a negative voltage. This reduces plate current, so the deflector plates become more positive. Electrons from the cathode strike a target, and the beam width is controlled by the deflector plate potential. Hence the display depends on the average audio power, and we adjust volume for correct recording.

If we apply a high frequency 'bias' oscillation to the head while recording, results are improved. The power output stage can be utilized as a bias oscillator. In Figure 189, C1

OTHER APPLICATIONS OF ELECTRONICS

Counting Electronically

Counting circuits record the number of objects produced by a machine, the number of oscillations each second, or speed, or distance. They also show the results of addition, and other operations.

Mechanical Counter

An odometer shows miles covered. An electricity meter counter shows units consumed. Seeing what actually happens mechanically is useful.

Revolving mechanical counters are often used [201]. Shaft A rotates to display numbers up to 9. When it has rotated from zero to the 10th unit, tooth X rotates the wheel on shaft B one place, moving the tens counter from 0 to 1. This happens with each revolution of A. One complete turn of B rotates the hundreds counter one place, and 99 revolutions of shaft A, counting up to 999, can be accommodated.

A solenoid, pawl and toothed wheel could rotate shaft A. An electrical circuit closes, current flows, and the pawl moves the counter one place. Such devices are occasionally connected after high-speed electronic counters, to record very large numbers.

What actually happens? As shown in Figure 202, each time the full 'units' capacity is reached, one impulse is transferred to the 'tens' counter and the units return to zero.

Similarly, the full capacity of tens results in one impulse being transferred to the 'hundreds' position.

Electronic circuits giving one output pulse for a number of input pulses similarly form a section of a counter.

Mechanical processes that are repeated can be counted by a closing circuit [203]. The counter is electrically operated. Current from the supply reaches the solenoid each time the circuit closes, moving the units counter. The switch may be operated by weight, or by any means.

Electronic methods perform the same function more reliably, easily and rapidly. Figure 204 has an infra-red light beam falling on a photocell. This causes an electrical output which is amplified. When the beam is interrupted an impulse is passed to the units counter. Every tenth impulse is transferred to the tens counter, and so on.

A ring counter gives one output pulse for a selected number of input pulses—for the decimal system, one output pulse for ten input pulses [205]. We may use controlled rectifiers, thyratrons or other devices which remain stable until 'triggered' by an input pulse, retaining the new state until returned to the original.

Pulses reach the rectifiers through diodes D. Diodes except the first have a large bias voltage from the associated controlled rectifier. So the first pulse triggers only the first rectifier. This one conducts, causing a low voltage across the second diode. Hence the next pulse can trigger the second controlled rectifier, and ten pulses progress along the circuit. The last rectifier gives an output pulse to a 'tens' panel, and back to the input to restore the units circuit to zero. Six panels would count up to 999,999.

Trochotron and Dekatron

The trochotron has a central cathode, ten grids, ten targets or plates, and ten electrodes [206]. Grids 1, 3, 5, 7 and 9 are connected to one circuit, and 2, 4, 6, 8 and 0 to another circuit. Suppose the electron stream is at 0. An input pulse cuts off the stream, while grid 1 causes the beam to form on target 1. Each subsequent pulse moves the beam around one step. The final position can transfer one pulse to a 'tens' counting tube. The trochotron can count one million a *second*.

The dekatron has ten cathodes. Ionization causes the discharge path to glow [207]. The X pins are joined and fed from pulses to be counted. Pulses reach the Y pins through a delay circuit. When a pulse pin X near 7 deflects the discharge clockwise, a further deflection arises as the delayed pulse reaches adjacent pin Y. When the pulse ceases, the discharge has been stepped to 8. This can be repeated as many times as required.

The Binary System

We need not count in the form '1, 2, 3, 4, 5, 6, 7, 8, 9, 0 and carry 1'. Electronically there are advantages in counting in other ways. The binary system counts by using 0 and 1. Figure 209 shows two counters, one with 0–9 dials and one for binary. They have rotating pointers. We record objects up to 9 on A of the decimal counter. For 10 we see there is no higher number than 9 here. So we set A to zero and transfer 1 to B. We proceed in this way to 999.

With binary the highest number on any dial is 1. When one object arrives, this is put on A, giving 000,001. For object 2 there is no number higher than 1 on A. So we restore A to 0, carrying one to B, to get 000,010. For object 3 we put A to 1 again: 000,011. The next object results in 0 for A and carry 1, 0 and carry one for B, turning C to 1 = 000,100. Similarly, 5 = 000,101; 6 = 000,110; 7 = 000,111; 8 = 001,000; 9 = 001,001, 10 = 001,010, and so on.

Each time we move to the left in decimal counting, we multiply by 10 [210]. Each move to the left in binary multiplies by 2 because there are two possibilities for each column (0 and 1). To register numbers from 0 to 9 in decimal systems, we need *ten* reliable states for an electronic device. For binary, we need *two*—for 0 to 1.

A lack of voltage or current can represent 0, and full voltage or current can show 1. The result is a definite 'on'—'off' system for each column [211].

Computers

Relays close when energized [212]. Early computers used thousands of relays. Vacuum tube plate current is low with strong negative grid bias, but high with little bias or a positive pulse. The PNP transistor does not conduct with a positive signal at the base, but conducts with a negative signal,

Bi-Stable Multivibrator or Flip-Flop Circuit

Figure 214 shows a circuit that will remain in either of two conditions. If transistor A base is negative, transistor A collector current is large, hence collector C1 is positive, and so is base B2 of transistor B. As a result, collector C2 current is small, and there is little voltage drop across R2, and so base B1 is held negative. An input pulse reverses these conditions. Collector C1 no longer passes a large current and the voltage drop in R1 has fallen, shifting base B2 of transistor B in a negative direction. This transistor conducts, so the increased voltage drop across R2 makes collector C2 positive, and therefore base B1. The circuit thus remains in either state, until a pulse is received. Output can be taken from collector C2.

Any device which can be placed in a steady 'on' or 'off' condition can be used for counting. Binary counters divide by 2 [215]. Decade circuits divide by 10. In counting frequencies, an electronic gate (switch) allows signals to pass for a known interval, while they are counted.

Geiger counters help measure radiation intensity. A central plate of high positive potential is used in an envelope of gas mixture [216]. High velocity particles cause ionization. Liberated electrons pass to the positively charged plate, causing small output pulses.

Analog to Digital Conversion

'Analog' information represents a fact in an analogous way. A voltmeter pointer or speedometer pointer position is an analog of voltage or of miles per hour. One means of converting analog to binary digital is shown in Figure 217. A photo-electric eye registers divisions as they pass.

The second method shown has sensing devices opposite the white 0000 sectors. Black sectors are 1. Rotating the disc one step at a time produces the binary count—0001, 0010, 0011, 0100, etc.

Output-Producing Circuits

Outputs are provided by oscillators, amplifiers, and other circuits, as needed.

If an inductor L and capacitor C are in parallel [218], and a potential momentarily arises in the inductance, the inductor electromagnetic field stores energy. When the field collapses, an e.m.f. charges the capacitor. The capacitor then discharges, returning power to the inductor. Resistance and other losses cause the oscillations to get smaller and finally cease.

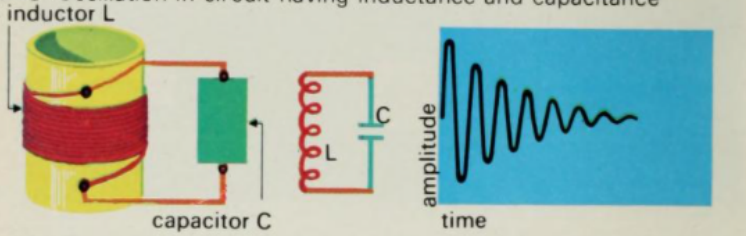
The oscillation frequency or 'resonant' frequency in cps

$$\text{is } \frac{1}{2\pi\sqrt{LC}}$$

where L is henrys and C farads.

Resonance occurs when inductive reactance is equal to capacitive reactance.

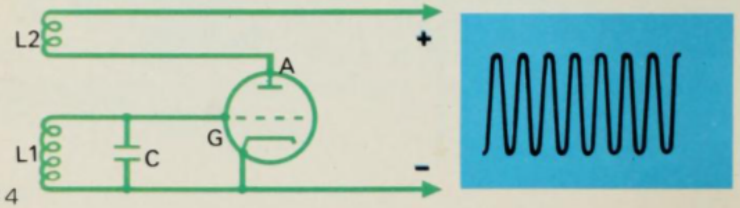
218. Oscillation in circuit having inductance and capacitance



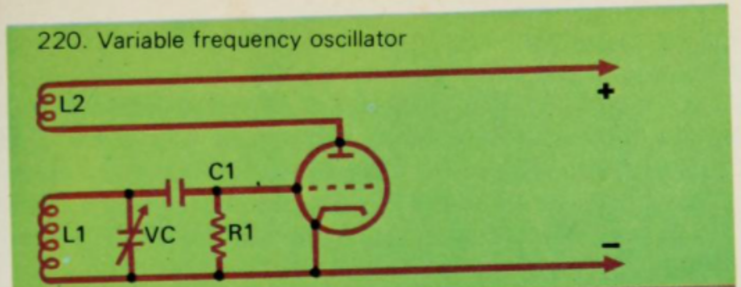
Sustained Oscillation

If we add a device which cancels circuit losses, oscillation continues. Figure 219 has resonant circuit L1 and C. L2 is a coupling winding returning energy to L1. The e.m.f. across L1 reaches the control grid G. An amplified signal arises at plate A, and if L2 feeds back energy to L1 in the correct phase this sustains oscillation.

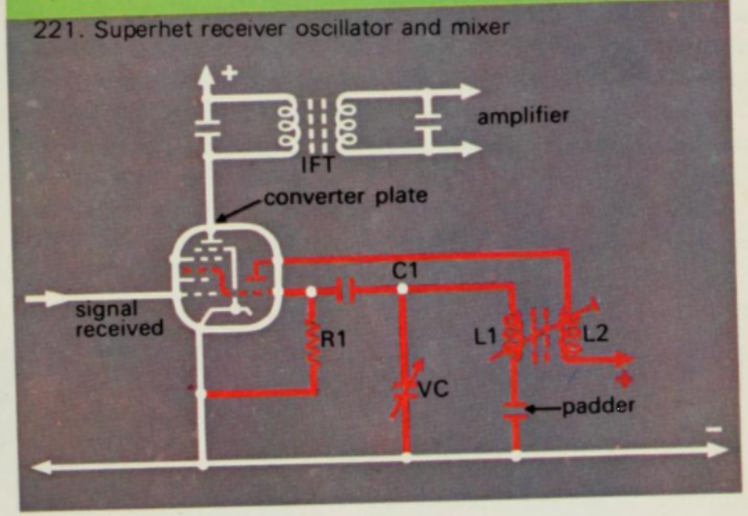
219. Positive feedback to sustain oscillation



220. Variable frequency oscillator



221. Superhet receiver oscillator and mixer



A variable capacitor VC [220] allows tuning over a band of frequencies. The inductor L1 is changed for other wavebands. Rectification between cathode and grid causes a negative charge to appear across C1 and R1, producing stable operation.

A circuit like this is found in most tube radio receivers. The oscillator is the triode part of a converter, or other mixer. Figure 221 has R1, C1, VC, L1 and L2 with the triode section. The triode grid also controls the flow of current to the converter plate. L1 is tuned so that the difference between the received signal and frequency of L1 is always the same. Mixing in the converter results in a signal of fixed frequency appearing at the plate. This output passes to the fixed tuned circuits of the intermediate frequency transformer IFT. The 'padder' helps make the coverage of L1 suitable.

Signal Generator

Oscillating circuits can produce a radio frequency output or radio signal. A signal generator is a source of low-power energy that we can tune to any frequency.

Figure 222 has R1 and R2 to provide suitable base working conditions, with emitter resistor R3. L1 is tuned with VC and has a feedback winding L2 to the base B. The output from the arrangement in Figure 222 is a radio frequency signal without modulation. If it is tuned in on an ordinary receiver, no sound is heard. It is termed an 'unmodulated' or 'carrier wave' output. When we need a wave modulated by an audio tone we can add an audio oscillator [223]. This modulates the RF signal. When the signal is tuned in, the audio tone is heard.

A use for the signal generator is in aligning the intermediate frequency transformers of a receiver [224]. Most IFT's have two tuned circuits, generally with adjustable cores for the coils. Trimmers could be used instead. We set the generator tuning to get the required output—often about 455kc/s. This is fed into the receiver circuit at a point ahead of the IFT circuits to be adjusted. Then we rotate the cores or trimmers with a trimming tool. Best output from the receiver shows that the circuits are suitably tuned.

The antenna and other tuned circuits in a receiver can be adjusted in this way. We set the generator to suitable frequencies, and adjust trimmers and cores so that wavelengths or frequencies are tuned in at the correct positions on the receiver dial.

Figure 225 is the radio frequency section of a signal generator for the 10–300 megacycle range, and is thus suitable for very high frequency alignment or testing.

Multivibrator

The 'multivibrator' circuit produces a wide range of outputs, according to working conditions. It uses two vacuum tubes, or two transistors [226]. Transistor A has collector resistor R1 and base resistor R2. B has R3 and R4. C1 couples A collector to the base of B, while C2 couples B back to the base of A. With each transistor driving the other, frequency depends largely on capacitor and resistor values. This circuit can produce outputs for receiver or amplifier testing. The multivibrator will produce both sawtooth and square waves.

Phase-Shift Oscillator

If the voltage of a PNP transistor base is moved positive, collector current falls. Less current flows in the collector resistor, less voltage is dropped here, and the collector potential moves negative. Feedback from collector to base would be in the wrong phase to sustain oscillation—negative when it should be positive, and vice versa. Two transistors, each reversing phase [226], overcome this.

So for a single transistor or vacuum tube we may need some way of reversing phase. Feedback then sustains oscillation. Capacitors and resistors can form a phase-shift circuit for this purpose [227].

Bias Oscillator

Figure 228 obtains oscillation by suitably connecting the primary P and secondary S of the oscillator coil. For example, reversing the connections to S would reverse the phase of feedback to the base. The frequency of oscillation depends on the windings and value of C1. The primary P is tapped for a suitable collector load. Output is taken from another tap through C2 to provide high frequency bias when tape recording.

Electronic Clock

Figure 229 is a circuit producing low-speed output pulses of great accuracy of occurrence. A piezo-electric crystal oscillator runs at set frequency, and this is stepped down by dividers, to obtain the low-speed output pulses used for timing. The apparatus is controlled by the crystal.

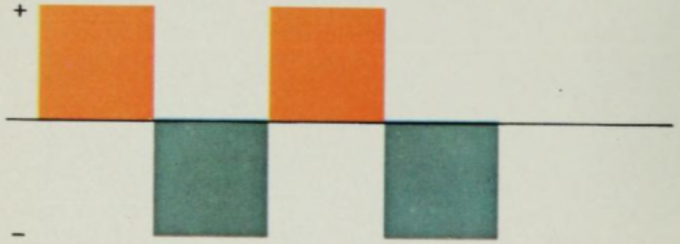
230. Two cycles of a sine wave



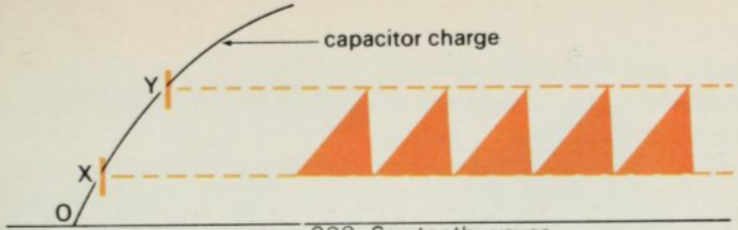
231. Two cycles of a square wave

Waveforms

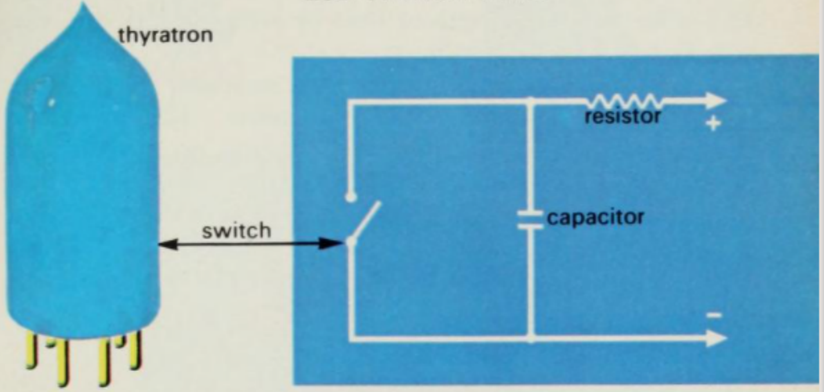
An important wave is the sine wave [230]. This is obtained from alternating current supplies. The voltage rises smoothly to a maximum, and falls through zero to a negative value of equal amplitude. If we used an oscilloscope, we would see this happening 60 times each second with 60 cycle per second house supplies. The sine wave could be of other frequency, perhaps a pure audio tone, from a signal generator. 'Frequency' means complete cycles per second.

The smooth rise and fall of voltage and current enables mathematical relations to exist between the peak voltage or current, and the effective voltage or current (which is less). An instrument such as an AC voltmeter cannot respond to the rapid changes, and indicates the effective value. The square wave is useful for test and other purposes. It rises and falls almost instantaneously [231]. It can be produced by generating a sine wave and clipping positive and negative peaks.

The sawtooth wave is quite different [232]. If a capacitor is charged through a series resistor from a high potential



232. Sawtooth waves



233. Circuit for producing sawtooth waves

the voltage across the capacitor rises. One section, from X to Y, is fairly linear ('straight'). To produce sawtooth waves, the capacitor is discharged rapidly when it reaches Y, so the voltage falls to that at X. The capacitor charges again. This is repeated. Rise from X to Y should be without curvature. Descent to X should be almost instant.

Figure 233 shows a circuit for producing sawtooth waves. Current flows through the resistor into the capacitor, so that the charge rises (X to Y). The speed and extent of this rise can be adjusted by selecting capacitor and resistor values and the supply potential. When the charge reaches Y the switch is closed, discharging the capacitor. The switch is then opened, so the charge begins to rise again. In practical circuits, a thyratron can replace the switch. This tube conducts abruptly each time the potential reaches a pre-arranged level (see page 53).

Sawtooth waves are used in an oscilloscope. The slow rise of voltage makes the cathode ray traverse the screen, and the ray returns almost instantaneously when the capacitor is discharged, to begin another sweep.

Radar and Other Devices

Radio waves travel outward at 300 million meters or 186,000 miles per second.

So if a signal has a frequency of 300 million oscillations a second, the wave length is 1 meter [234]. The radiated signal has magnetic and electric fields at right angles. Unless reflected by the earth or bent by ionized belts, etc. the signals travel in straight lines.

A directional antenna or dish gives strongest reception of signals when pointed at the transmitter. The direction-finding receiver Rx [235a] takes bearings on transmitters Tx. These bearings on a chart cross to show the receiver position.

If the position of a transmitter Tx is not known [235b] bearings are taken from two positions. The lines cross at the transmitter.

Radio Astronomy

Observations made directly by ordinary telescope are confined to visual frequencies. Photographic time exposures record dim stars. Visible light and similar rays are absorbed by haze, but radio frequency radiations are of longer wave length, and are not hindered.

Remote galaxies and systems generate radio 'noise'—that is, random bursts of radio-frequency radiation. A directive antenna can locate the bearing of these. The dish reflector [236] may be hundreds of feet in diameter, and concentrates signals on an antenna. The dish can be pivoted. Signals pass to a sensitive receiver, and are recorded. Radio noise sources are often located near systems observed optically [237]. Sources of radio noise have been mapped at enormous distances, beyond the reach of an optical telescope and where no systems can be seen or photographed. In this way, information has been gathered outside the range of optical observation. Radio waves travel 186,000 miles per second. Radio telescopes have located galaxies over 4,500 million light-years away.

Radio Detection And Ranging (Radar)
If aircraft are in the path of a radio signal, some energy is reflected as an 'echo' back to the transmitter. In Figure 238 a transmitter radiates 1 micro-second pulses T of very high frequency at 2,500μs intervals and followed by periods in which a receiver picks up echoes E. As signals travel at known speed, the distance of an object is measured by noting the time taken for the echo to return. The interval can be shown by a cathode ray traveling rapidly from left to right across the screen [238]. A scale can be marked in distances.

Plan position radar equipment shows the distance of an object. By rotating a directional antenna [239], and causing the trace to scan from the center of the tube outward and rotate with the dish, the compass bearing of an object is shown, as well as its distance. As the antenna and trace revolve, echoes from surrounding features build up a plan or picture on the screen. The cathode ray may be brightened at regular intervals to produce range rings [240]. These can be expanded or contracted at the same time as the trace speed is adjusted, to change the 'scale' so that large or small areas can be examined. Bearing marks can also be provided [240].

Some precision-approach radar for ground aid to landing aircraft has two antenna systems. One directive system sweeps a narrow beam in a horizontal plane, and the other sweeps a vertical plane [241]. One instrument low-approach system for landing aircraft has a vertical signal to mark the runway, and a horizontal signal for the landing path. Beacons radiate vertically at 'outer', 'middle' and 'boundary' positions [242].

Sonar (Sound Navigation And Ranging) systems allow the distance to be found to the seabed and to a submerged vessel. High-frequency signals are amplified and passed to an electronic switch circuit, which directs them to a transducer [243]. Echoes are diverted to a receiver by the electronic switch, and the delay allows the cathode ray tube to give a distance reading.

Pictures by Radio (Facsimile Transmission)

News pictures can be sent across the world by radio. A picture secured to a rotating drum can be scanned electronically in lines which lie closely side by side [244]. Radio signals corresponding to light and dark areas are produced. At the receiver, a drum rotates at the same speed, and a writing head slowly moves the length of the drum, producing light and dark marks. So a complete picture is built up during many rotations of the drum.

Radio signals for pictures may be tape-recorded for storage, or for re-transmission when long-distance short-wave radio conditions are suitable. To synchronize a tape, the tape can have two tracks, one for picture information, and the other recording from a crystal oscillator. These signals are amplified and applied to a synchronous motor, the speed of which depends on the frequency [245]. A second motor receives amplified signals from a second crystal oscillator, and rotation operates a differential gear. If the motor running from the taped signals changes speed, the differential gear cage turns. This operates a correction circuit which increases or reduces the tape motor speed. So movement of the tape is synchronized.

246. Radio telemetry for temperature information

Telemetry is conveying information from instruments to a recording device at a distance—for example, from a satellite to earth. One way is to convert the 'information' into an audio tone, which changes to convey data. As an example, a thermocouple produces a voltage which changes with temperature. This can be taken to an oscillator whose frequency changes with voltage. The tone is transmitted, picked up by a ground station, and decoded [246].

Satellites

Satellites can investigate conditions far above the earth, and send radio reports to ground stations. One employs an orthicon camera to take cloud pictures [247]. Pictures may be taken in daylight and are stored on tape in the satellite. When it is within range of a receiving station, the taped signals are radiated for decoding and printing.

A satellite can measure electron temperature, galactic radio noise, earth-generated noise, oxygen density and other factors. In Figure 248 winged booms with solar cells produce current to operate internal equipment, and to charge storage batteries. Loop, extended and other antennas transmit and receive signals, to convey information to earth, or receive commands. Channels for radio signals are in the high frequency bands. Sun attitude cells receive illumination according to their bearing with relation to the sun's rays, and this can convey information on the tilt or rotation of the satellite.

A relay satellite can be situated thousands of miles above the earth, in a stationary orbit. Solar cells generate power. The satellite has antennas and equipment to receive transmissions, and re-transmit them on a frequency [249]. Transmissions are received on the ground by a large paraboloid dish, which reflects signals to a focus at a pick-up point. The efficiency of such dish parabolics is many thousands of times greater than that of an ordinary antenna and the receiver is specially designed for high sensitivity.

Measurements in Electronic Circuits

Various measurements allow the working conditions of a circuit to be found. The simplest measurements are those which show a steady or uniform voltage or current.

A moving-coil meter winding is in a strong magnetic field, and receives current through hairsprings [250]. It turns slightly when current flows. This meter has a 'full scale deflection' or FSD of 6mA. A current of 6 milliamperes would move the pointer fully across the scale.

Current Through a Resistance = Voltage Divided by Resistance. So resistors in series with the meter allow various voltage ranges to be read.

Figure 251 has R1, R2 and R3 for ranges of 2.5 volts, 10 volts and 100 volts, and a 0.25mA meter. So R1 is 10,000 ohms; R2, 40,000 ohms; R3, 400,000 ohms.

To measure heavier currents we connect a resistor across the meter. Suppose $\frac{9}{10}$ of the total current flows through this resistor, and only $\frac{1}{10}$ through the meter [252]. The original range is multiplied 10 times.

The multi-range instrument in Figure 253 has a switch with nine positions.

Positions 6, 7, 8 and 9 move along a tapped shunt for higher current ranges. The shunt is permanently across the meter. Suppose the meter has a FSD of 0.5mA, or 1mA FSD with the shunt added. Then R1 is 2.5k for 2.5 volts, R2 is 10k for 10 volts, R3 is 90k for 100 volts (10k already present) and R4 is 150k for 250 volts (10k plus 90k already in the circuit).

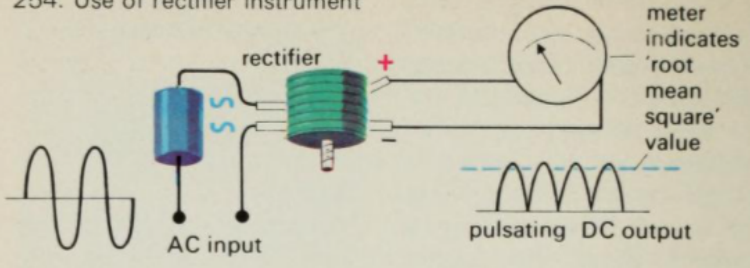
254. Use of rectifier instrument



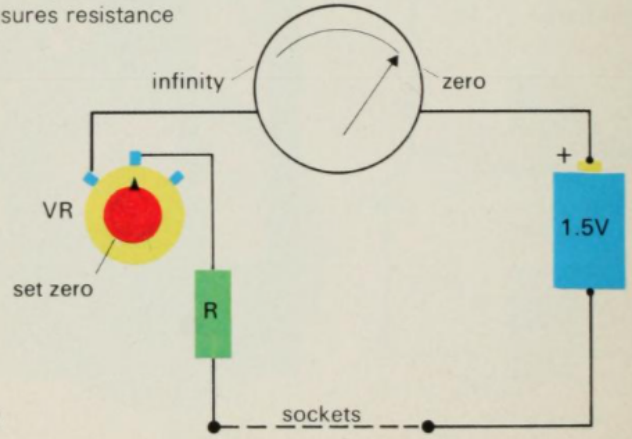
Alternating Current

The moving coil cannot respond to AC. For AC ranges we add a rectifier [254] to a meter like that in Figure 250. This changes AC to pulsating DC. The meter shows the 'Root mean square' or effective value—what we generally need to know. 'Effective' value is that which has the same heating effect as equivalent direct current.

Resistances Too

We may need to measure resistance values. We use a battery, variable resistor VR, fixed resistor R, and the meter all in series [255]. We join test leads from the sockets together and adjust VR until the meter reads full scale. This is *zero ohms*. If we separate the test leads, no current flows, and the meter reads zero current, which is infinitely high resistance, or *infinity*. If we take the leads to a resistor, or circuit being tested, the meter will indicate some intermediate current, depending on the resistance in the circuit. From Ohm's Law we can make a scale for the meter, showing resistance values.

255. This circuit measures resistance

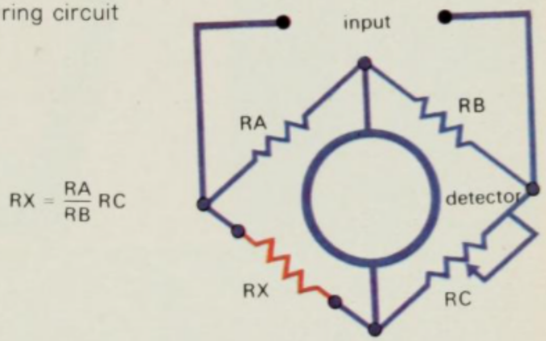


A 'bridge' [256] permits accurate determination of resistance.

If $\frac{Ra}{Rb} = \frac{Rx}{Rc}$ there is no e.m.f. across the detector.

Rx is is the resistance to be measured and Rc an accurately calibrated variable resistor, or a decade box with values selected by switches. Ra and Rb are of known value or ratio. We find the value of Rx by noting what value of Rc produces no current at the detector.

256. Bridge measuring circuit



Power Also

Power in Watts = I^2R that is, *Current Squared* × *Resistance*. A known resistance in series with a meter allows watts to be found [257]. This is handy for some uses. Suppose R is 50 ohms and I is 2 amperes: 2 × 2 × 50 = 200 watts.

Sometimes voltage drop across a resistance may be more readily found. Suppose R is a 2 ohm resistor replacing a loudspeaker and E proves to be 3 volts. From $watts = \frac{E^2}{R} = \frac{3 \times 3}{2} = \frac{9}{2}$ we find that our amplifier is delivering 4.5 watts of audio power.

For direct current circuits, a DC meter is used. But for radio frequency, audio frequency, or alternating current circuits we must use a meter of appropriate type. Popular multi-range meters have scales, with range, AC/DC and ohms controls [258]. The switches bring into use the various parts of the circuit wanted.

Millivoltmeters

A vacuum tube plate current changes with grid voltage. A plate meter can be calibrated in terms of voltage at the grid. Voltages to be tested are placed across a high value resistor R1 [259]. A range switch with resistors R1, R2, R3, etc. could be added.

A vacuum tube voltmeter allows extremely small voltages to be measured. The tube is very sensitive to grid voltage,

and so it has a cap for this connection, to avoid leakage.

Sensitive meter circuits are used to investigate exceedingly low voltages and currents, and to test circuits where current is too small for a moving-coil meter.

Sensitivity can be raised by using an amplifier [260]. V1 is the vacuum tube. Changes in plate current produce a change in voltage across R2. This voltage is taken across R3 to V2, so changing plate current through R4. With no input, VR1 is adjusted until the current through R5 is equal to that through R4, when the meter gives no reading. current or voltage at the 'Test Points' produces a reading on the meter. VR2 adjusts sensitivity.

The amplification from transistors allows sensitive measuring instruments to be made [261]. Here, a low voltage or current at 'Test' changes TR1 current, which flows through R1. This changes TR2 current through R2, which in turn changes TR3 current through R3. VR1 is first set for no reading, with no input. Zener diodes stabilize the emitter voltages of TR2 and TR3 because they maintain a certain voltage. The three transistors each amplify in series. Balanced circuits are often used to avoid errors due to transistors drifting.

Oscilloscope

A cathode ray tube will display visually changes in current or voltage not shown by a meter. The cathode ray strikes the screen center, producing a bright spot [262]. Applying an alternating potential to the vertical plates deflects the beam up and down, making a vertical line. This deflection shows voltage amplitude. An alternating potential on the horizontal plates results in a horizontal line. By combining horizontal and vertical deflections we can display instantaneous events in a continuous pattern.

If we let an AC potential cause vertical scan, with horizontal scan from a sawtooth oscillator, we get a picture of the wave [263a]. Or we can take inputs to vertical and horizontal plates, causing wavy patterns in which the number of loops shows the relationship between one frequency and the other [263b].

The signals may need amplification [264]. Signals pass to the 'vertical amplifier' which raises the amplitude of weak inputs. The 'time base' is the generator of sawtooth waves, which sweep the spot across the screen. The 'sync' or synchronizing circuit takes a small part of the input signal and uses it to trigger the time-base, so that complicated traces remain stationary on the screen. A 'horizontal' amplifier is used. Another signal moves the spot horizontally. A 'power supply' provides current for each section, and for the tube, which may require 1,000 volts or more, at low current.

All sorts of phenomena can be displayed by the oscilloscope. For example, if an amplifier introduces third harmonic distortion, it combines with the fundamental frequency to produce an unpleasant result [265].

More Uses for Electronics

Electronics does remarkable things—if a process is wanted, an electronic circuit is usually possible.

Gasoline Pump

An electronic gas pump can replace the familiar electric pump. Coils on the pump are the windings for a low frequency oscillator [266], so the collector and coil current rise and fall. Valves in the piston and cylinder transform the rapid piston movement into a steady gasline pressure, exerted by a spring. This action provides a constant supply to the carburetor.

Interval Timer

An interval timer can automatically time a short period, and this can be repeated as often as is needed.

An electronic timer in Figure 267 makes use of the time constant of the large capacitor C. Transistor collector current holds the relay armature down. When the collector current falls, the armature is released. The potentiometer can be calibrated in seconds. Closing and opening of the relay contacts can control other apparatus.

Controlling Currents

The silicon-controlled rectifier or SCR can be turned on by applying current to a control electrode [268]. The SCR can deal with high power for motors and other appliances.

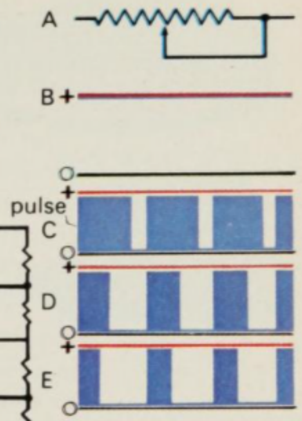
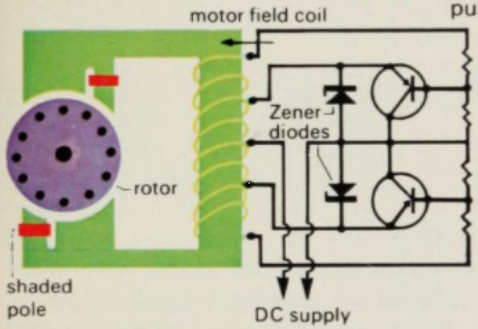
269. Pulse width power control





270. Brushless direct current motor

A gate-controlled switch or GCS is somewhat similar in effect. The speed of a direct current electric motor can be reduced by a variable resistance in one conductor: voltage to the motor is less [269a]. This dissipates unused power as heat in the resistance. Another way is to employ a 'pulse width' oscillator to control a solid state rectifier which allows current to reach the motor. At [269b] current is present the whole time for full speed. In Figure 269c short 'off' intervals reduce the average motor current. In Figures 269d and 269e the 'off' intervals are longer, reducing speed further. No power is dissipated in heat.

Brushless DC Motor

The brushes of a DC motor can be noisy; they wear out, and the sparking may cause R-F interference. The brushless direct current motor employs power transistors to cause an oscillating current [270]. The motor has shaded pole windings, as used for an AC machine, and needs no brushes or commutator. R-F interference and sparking is eliminated.

271. Transducers

Transducers and Ultrasonics

A ‘transducer’ supplies an electrical signal under the influence of pressure or other effects. A pressure transducer [271], alters its electrical resistance with changes in pressure, and so can operate a meter or other indicator. Microminiature pressure transducers have elements formed in silicon crystal, and may be fitted to engine parts, or even in the human body.

In ultrasonic flaw detection [272], steel bars or other materials tested receive the ultrasonic waves upon one surface. The bars may move through a tank, or the equipment may rest on the objects tested. The ultrasonic wave is reflected by the more distant surface, and by internal flaws. A cathode ray tube shows the interval of time taken for the reflection, and thus whether a flaw is present.

274. Finding pH value of a liquid

Another use for ultrasonic equipment is in transmitting signals from a vessel into the water and receiving echoes from the seabed, fish shoals, etc. The time for the echo to return depends on the distance. (See also page 126.)

Electro-Analysis

Various methods allow chemical analysis by electronic means. In electrolysis, compounds are chemically separated by the passage of an electric current. In the electrolysis of water, hydrogen escapes at the negative electrode, and oxygen at the positive electrode [273]. Ions migrating in the direction of the positive current are called cations, while those moving in the direction of the negative current are anions. Substances in solution may be deposited upon neutral electrodes, and afterward weighed.

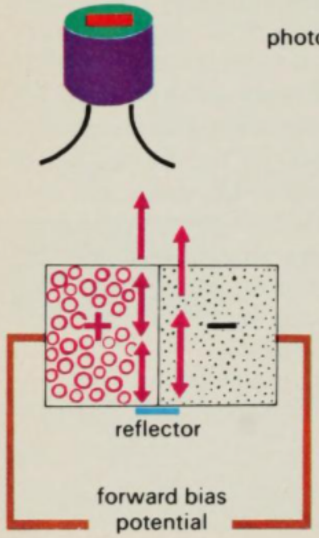
The degree of acidity or pH value can be found by a sensitive instrument with immersed electrodes. One electrode is neutral and the other responds to the pH value, so the output from the electrodes depends on the latter. An extremely sensitive measuring circuit is needed [274].

More Semiconductor Effects

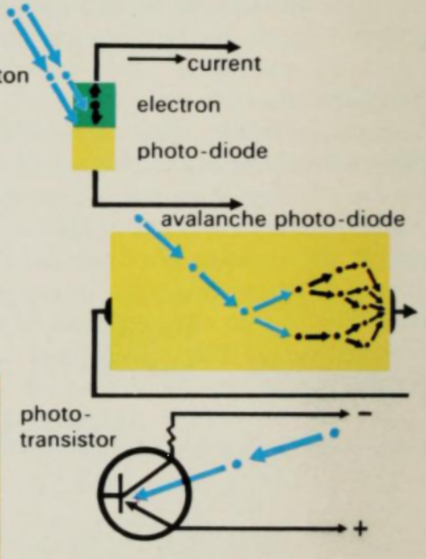
Gallium phosphide alloyed junction diodes and gallium arsenide diffused junction diodes produce light when current is passed in the forward or conducting direction. The gallium arsenide diode junction region has a high concentration of electrons and positive carriers. Photons are emitted when electrons change their energy level. The diode is a form of semiconductor laser or light amplifier—photons traveling along the junction region stimulate re-combination and extra photon emission, so producing more light [275].

Stimulation of a junction by light photons produces a current. A small-current diode may produce one electron for each photon [276]. In the avalanche silicon photo-diode, a potential is applied across the junction. The photons have a higher energy level, and more electrons are liberated. In the photo-transistor, the photo-diode junction forms the base-emitter elements, and transistor action amplifies the base current, so a larger collector current flows from a battery [276].

275. Light-producing diode



276. Photo-diodes and photo-transistor



The Field-Effect Transistor

This has source, gate and drain connections. It is P-channel or N-channel. Figure 277 is a field-effect transistor with a P-type gate in the N-type channel. Electron carriers flow from the source to the drain. Changing the gate voltage alters the current which can flow through channel and external circuit. With no gate potential, the channel is at maximum width, A. Current passes readily. With a small negative voltage at the gate, the channel is depleted of carriers, and therefore is smaller, B. Current is reduced. Increasing the voltage causes the channel to become narrower until it is 'pinched off' or scarcely able to conduct at all, C. The transistor has a high input resistance. It imposes a smaller load on a circuit that supplies the gate. Ordinary transistors are operated by the current flow at the base, and thus draw a current which loads the base circuit. The field-effect transistor is controlled by the voltage. Figure 278 is a field-effect transistor audio amplifier. This type of transistor is rapidly becoming more popular in radio and other equipment.

Television Cameras

A television camera supplies a video signal, afterward amplified and radiated from a transmitter. As the whole scene cannot be changed simultaneously into electrical signals, it is 'scanned' or covered in regular lines. Covering the picture area constitutes a 'frame'. Frames follow each other with sufficient rapidity to avoid flickering at 30 frames per second.

A television picture is built up by a tiny spot of light from the cathode ray, which scans the screen rapidly. A television camera performs the reverse action, generating signals which correspond to the light and shade of the scene transmitted. With space vehicles, the impulses may be stored on tape, later used to supply the transmitter.

Figure 279 shows how a picture area is scanned or sampled by a moving area X of small size. During one frame, the small area X has covered the whole picture. (See the section on television receivers, page 88.)

A camera lens throws an image of the scene on a film [280]. A variable zoom lens, or interchangeable lenses, can give a choice of ordinary, wide-angle, close-up and other views.

279. Scanning of a picture image area

280. Formation of image by a convex lens

The image orthicon camera optical system projects an image on light-sensitive photocathode [281]. When light strikes the photocathode, photoelectrons are emitted from the other side. They are most numerous at bright areas of the image. An electric field attracts them to the target. This is extremely thin glass covered by a wire mesh having very many holes per square inch. The photoelectrons knock electrons from the glass, leaving a positive charge. So the positions and intensity of the positive charges correspond to light areas of the image.

The beam from an electron gun scans the back of the glass. When passing over an area where there is a positive charge, the beam leaves electrons to neutralize the charge. When the beam passes over an uncharged area, few if any of the electrons are left. Thus the beam current corresponds to light or dark picture features. An electron multiplier amplifies the changes in beam current. A series of electrodes receive progressively higher voltages [282]. Electrons striking these electrodes cause secondary electrons to be liberated, and the intensified signal can be passed on to other amplifiers.

Logic Gates

Processes of logic can be carried out by 'gates' whose output depends on the logical process or 'truth' required. Computers use very many of these gates. Figure 283 is a 2-input AND gate. Input pulses arrive at A and B. Transistors 1 and 2 are normally non-conducting. There is no current through R1, no voltage drop here. Transistor 3 base is negative. Current flow through R2 causes a large voltage drop. Output level remains near zero (positive).

A pulse at A or B makes one transistor conduct, but no current flows in R1 unless *both* conduct simultaneously—that is, when pulses arrive at A *and* B together. Then voltage drop in R1 moves collector C positive, transistor 3 ceases to conduct, and a negative pulse appears in the output. Figure 284 is a 2-input OR gate. A pulse at either A OR B will cause an output pulse. Such units may operate at 500,000 pulses or more a second. They work with low voltage (typically 5 volts) and require little power.

286. Thermo-generator produces current from heat

Power in Space

Various unconventional ways of generating electrical power have been used in Polar weather stations, for automatic warning lights, satellites and space probes.

A convenient source of power for a space probe is the solar cell. Silicon solar cells have an N-type base containing antimony or other impurity, and a P-type surface layer. Photons or light from the sun striking the cell cause extra electron and hole pairs, and a current which flows through an external circuit [285]. This produces about 0.5 volt. The solar battery can charge accumulator-type cells, which provide power for equipment requiring more current and when the satellite is in darkness.

The thermo-generator is an improvement on the thermocouple. In N-type material, electrons move away from a heat source. So a device can be made in which current is produced if one surface is hot, and the other cold [286]. The heat is a by-product of environment (solar) or of relevant activity. In a reverse or 'refrigeration' system the passage of an electric current makes a semi-conductor junction drop in temperature.

Looking Ahead

Analysis of gases, once needing considerable time, can be completed almost instantly. After ionization, the particles are accelerated down a drift tube [287]. Low mass ions accelerate most rapidly, so the ions are separated according to mass.

'Printed circuits' have revolutionized construction of miniature equipment. Conducting paths are arranged to run without overlapping. A large drawing is prepared, and reduced by photocopying methods. Further processing leaves printed copper conductors [288]. Large numbers of similar panels are readily made. When components are connected, the printed conductors act as wiring.

Printed circuits and similar methods lead to the production of modules, or small units of similar type. A defective unit is removed and replaced by one in working order.

Computers contain thousands of 'logic' elements, such as those for AND and OR functions. These and other circuit units can be tested automatically at high speed by a machine which applies suitable signals, and records the outputs [289]. Errors in outputs from the unit result in it being set aside for repair.

A Step Smaller

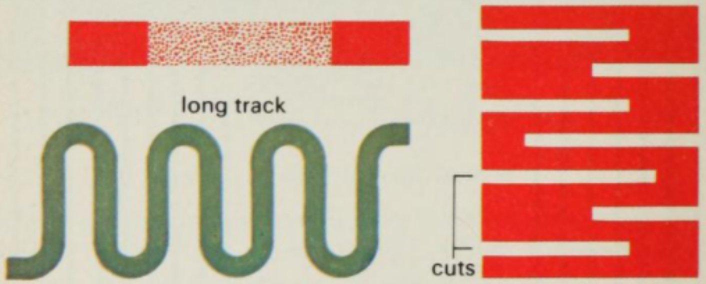
Even miniature individual resistors have wire ends and occupy unnecessary space. Instead, resistor material can be deposited directly on an insulated panel, between conductors [290]. The resistor has almost no thickness. If the process is carefully controlled, the resistors will be reasonably accurate in value. For high accuracy, the resistor is made a little low in value, and the value is increased by cutting or etching material away.

Conventional capacitors are of foil, separated by insulating paper; or have sheets of mica to separate the plates, or consist of conductive deposits on an insulator. Capacitors of almost no thickness are made [291]. Conducting layer A is deposited, then the insulator or dielectric B. A further conducting layer C is deposited on the insulator. Surfaces A and C form the capacitor.

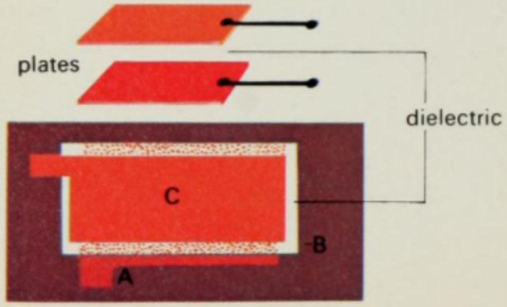
Thin Films

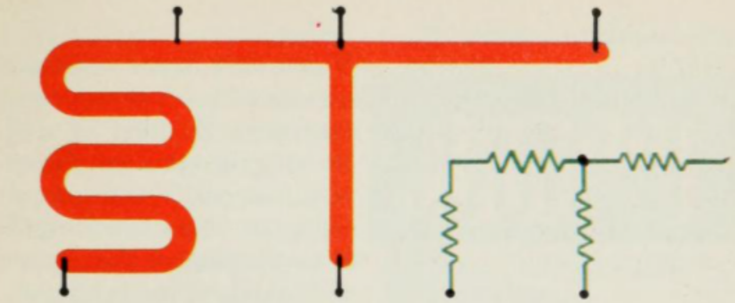
In integrated circuits, the insulating base or panel is the 'substrate'. Surface roughness would result in irregular deposits, so ceramic, glass, and other smooth substrates are used.

290. Thin film resistors

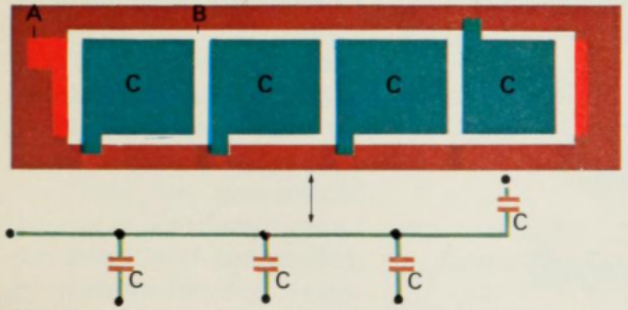


291. Thin film capacitors





292. Thin film resistor network



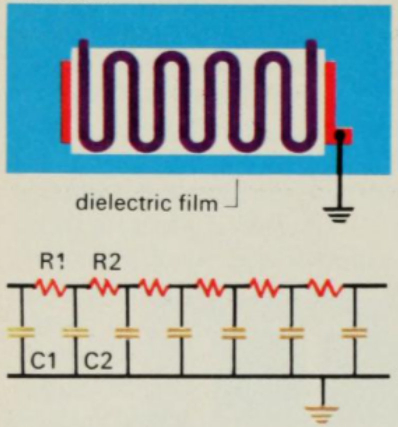
293. Thin film capacitors and equivalent circuit

Resistors can be deposited nichrome, of extreme thinness, and resistance paths can be shaped as wanted, and tapped if required [292].

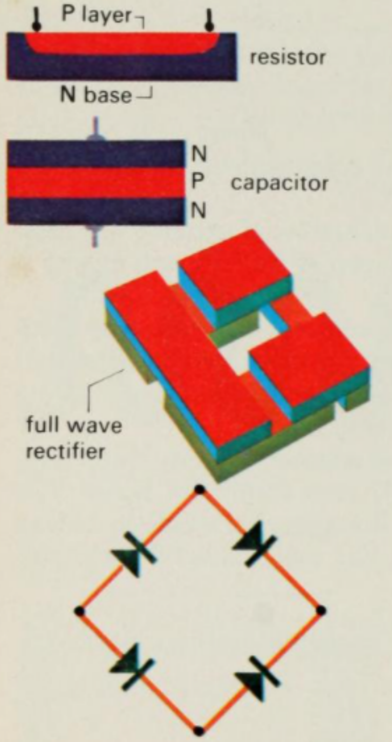
One method is to cover a prepared substrate chip with lacquer and photoresist, so that when the pattern is printed and etched the nichrome can afterward be deposited, giving the required thickness and shape.

Capacitors are made by vacuum depositing aluminum, then the dielectric (insulator), then aluminum again. The dielectric may be magnesium fluoride, zinc sulphide, silicon monoxide, or other material. For high capacities in small size, the film is very thin.

Deposits can be shaped to give the desired result. In Figure 293 the single conductor surface A is covered with dielectric B, then four top surfaces C, thus obtaining the equivalent of four capacitors.



294. Resistance capacitor network



295. Semiconductor components

Other Units

Figure 294 has a resistance element, then a dielectric or insulator. A film of conducting material is deposited on the insulator, so there is capacitance from it to the resistor throughout its length. This is approximately equivalent to a number of individual resistors R1, R2, etc. with small capacitors C1, C2, etc. Phase-shift networks for oscillators and other purposes have been made in this way.

A completed integrated chip having resistors, capacitors and interconnecting conductors can be of extremely small size. The chip could be 0.1mm. thick, or less, and have many components in an area of a few square millimeters. A number of chips can be placed one on top of another, to build up a thicker unit, or cube, in which are many circuits.

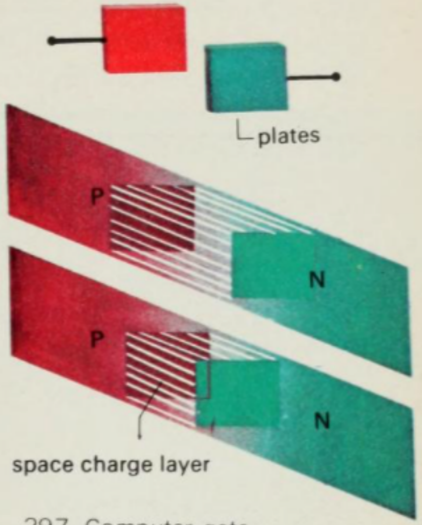
Semiconductors Too

Semiconductor material can be fabricated into microminiature circuit elements. Silicon is preferred, for some increase in temperature is less important than it is with germanium.

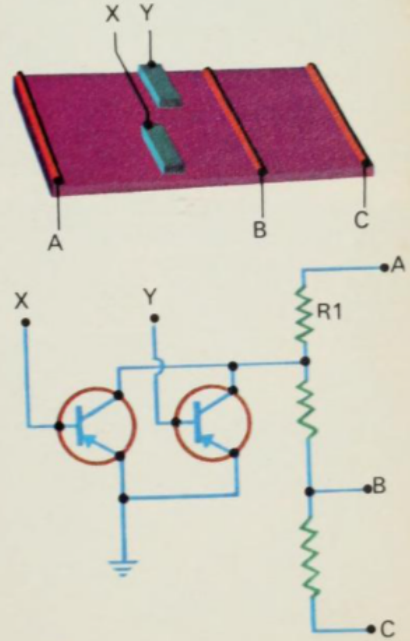
A resistor is obtained by having a thin track of P-type material in the N-type base [295]. Capacitors can be derived by having N-type material separated by P-type material. Arrangements of suitably chosen material can provide more complicated circuit equivalents, such as the full-wave bridge rectifier.

Effects present in conventional semiconductor devices can be employed. In Figure 296 the variable capacitor has two metal plates, which are moved to change the capacitance. In the semiconductor variable capacitance diode, capacitance exists between the carrier areas. Applying a bias voltage effectively moves these areas together or apart, changing capacitance.

Planar transistors occupy little space and thickness. Another method adopted is shown in Figure 297. A base carries a resistance element acting as three resistors in series, with conductor strips A, B and C. Transistors are formed on the material. Input to X or Y will cause a voltage drop in R1, so that a pulse is obtained at B. This is a computer 'OR' gate.



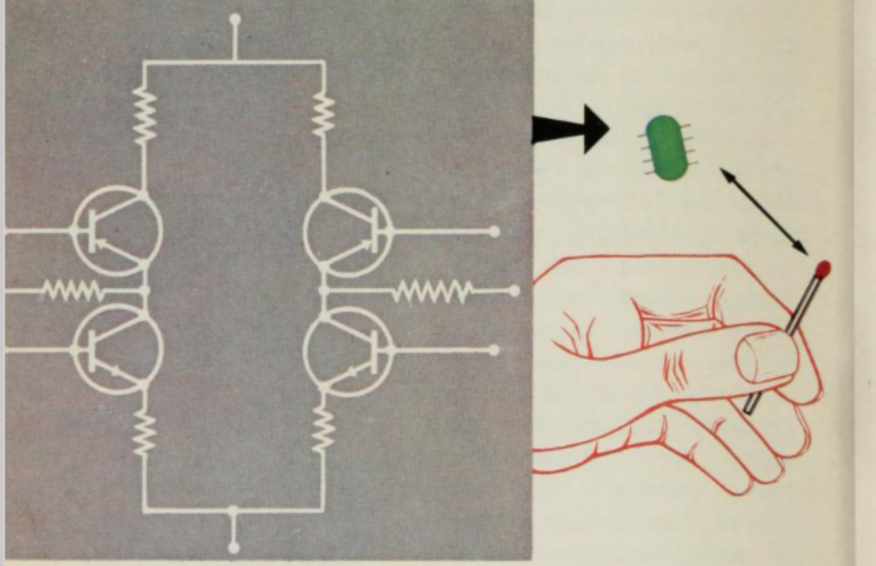
296. Semiconductor variable capacitor



297. Computer gate

Figure 298 is an integrated circuit formed by diffusion processes in a piece of semiconductor. With suitable external connections, it may form part of an amplifier, counter, oscillator, etc. With direct couplings and complementary circuits having PNP and NPN transistors, full use can be made of I.C. techniques.

298. Integrated microminiature circuit



299. Thin film multivibrator

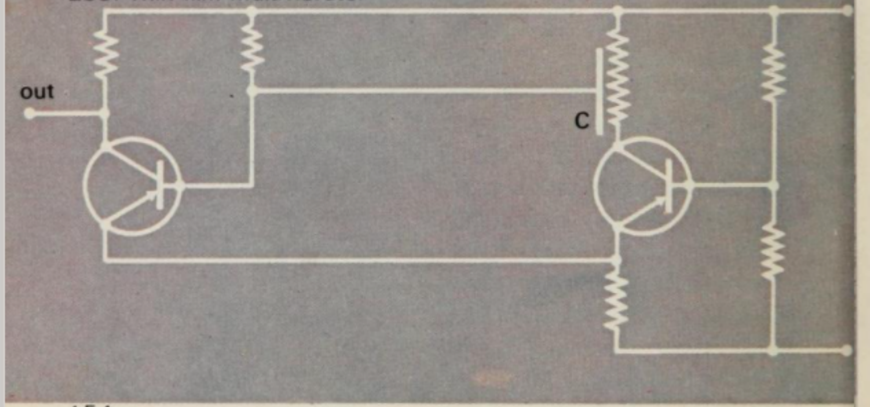


Figure 299 is a thin film multivibrator or oscillator, which requires only the distributed capacitance resistor C for feedback, in conjunction with directly connected emitters.

Thin metal film resistors can be cut by electron beam. A powerful discharge tube produces a beam concentrated electromagnetically to a point 0.0005 in. in diameter. The beam is moved by magnetic deflection [300]. The process is carried out by automatic mechanisms [301].

It is interesting to imagine what electronics may accomplish in the future. A tidy picture of a central nucleus surrounded by negative electrons racing around at tremendous speed does well for many purposes. But much is still unknown. Many discoveries will be made.

ABOUT THE AUTHOR

Øyvind Nydal Dahl has been an electronics enthusiast since he was a kid—he's always loved figuring out how things worked so he could try to build them for himself. He studied electronics and computer science at the University of Oslo, where he received a master's degree after building his own microchip. He then co-founded the company Intelligent Agent to develop sensors that allow robots to see through walls.

After a few years at Intelligent Agent, Øyvind set out on a mission to teach the world electronics. He gives workshops, develops courses, and writes about electronics and technology for a variety of outlets. He's posted hundreds of articles, tutorials, and videos on his blog (*http://www.build-electronic-circuits.com/*) and maintains Ohmify (*http://ohmify.com/*), a membership site that makes learning electronics fun and easy.

ABOUT THE TECHNICAL REVIEWER

John Hewes began connecting electrical circuits at an early age, moving on to electronics projects as a teenager. He later earned a physics degree and continued to develop his interest in electronics, helping school students with their projects while working as a science technician.

John has taught electronics and physics up to an advanced level in the United Kingdom and ran a school electronics club for children aged 11 to 18 years, setting up the website *http://www.electronicsclub.info/* to support the club. He believes that everyone can enjoy building electronics projects, regardless of their age or ability.

FOREWORD

There’s something special about bringing a project to life that you read about in a book or that started as an idea in your head. And sometimes the simplest things are the most satisfying.

One of my favorite childhood projects was a mischievous little device made of a single resistor connected between the tip and ring of a telephone line. I used a piece of one-sided copper circuit board with rub-off symbols to lay out the design, and then I etched the unprotected copper away using ferric chloride in my basement. You could still use the phone normally to make outgoing calls, but anyone calling the house would receive a busy signal. This was the perfect way to make sure my parents didn’t receive any phone calls from my teachers during dinner!

A few years later, I modified a garage door opener to open any door of the same brand. In normal operation, the passwords on the transmitter and receiver were manually set with a series of 10 DIP switches. If the transmission signal matched what the receiver was expecting, then the garage door would open. I replaced the switches on my transmitter with a common 555 timer IC, to generate a clock signal, and a 10-stage binary counter, a type of digital logic device, to automatically try every single possible combination (that’s 2^{10} or 1,024 attempts). Within a few minutes of holding down the button, the correct password would be transmitted and the garage door would open! I never used my universal “brute-force” garage door opener for malicious purposes, but it reinforced my hacker mindset—solving problems with unconventional solutions, pushing the limits of technology, harming no one, and learning through constant questioning and experimentation. I also thought it was pretty cool to be able to modify an off-the-shelf device and make it do something the original designers probably never anticipated.

When I was much younger, I somehow ended up with a 6 V lantern battery and a spring from an adjustable lamp. I wondered, “What would happen if I connected the spring between the battery terminals?” So of course, I tried it. The spring got hotter and hotter until I freaked out, plucked it off the terminals, and threw it into the bathroom sink. I had created a short circuit by connecting the positive and negative terminals of the battery together, causing current to flow between them. I never looked at batteries and springs the same way again.

I remember trying to build my own alarm system for my bedroom door, sort of a low-tech version of the one you’ll build in Chapter 1. I hung an old AM/FM radio from a hook on the back of my door, tuned it to static, turned the volume up to maximum, and “armed” it by connecting the sliding power switch to a wire I had attached to my wall. In theory, when the door opened, the wire would pull the switch and turn on the radio, blasting white noise at the intruder. That didn’t happen. Instead, when my dad opened the door, the radio slid off the hook and crashed onto the floor. Back to the drawing board on that one!

These stories are meant to do one thing: inspire you to explore the wonderful, wild world of electrons—and this book is the perfect launch pad! Øyvind breaks down complex electronics fundamentals in an enjoyable, fun way. His passion for electronics and his love for teaching shine on every page. Starting with the basics and building up from there, you’ll end up with the power to create bigger, better, faster, and more intelligent projects on your own. There’s no better way to learn than by *doing*. So go ahead, turn the page and begin your adventure into all that electronics has to offer!

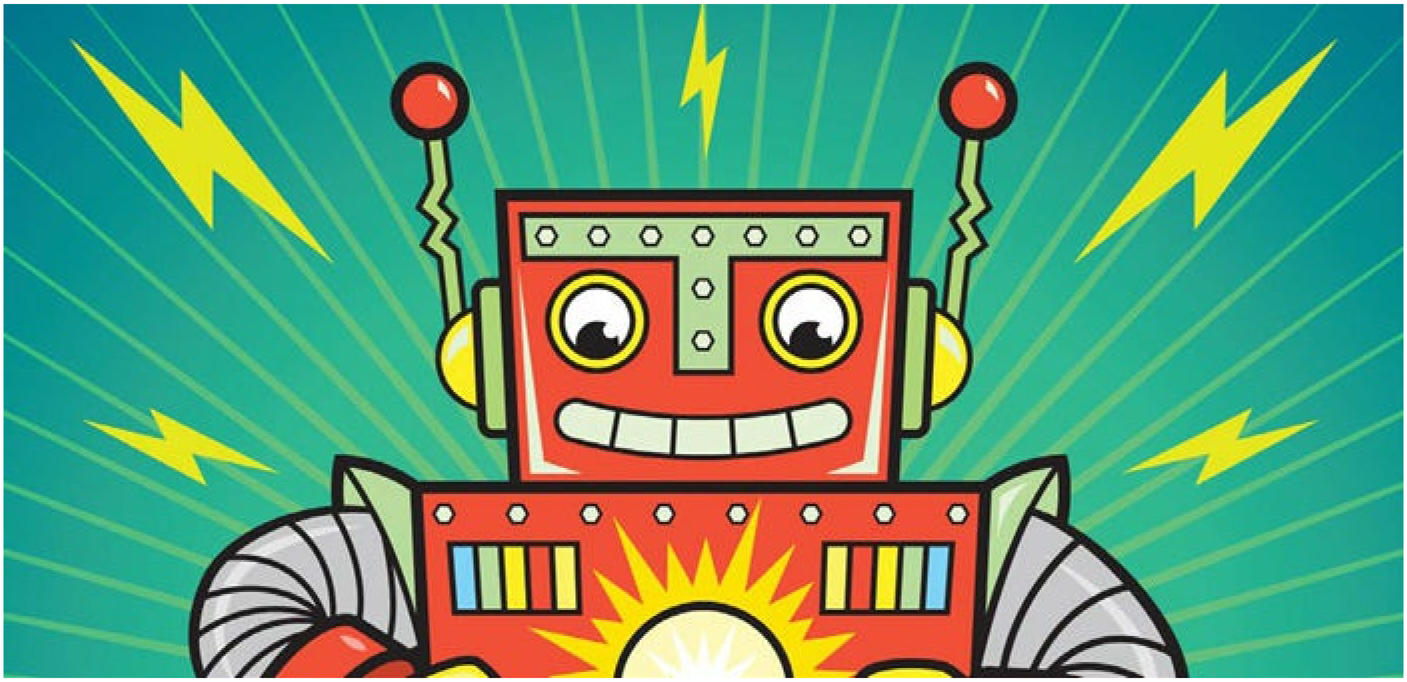
ACKNOWLEDGMENTS

First of all, thanks to my father for explaining how things work based on practice instead of theory when I was a kid. His great explanations got me started in the world of electronics. Also, many thanks to my mother, who had to endure all those technical discussions around the dinner table.

Thanks to Jennifer Griffith-Delgado, Riley Hoffman, Tyler Ortman, and the rest of the team at No Starch Press—first of all for believing in me, but also for guiding me through the editorial process in such a good way. You have been a dream to work with!

Thanks to my technical reviewer, John Hewes, for finding my errors, challenging me in some areas, and making me think through some parts of the book a few extra times.

Finally, a special thanks to Garry Booth for the cover illustration, to Beth Middleworth for designing the layout and background illustrations, and to Riley once more, for drawing the technical diagrams. Those three really made this book come alive.



INTRODUCTION

Welcome to *Electronics for Kids*! This book will teach you how to make cool things by putting together the same parts that are inside televisions, electronic toys, radios, and all the other gadgets in the world. You'll build fun experiments, like a light powered by lemons, as well as useful (but still fun) projects, like an intruder alarm and a musical instrument.

You'll do more than just follow directions, however: you'll also learn how every component in each project works.

My hope is that when you know how those components work, you'll see how to create your own inventions by combining the components in different ways. Blinking a light is one of the first things I learned how to do with electronics. When I saw how that worked, a whole new world suddenly opened up to me. Since then, I've built robots, music players, miniature computers, and even a device that lets you see through a wall! With practice, you can build those things, too—and this book will teach you the basic skills you need to start the journey.

ABOUT THIS BOOK

When I was about 14 years old, I thought computers were cool, but I had no idea how they worked. They seemed magical, and I thought I'd never understand them or be able to build one. Luckily, my dad was an engineer, and he had a very good way of explaining things. When I asked questions, he showed me not only how things worked but also how I could build something similar myself.

I wrote this as the book I would have loved to have had as a kid, and I hope you enjoy it!

Who Should Read This Book

If you've ever looked at an electronic gadget and thought, "How does that work?" or "How can I make that?" as I did, then you're in the right place. Whether you're 8 or 100 years old, as long as you're curious and have a playful spirit, this book is for you.

How to Read This Book

I recommend you read this book in order, because every chapter builds upon concepts and skills covered in previous chapters.

Each chapter has at least one hands-on project. Build these projects! Electronics is a very practical skill, and reading about how a component works or what a project should do is different from experiencing it yourself. Just be sure to read a project in full before you dive into it so you understand the steps involved.

If you encounter problems as you build a project, don't worry: that happens to everyone at some point when working with electronics—even me. Just keep at it, study your circuit, and rewire the whole project if needed to get it working. When you've been battling to get a circuit working for a couple of hours, then suddenly find the error and your circuit works, you'll feel amazing! If you get stuck, grab a friend or family member and ask them to help out.

If there are parts of the book you don't understand right away, I recommend you keep on reading. Don't let details stop you. Come back to that particular topic later when you have some more projects under your belt.

What's in This Book?

As you work through this book, you'll build your knowledge of electronics gradually, starting with basic—but essential—information and simple circuits. After the basics, you'll build more complex circuits and meet components like resistors, capacitors, transistors, and integrated circuits. To see how the components work and to understand electronics in a practical way, you'll build fun projects in every chapter.

At the end of the book, you'll build one final, epic project: a game to play with your friends. By then, you'll have enough experience and knowledge to modify the game or even build a totally new game you invent yourself!

This book is divided into three parts. **Part 1: Playing with Electricity** is the foundation for the rest of the book. It's all about fundamental knowledge and how electricity actually works.

- **Chapter 1: What Is Electricity?** introduces the science behind electricity and describes the basic requirements for a circuit to turn something on.
- **Chapter 2: Making Things Move with Electricity and Magnets** shows you how you can move objects with electricity. In this chapter, you'll build a motor from scratch.
- **Chapter 3: How to Generate Electricity** describes how batteries and power plugs in the wall provide electricity. Of course, you'll build your own electricity sources, too!

Part 2: Building Circuits is where you'll really get your hands dirty. You'll meet some of the most important components in electronics, and you'll learn how to build both permanent and temporary circuits.

- In **Chapter 4: Creating Light with LEDs**, you'll build circuits on a breadboard for the first time to create a *prototype*, which is just a temporary circuit. You'll learn about resistors, light-emitting diodes (LEDs), and how to use those parts together.
- **Chapter 5: Blinking a Light for the First Time** shows how two new components, capacitors and relays, work. You'll even combine these with an LED to create a circuit that blinks a light.
- **Chapter 6: Let's Solder!** teaches you how to solder. With soldering, you can transform a circuit from a prototype to a proper device that will last for years to come.
- **Chapter 7: Controlling Things with Electricity** introduces the transistor, a component that lets a circuit control other circuits. You'll learn how transistors work and how to use them to build a touch sensor and a simple alarm clock.
- In **Chapter 8: Building a Musical Instrument**, you'll learn what an integrated circuit is and how circuits can make sound. You'll combine this knowledge to build a musical instrument.

Part 3: The Digital World introduces digital electronics, which almost all modern technology is based upon.

- In **Chapter 9: How Circuits Understand Ones and Zeros**, you'll learn about 1s and 0s, bits and bytes, and how to use them to communicate.
- **Chapter 10: Circuits That Make Choices** teaches you how to build smart circuits that use logic to make decisions. You'll build a secret code checker and learn how you can combine it with your intruder alarm.
- **Chapter 11: Circuits That Remember Information** shows how you can use logic gates to create circuits that remember information in a way similar to a computer. Then, you'll use this to create an electronic coin tosser.
- **Chapter 12: Let's Make a Game!** is dedicated to one large project. You'll get to show off your new skills by combining all the knowledge from the book to make a reaction speed game.

Finally, you'll find a **Handy Resources** appendix at the back of the book, which includes cheat sheets for figuring out component values, doing some essential electronics calculations, and so on. You'll learn about those concepts in detail throughout the book, but even electronics experts need a quick reference every now and then!

YOUR ELECTRONICS LAB

The wonderful thing about electronics projects is that your "lab" can be anywhere you want—it doesn't have to be a garage or workshop. All you need is a flat surface to work on, with enough room for your tools and components. Just gather the supplies to build your latest invention, and you're set.

Each project in this book includes a convenient list of the electronic components and tools needed to build it. Before you dig into a project, check its Shopping List to make sure you have all the materials. I've also created a complete list of all the components and tools you'll need for all the projects in this book, which you can find linked from the book's web page at *https://www.nostarch.com/electronicsforkids/*. This list should always have the most up-to-date part numbers and links to kits you can buy that contain all the necessary components.

Useful Supplies

Whether you're building the projects in this book or other projects on your own, there are a few supplies that will always come in handy:

- **A digital multimeter** (Jameco #2206061, Bitsbox #TL057, Rapid Electronics #55-6662) for testing connections and making sure a project is working correctly.
- **A pair of wire cutters** (Jameco #35482, Bitsbox #TL008)
- **A big spool of insulated wire** (Jameco #36792, Bitsbox #W106BK)
- **Electrical tape** to protect bare wires or fasten stuff.
- **9 V batteries**—nearly every project in the book uses one!
- **A bunch of LEDs** (Jameco #18041, Bitsbox #K033)

- **A bunch of resistors** (Jameco #2217511, Bitsbox #K017)
- **Safety glasses** to wear when snipping component leads, stripping wires, or soldering.

You can buy most of these from your local hardware store or from any online electronics retailer, like Jameco (*http://www.jameco.com/*), SparkFun (*http://www.sparkfun.com/*), or Bitsbox (*http://www.bitsbox.co.uk/*). Check out "Online Electronics Shops" on page 286 for more options.

You might also want to have a pair of scissors, some scrap paper, and pencils to take notes.

Safety First!

All the circuits in this book use a low voltage, and they're not dangerous to build and play with. That said, there are a few safety tips to keep in mind when using electronic components and tools:

- Wear safety glasses when trimming components or soldering.
- Use tools only for their intended purpose. Soldering irons are hot, and wire cutters are sharp—if used improperly, they can hurt you. If you're confused about how to use a tool, ask an adult for help.
- An adult should supervise younger children when they're working with small components, solder, tools, and so on to teach them how to use everything safely.
- Keep electronic parts out of reach of babies and very young children.
- Most projects in this book use batteries, but some do use power from a wall outlet. Follow the instructions for those circuits carefully. Never plug components directly into a power outlet, or you will get hurt.

Some projects do have steps you should take special care with, and I will clearly state that in the instructions with a warning, like this:

WARNING

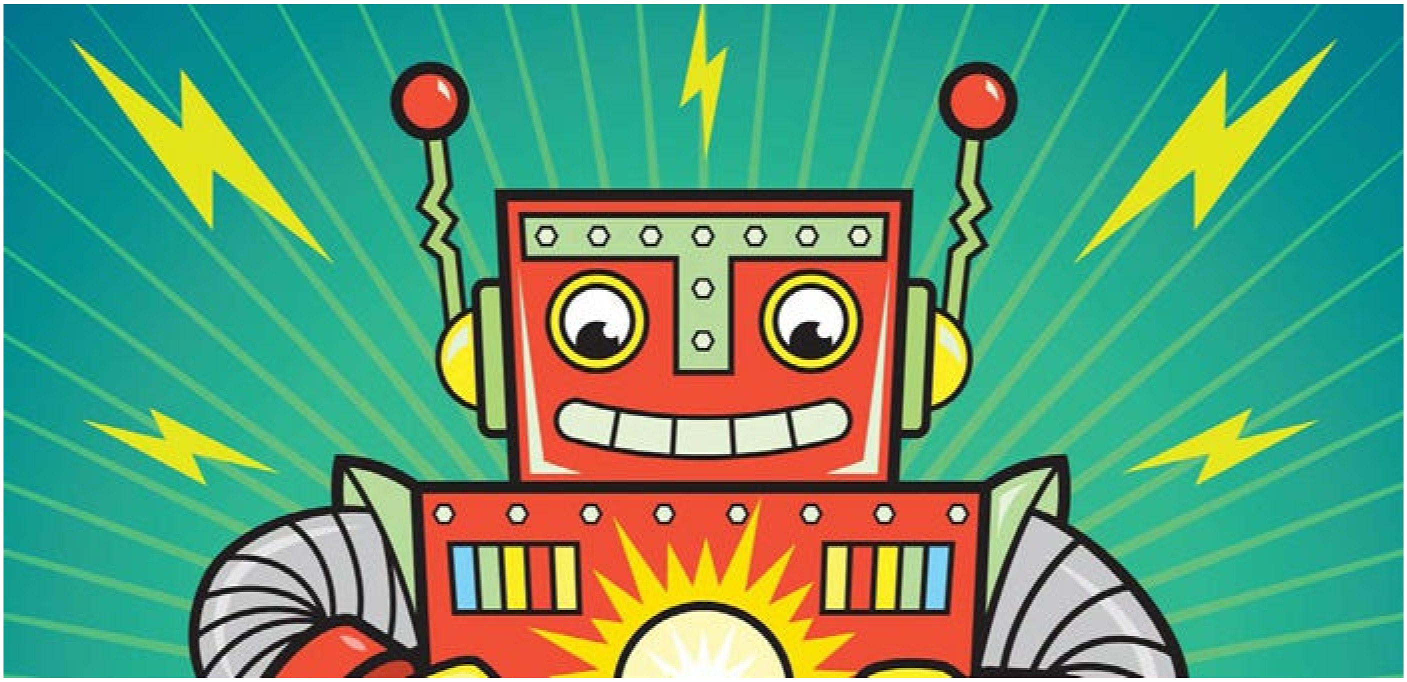
When you see this type of note, be careful with the step it talks about.

Electronics is a safe hobby, though, so you won't see very many of these warnings. When you do see one, don't let it stop you from having fun. If you use common sense and follow the directions, you'll have nothing to worry about.

Now let's get started!

PART 1

PLAYING WITH ELECTRICITY



1

WHAT IS ELECTRICITY?

Push a button on a music player, and a song suddenly comes out of the speakers. Push a button on a TV's remote control, and your favorite shows come to life instantly. These wonders happen thanks to the magic of *electricity*, a type of energy that powers all the technology in your home. By the time you finish this book, you'll be an electronics wizard, and then you can try using your powers to build any invention you can imagine!

This book is all about understanding electricity and using it to make amazing things. In this chapter, we'll explore how electricity works, and then you'll build a complete electronics project: a burglar alarm that warns you if intruders have entered a room. Once you get the hang of using electricity, you can build all sorts of fun contraptions, like a musical instrument or a light-up game to play with your friends. In fact, you'll build these in this book.

PROJECT #1: TURN ON A LIGHT!

When you flip the light switch in a room, the bulb brightens right away. Let's look at how electricity makes that bulb shine, starting with a little experiment.

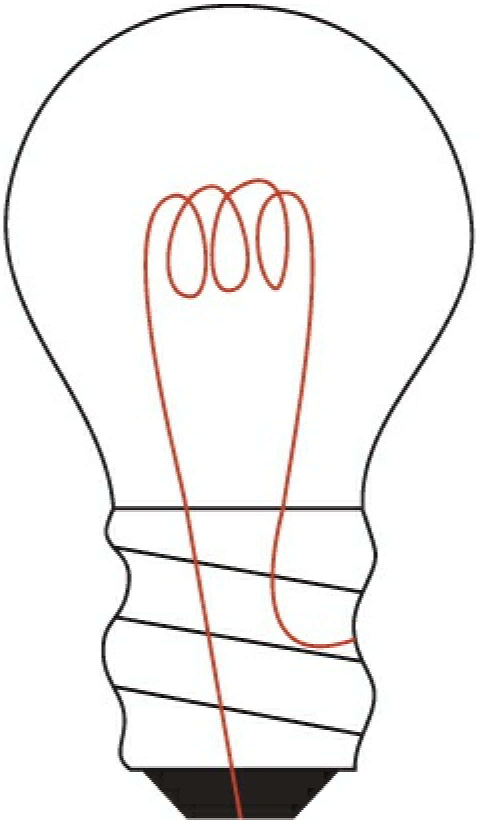
Shopping List

For this project, you'll need the following parts:

- **A standard 9 V battery** to power the circuit.
- **A small, incandescent light bulb** rated for 9 to 12 V (DigiKey #CM394-ND, Bitsbox #OP037, or a similar light bulb from a hardware store).

Step 1: Inspect the Light Bulb

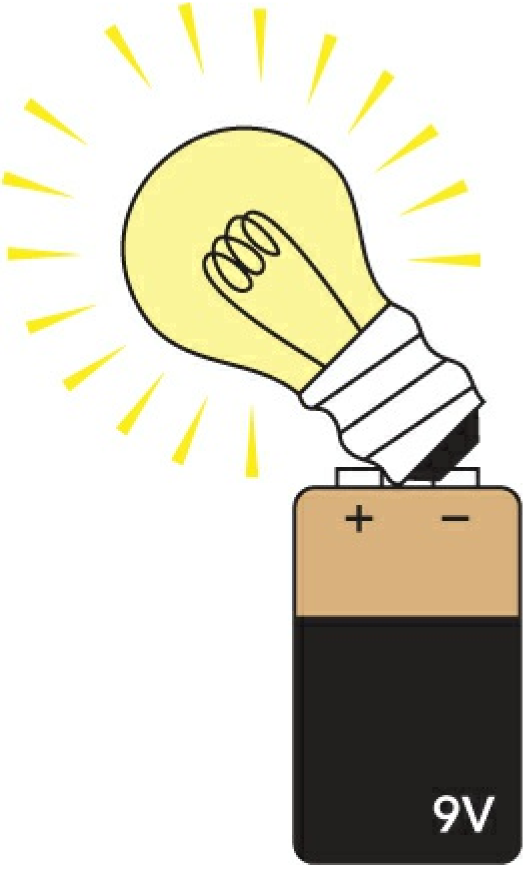
Look closely at your light bulb; you should see a thin metal wire filament inside the glass. One end of this filament is connected to the metal side of the base, and the other end is connected to the metal contact on the bottom.



Step 2: Connect the Light Bulb to the Battery

Place your 9 V battery upright on a table. Take the light bulb and gently place it so that the bottom point touches one battery terminal and the metal side touches the other battery terminal. When both the bottom and the side are touching the battery, the bulb should light up.

Congratulations: you just generated light with electricity! The bulb lights because when you touch it to the battery contacts, electricity runs through the wire filament inside. The filament then heats and starts to glow, creating light.



HOW DOES ELECTRICITY LIGHT A BULB?

But *how* does electricity cause the wire to heat up, and why does the light turn on instantly? There are four concepts that combine to make that happen:

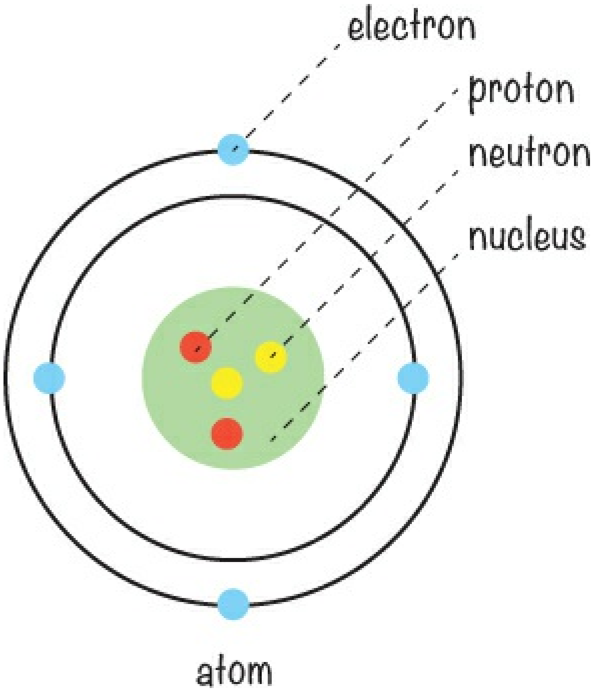
- Electrons
- Current
- Voltage
- Resistance

These fundamental concepts of electricity all depend on each other, and we’ll explore them in this section.

What Is an Electron?

Everything you see around you is made of *atoms*, which are particles so small you can’t see them without a special type of microscope. But atoms are made of even smaller particles, called *protons*, *neutrons*, and *electrons*.

Protons and neutrons form an atom’s *nucleus* (its center), and electrons orbit the nucleus like planets orbiting the sun. Protons and electrons are both *electrically charged*: protons have a positive charge, and electrons have a negative charge. That’s why the electrons stick with an atom in the first place. The positive and negative charges act like opposite sides of a magnet and attract each other.



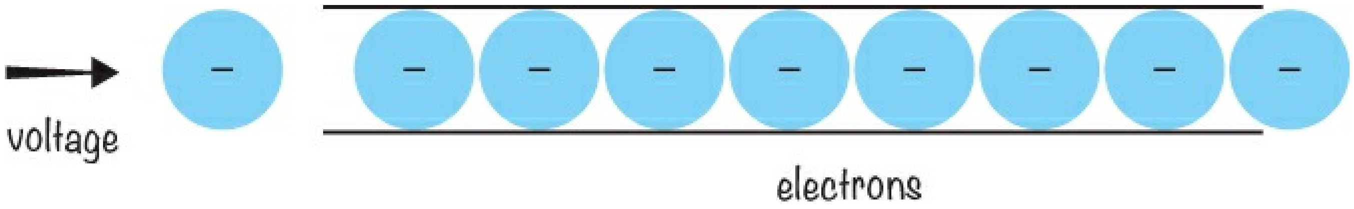
Certain materials are *conductive*, which means that if you apply energy to them (like the energy stored in a battery), the electrons will start moving from one atom to the next!

The filament inside your light bulb is made of a conductive metal, meaning it's full of electrons just waiting for a push to move them.

Voltage Pushes Electrons

When you attach a battery to the light bulb, you're applying a *voltage* across the filament inside. Voltage pushes electrons through the wire and is measured in *volts (V)*. The higher the voltage, the more electrons will flow through the wire.

Think of a wire like a tube filled with marbles: when you put a marble in on one side, a marble pops out on the other side at the exact same time, with no delay.



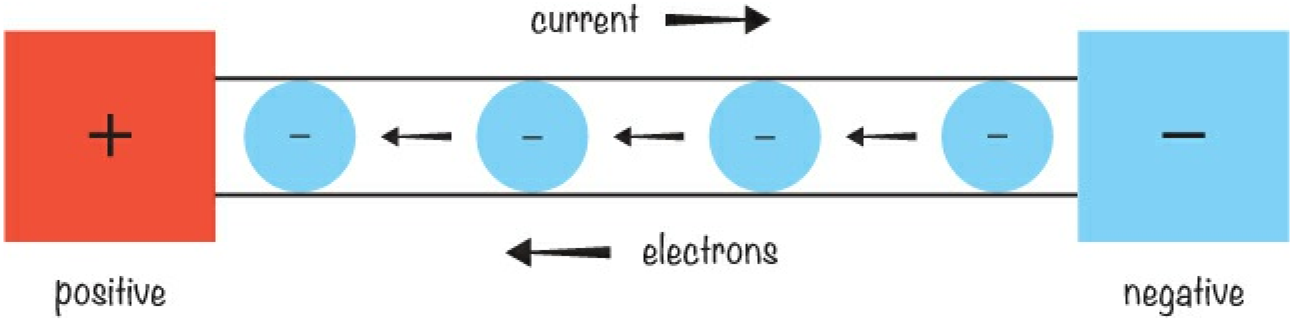
The more marbles you push in one side, the more pop out of the other. That's how electrons behave inside a wire, when a voltage is applied to them.

Current Flows

Current is the amount of electrons flowing through a wire, and it's measured in *amperes (A)*, which we usually shorten to *amps*. You might have also heard the word *current* used to describe a river, as in "This river has a strong current." That means there's a lot of water moving down the river.

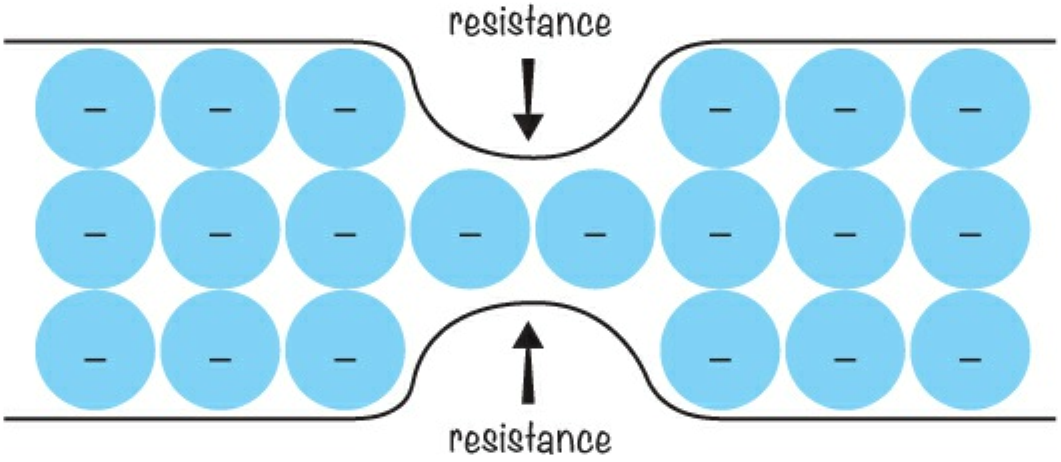
Electrical current is similar: a strong current means there are a lot of electrons flowing through a wire. When you increase the voltage in a circuit, the current also increases.

Just as water flows downhill due to gravity, electric current flows from the positive battery terminal toward the negative battery terminal. Actually, the electrons themselves flow in the opposite direction, from the negative side of your battery to the positive side.* But when we talk about electrical current, we say that it flows from positive (+) to negative (–).



Resistance Reduces Current

Voltage pushes electrons to form a current, and *resistance* restricts the current. It's like playing with a garden hose: if you squeeze the hose, you add resistance to the flow of water so that less water comes out. But if you turn the tap more (like increasing the voltage), the pressure increases, and more water flows even though you're still squeezing the hose in the same way. Resistance in electricity works just like this, and it's measured in *ohms* (Ω).



Now that you know about electrons, current, voltage, and resistance, I'll explain how they work together to turn on your light bulb.

Lighting the Bulb

The two ends of the wire filament inside your light bulb are connected to the outside of the bulb: one end is connected to the metal side of the base, and the other end is connected to the metal contact on the bottom. When you connect a battery to the light bulb, you create what's called a *circuit*. A circuit is just a closed path that allows current to flow from the positive terminal of your voltage source to the negative terminal.

The voltage on the battery pushes electrons through the circuit, including the filament inside your light bulb. The filament has resistance and restricts the current in your circuit. As the electrons struggle to make their way through the resistance of the filament, the filament becomes so hot that it starts to glow and generate light. For the battery to be able to push the electrons, there must be a *closed loop* going from the positive terminal on the battery to the negative terminal.

Electricity always needs a *closed circuit* to work. If you disconnect even one of the sides, the light bulb turns off right away! Let's look at circuits in a little more detail.

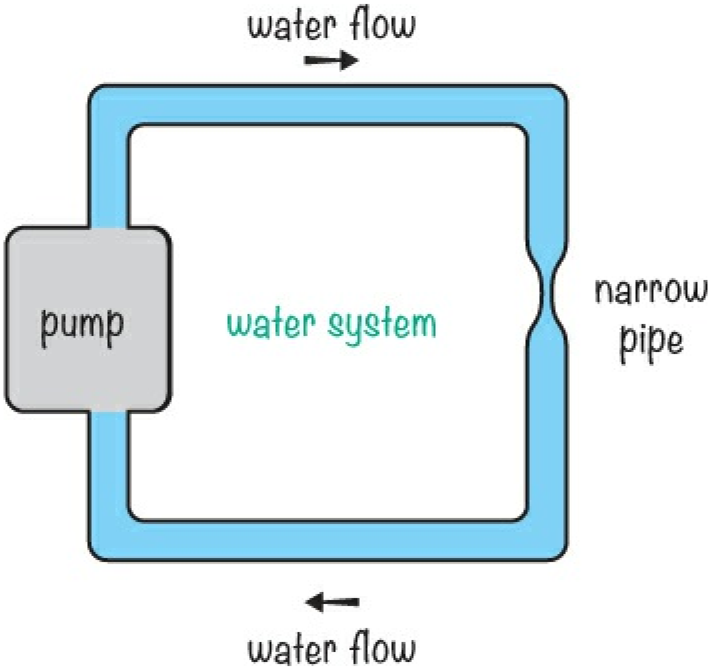
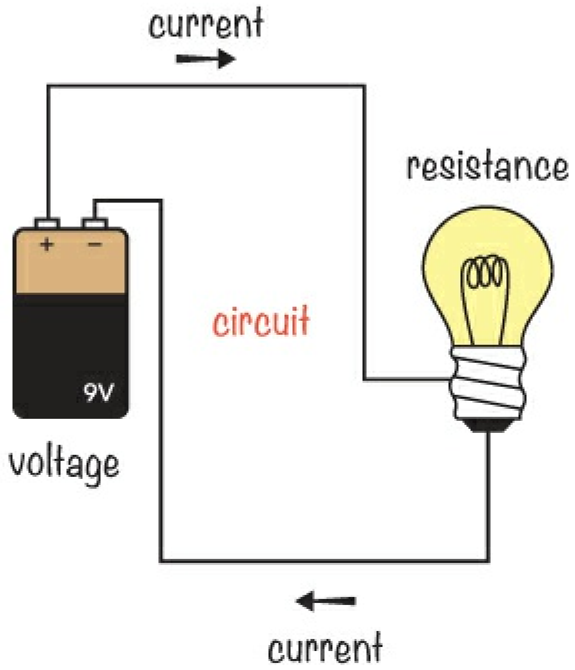
HOW IS A CIRCUIT LIKE A PIPE SYSTEM?

Let's continue to think about electricity by comparing it to water. Imagine a pipe system in a loop with a pump, and imagine the pipe is always totally filled with water. At one point, the pipe is narrower.

The pump is like a battery that gives power to a circuit. The narrow part of the pipe reduces the flow of water. This narrow pipe is the resistance. The amount of water that flows through the pipes is the current.





Now imagine that you could insert a measuring device somewhere in the pipe system that tells you how much water is flowing through it per second. Note that I’m talking only about how much water flows through one randomly selected point in the pipes, not the total amount of water in the pipes. This is how we’ll talk about current in an electric circuit, too: it’s the amount of electrons flowing through a certain point per second.

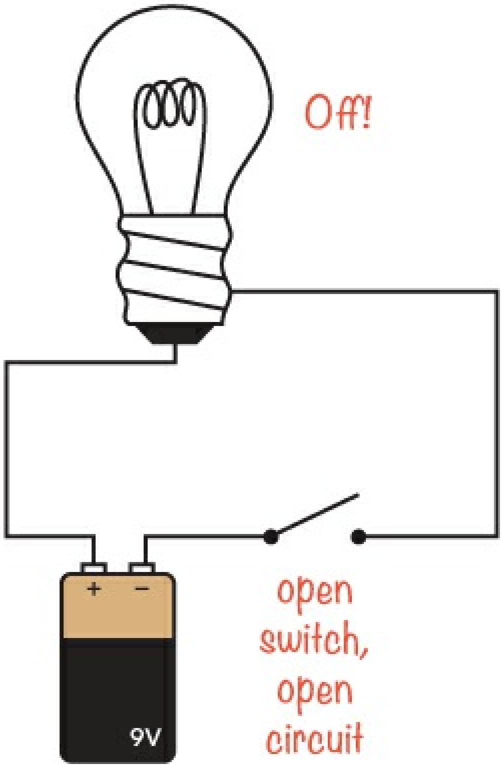
MEET THE SWITCH

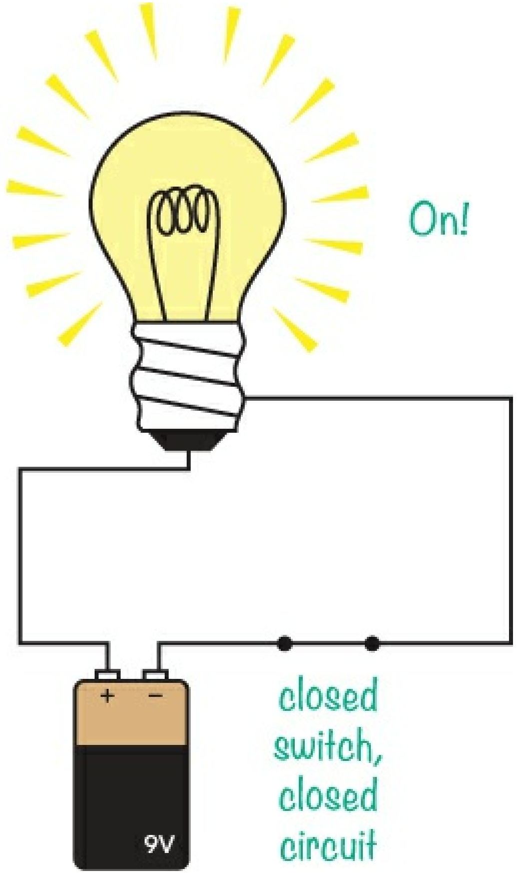
When you look around your home, you probably see switches everywhere. You use them all the time to turn lights on and off! When the light in a room is turned on, it must be part of a closed loop because the bulb has current running through it. But what happens when you flip the switch off? Flipping the switch off is the same as disconnecting a wire in the loop: it stops current from flowing and turns the light off, just like the disconnected circuit we saw earlier.

What other switches can you find around you? You might find a switch that turns a computer on and off, a switch to ring a doorbell, a switch to determine whether a refrigerator door is open, and more.

Switches control electricity, and they’re very simple devices. They connect two wires to close a loop or disconnect two wires to open a loop. Inside, a switch is just some pieces of metal that connect or disconnect.

When the switch is open, the light is off. When the switch is closed, the light turns on! It’s very simple, but very useful. With only this knowledge, you can create some nifty circuits, and that’s what we’re going to do next.





PROJECT #2: INTRUDER ALARM

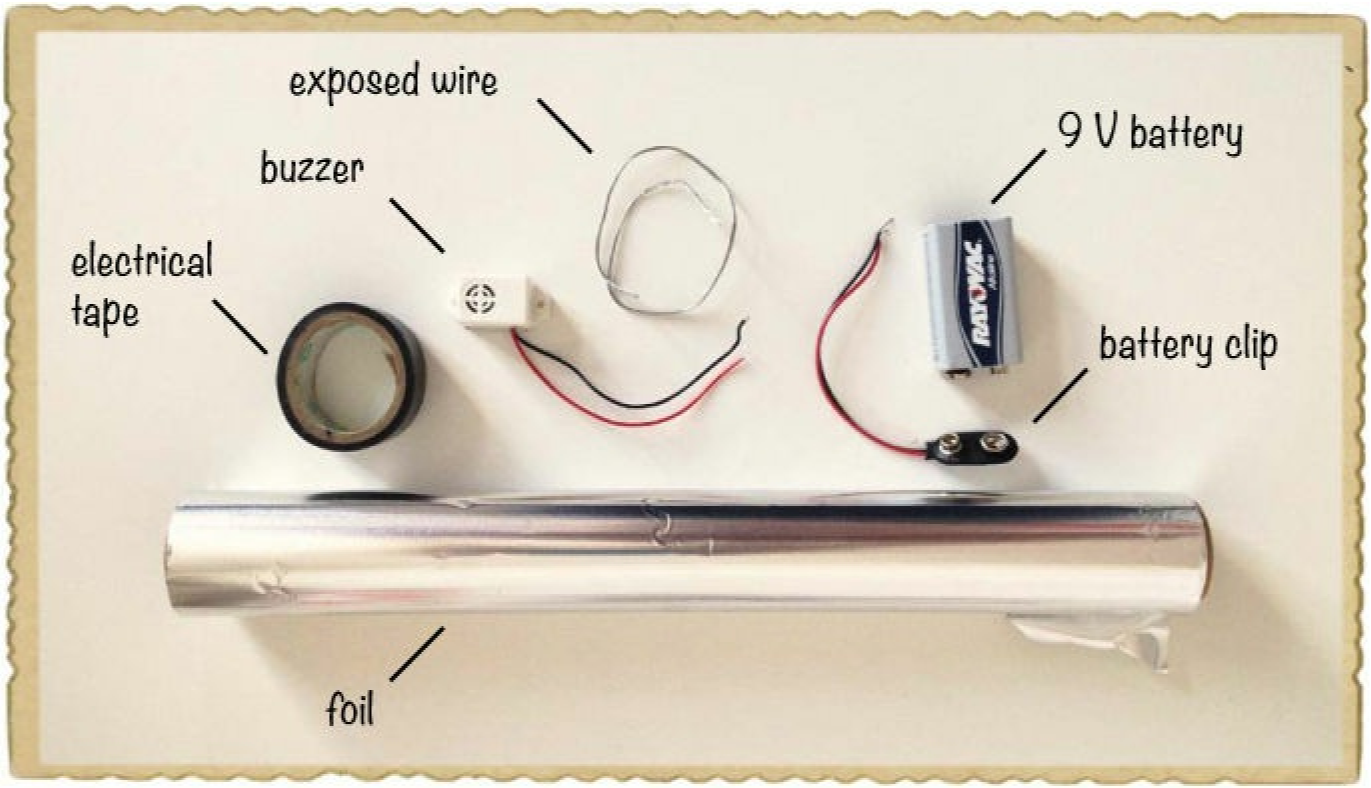
In this chapter, we learned that electricity needs a closed circuit to make a circuit do anything interesting, and we’ve looked at how a switch works. Let’s build a circuit with a switch!

You can build a switch out of a lot of different things—even a door. In this project, you’ll turn a door into a gigantic switch and use it to build an intruder alarm that tells you when someone tries to enter the room.

To create the alarm, we’ll attach some wires and aluminum foil to your door so that when the door is closed, your circuit is open and nothing happens. But when the door opens, the loop closes and a buzzer sounds to set off a red alert.

We’ll hang an exposed wire down from above the door, place a strip of aluminum foil on top of the door, and connect each of these parts to a different side of the circuit. Then, when the door opens, the exposed hanging wire will touch the aluminum foil and close the loop so that the buzzer will sound.

Shopping List



- **A buzzer** (Jameco #2173870, Bitsbox #ST016) that beeps. Buzzers come in both passive and active versions. Passive buzzers need an audio frequency input, while active buzzers need only a voltage. For this project, you need an active buzzer that works with 9 V.
- **A standard 9 V battery** to power the circuit.
- **A 9 V battery clip** (Jameco #11280, Bitsbox #BAT033) to connect the battery to the circuit.
- **Aluminum foil**
- **Exposed wire** (Jameco #2098478, Rapidonline.com #05-0320), like some soft electrical wires, an old steel guitar string, or something similar.
- **Tape** to fasten everything. You can use masking tape, electrical tape, or whatever you have.

Tools

wire cutter
scissors

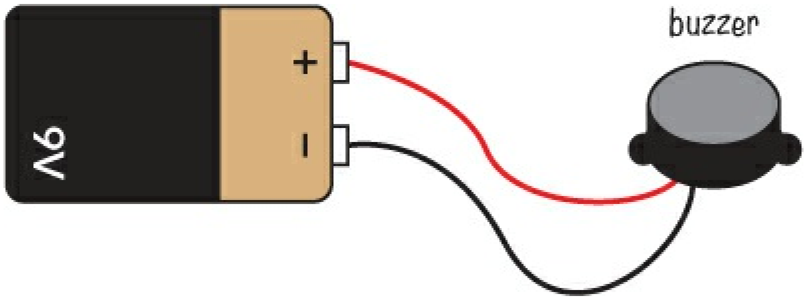
- **A wire cutter** (Jameco #35482, Bitsbox #TL008) to cut or remove the insulation from wire.
- **A pair of scissors** (optional) is useful for cutting the aluminum foil nicely.

TIP

If you want to make stripping wires even easier, you could buy a pair of actual wire strippers, like Jameco #78992, which are slotted so that you won't cut through the wire by accident.

Step 1: Does the Buzzer Beep?

First, test the buzzer to see that it beeps. Hold the red wire from the buzzer to the positive terminal on your battery (marked +) and touch the black wire to the negative terminal on your battery (marked –).



The buzzer should now make a loud, clear buzz or beep. If you disconnect one of the wires from the battery, the buzzer should stop making a sound because the circuit won't have a closed loop anymore.

NOTE

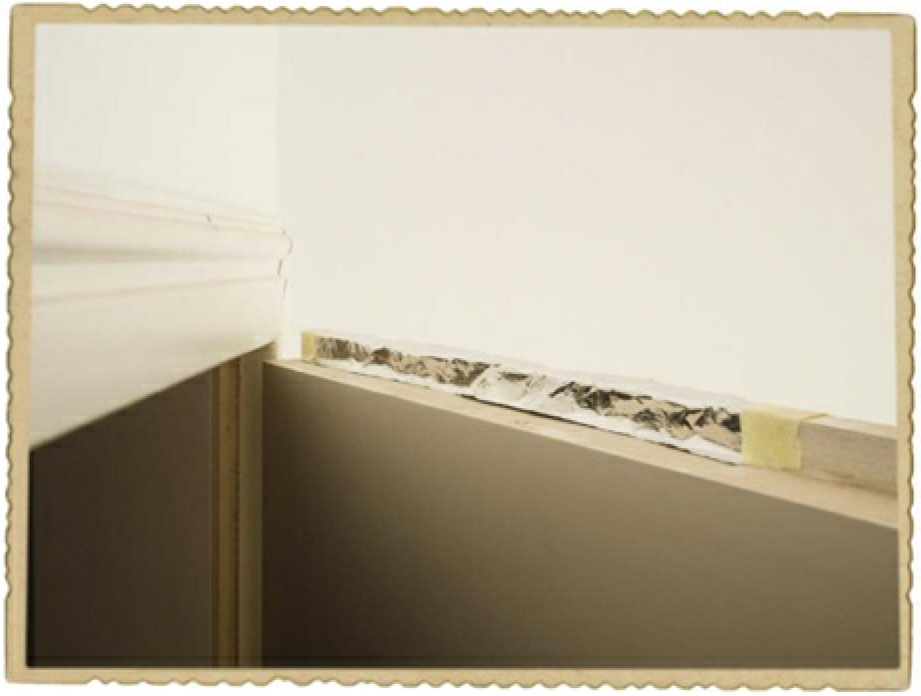
If your buzzer just made a click or didn't make any sound at all, you might have a passive buzzer. A passive buzzer can't create sound by itself, so you need an active buzzer for this *project. The buzzer recommended in this project's Shopping List (page 12) should do the trick.*

Step 2: Prepare the Aluminum

Use a pair of scissors to cut a big, shiny strip of aluminum foil to go on the top of the door. Cut a straight piece of foil, about 1 inch wide and as long as the roll of aluminum foil is wide.

Step 3: Foil Your Door

Fasten the strip of aluminum foil on the top of the door by using a piece of tape on each side of the strip. The foil will act as a contact for the battery and buzzer wire.



Step 4: Prepare a Trigger Wire

Get a piece of exposed soft wire about 10 inches long. An *exposed wire* is a wire that doesn't have any plastic around it, as opposed to *insulated wire*, which is metal enclosed in plastic. Just find some wire that is already exposed, such as a steel string from a guitar, or use your wire cutters to snip a piece from the spool in the Shopping List (page 12). This is going to be your trigger wire.

NOTE

You could also use a wire cutter to remove, or strip, the plastic from insulated wires. If you want to do that, ask an adult for help!

Step 5: Connect the Buzzer and Trigger Wire

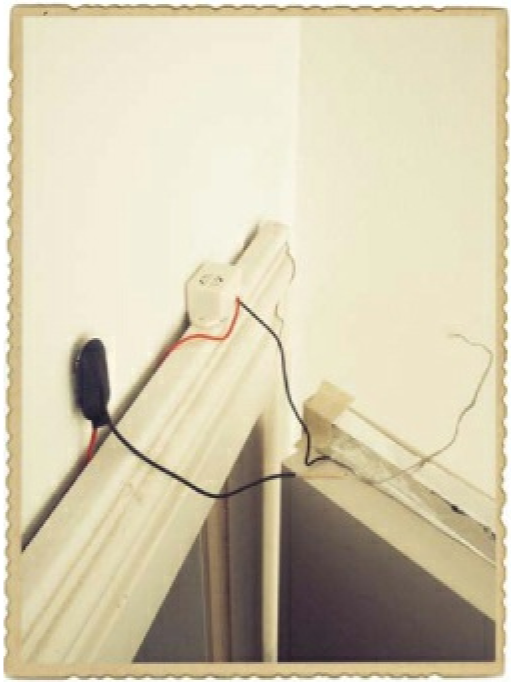
Connect one side of the exposed trigger wire to the exposed metal end of the battery clip's black wire with some tape. Connecting two wires is easy. Here's how you do it: Pick up the two wires you want to connect and twist their ends together. Make sure the two pieces of metal are touching! Then wrap them inside the tape together.

Following the same process, connect the red wire from the battery clip to the red wire on your buzzer.

Step 6: Mount the Buzzer and Trigger Wire

Now, let's place the trigger wire and the buzzer above the door. First, tape the trigger wire onto the door frame above the door so that it's hanging in front of the door when the door is closed and lying on top of the door and the aluminum strip when the door is open.

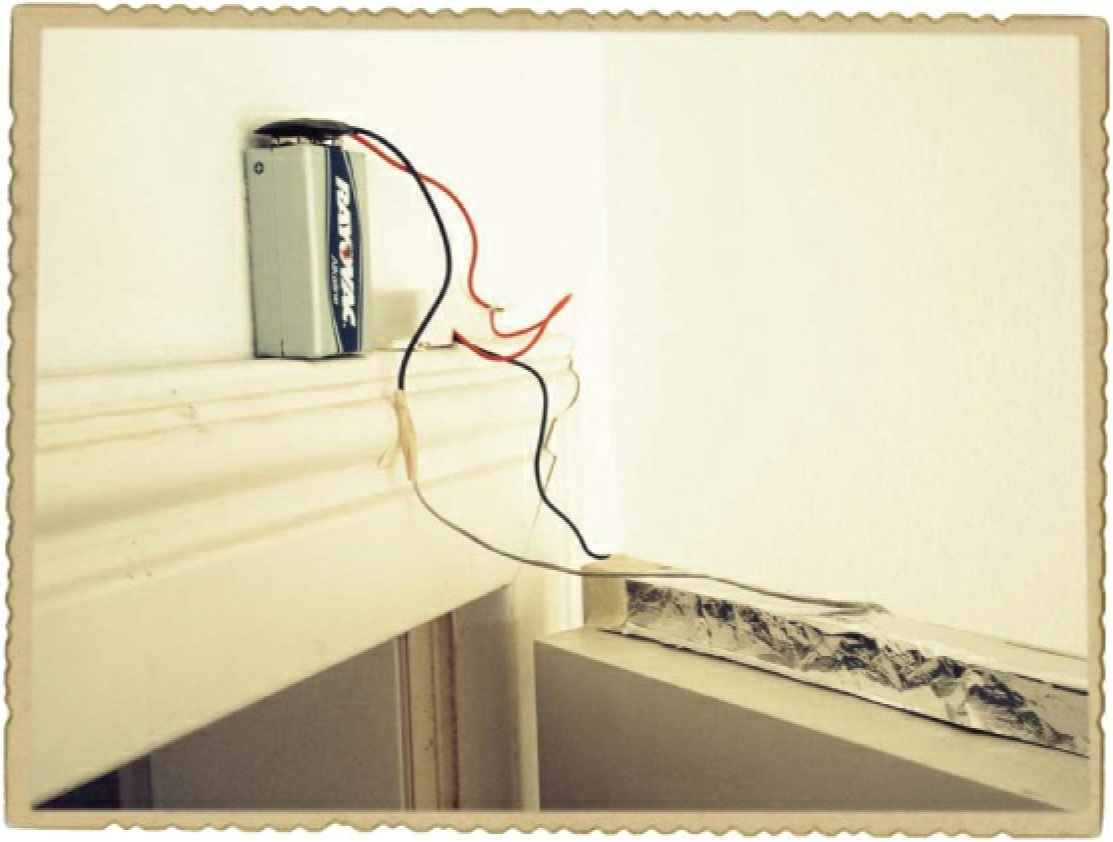
Next, tape the buzzer to the door frame in such a way that the black wire can touch the aluminum foil on top of the door. Tape the black wire onto the foil so that the exposed part of the wire touches the foil.



Step 7: Add a Power Source

Place the battery on top of the door frame, close to the battery clip. Use some tape to hold it in place if necessary. Then connect the battery clip to the battery.

Once the battery is connected, your finished intruder alarm should look something like this:



Step 8: Stage an Intruder Alert!

Test the alarm by opening and closing the door. As the door opens, the exposed wire should hit the foil, causing the buzzer to sound a loud alarm. For a more realistic test, invite someone else to open the door instead!

Step 9: What If the Intruder Alarm Doesn’t Work?

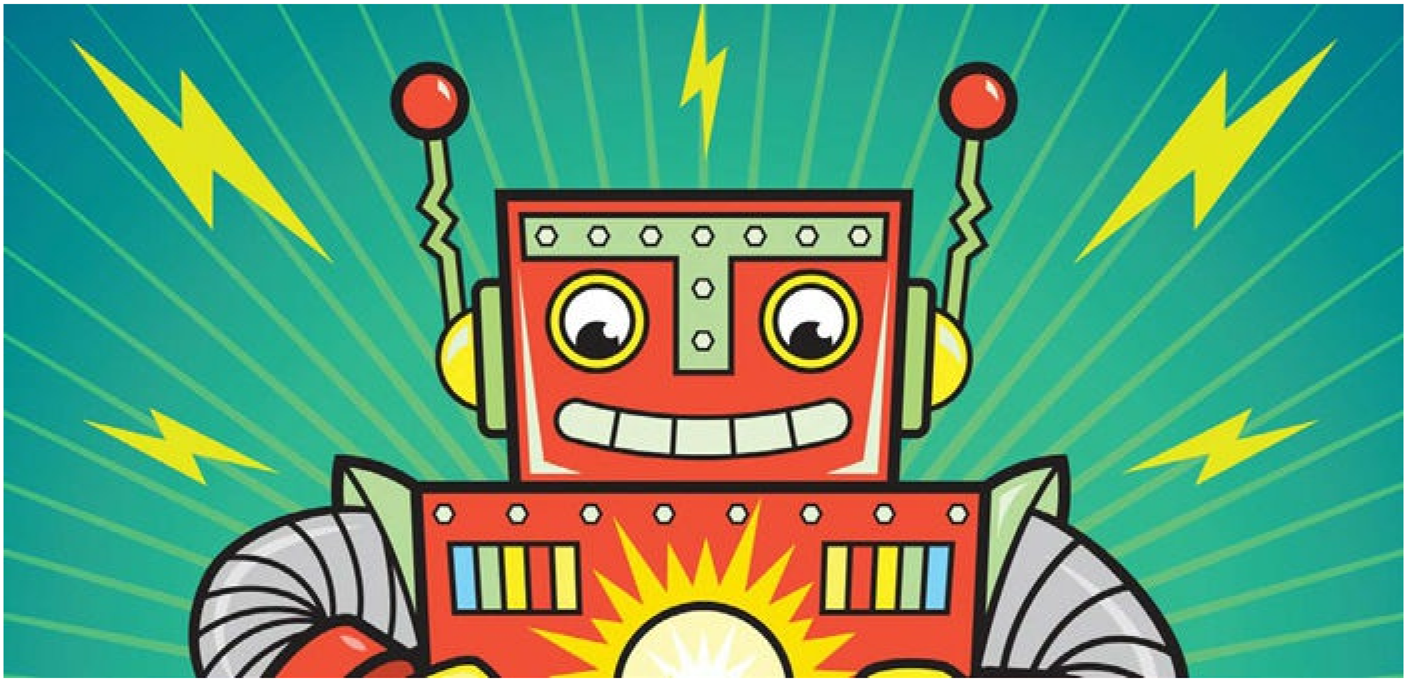
If the buzzer doesn’t go off, you might need to adjust the position of the trigger wire a bit, just to make sure the wire touches the strip of aluminum foil when the door opens. If the trigger wire touches the foil just fine, try a different battery. If that doesn’t work, you might need to retape your battery leads to their wires.

WHAT’S NEXT?

Now you know the basics of electricity—a current of electrons flows through wires and makes something happen, like lighting a light bulb or sounding an alarm. And you also know that to make the electrons flow through the circuit, you need a voltage source, such as a battery, and a closed loop. That’s all you need to start tinkering with electronics!

What else can you think of to make with what you’ve learned? There are many other things that can be made into switches. For example, try making an alarm for your closet to keep nosy siblings or friends away from your personal stuff. Or how about making a silent alarm? Just replace the buzzer with a light bulb!

In the next two chapters, we’ll look at how electricity is generated and how we can use electricity to make things move.



2

MAKING THINGS MOVE WITH ELECTRICITY AND MAGNETS

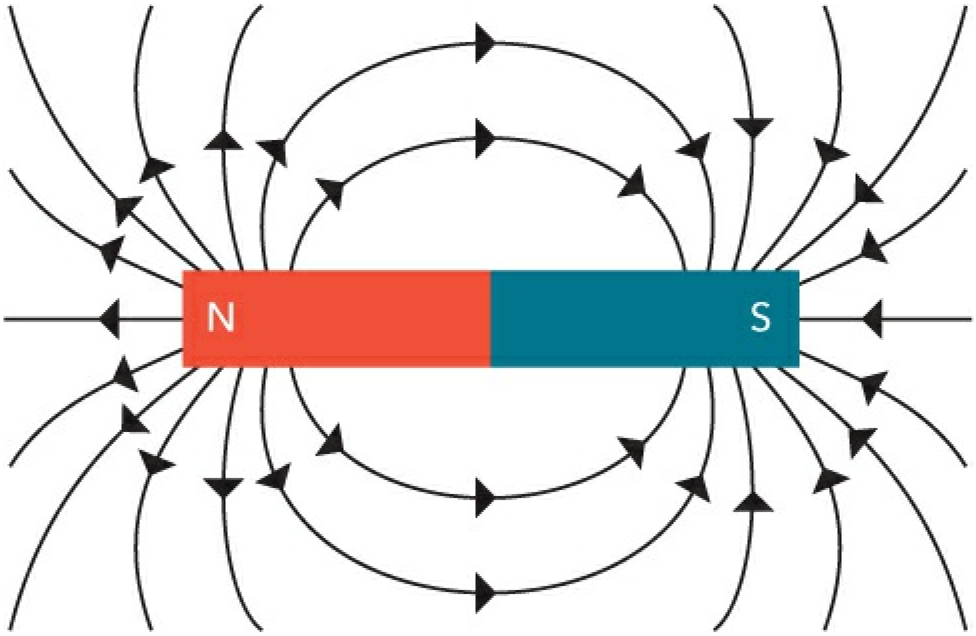
Big magnets attract small metal objects; small magnets stick to large metal objects. For example, refrigerator doors are usually big pieces of metal, so it's easy cover them with tiny, decorative magnets. You've probably seen magnets in cartoons, too: characters like to use giant horseshoe-shaped magnets to cause mischief. You can find magnets in nature or create them with electricity. A magnet created with electricity is called an *electromagnet*.

You can use an electromagnet to make things move, and you don't even have to be a superhero to do it! In fact, many things you see every day—like motors, loudspeakers, and the automatic doors in shops—work because electromagnets make something in them move.

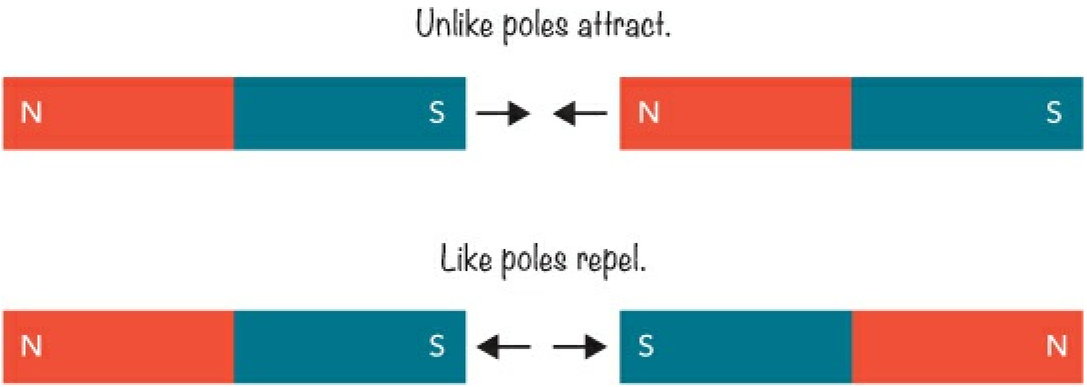
An electromagnet is very easy to make, and in this chapter, you'll build an electromagnet that you can turn on and off with a switch. Then, you'll use an electromagnet to build your very own motor!

HOW MAGNETS WORK

Magnets have two poles, the *north pole (N)* and *south pole (S)*, and they're surrounded by a magnetic field.



If you place two magnets side by side, the north pole of one magnet attracts the other magnet's south pole and repels that magnet's north pole. Try pushing two magnets together. If you don't force them, they should naturally attach to each other at their opposite poles. Now, try to force two of the same poles toward each other. That's harder, isn't it? Opposite poles are attracted to each other, and identical poles repel each other.



NOTE

Thin, flexible refrigerator magnets don’t have two distinct poles. Instead they have many poles of opposite polarity next to each other, so it’s harder to feel the magnets attract and repel.

But magnets don’t attract all materials. For example, plastic is unaffected by magnets. Try testing some metal objects around you!

TRY IT OUT: FIND SOME MAGNETIC OBJECTS!

Take any magnet and place it over objects made out of different materials, such as:

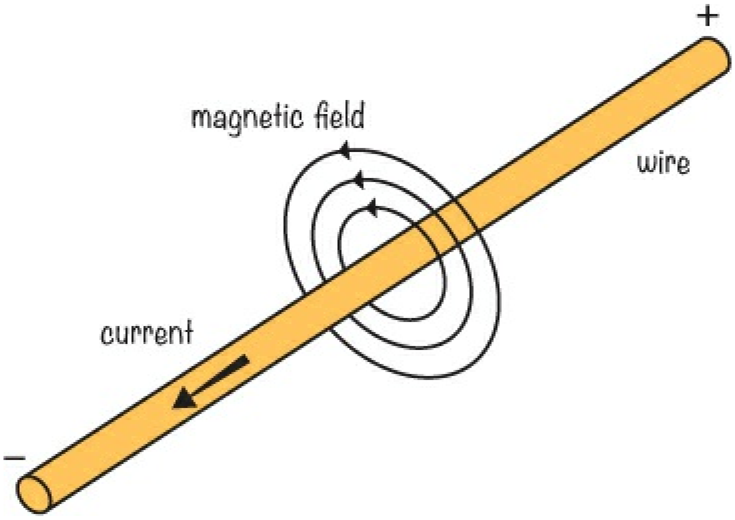
- Aluminum foil
- A stainless steel spoon
- A soda can
- An iron nail
- A piece of metal jewelry
- A few different coins

Which objects does the magnet attract or stick to? You should find that the magnet attracts some metals, but not all metals. What happens with aluminum foil?

It turns out that some metals can turn into magnets if you apply a little electricity. That’s where electromagnets come in.

MEET THE ELECTROMAGNET

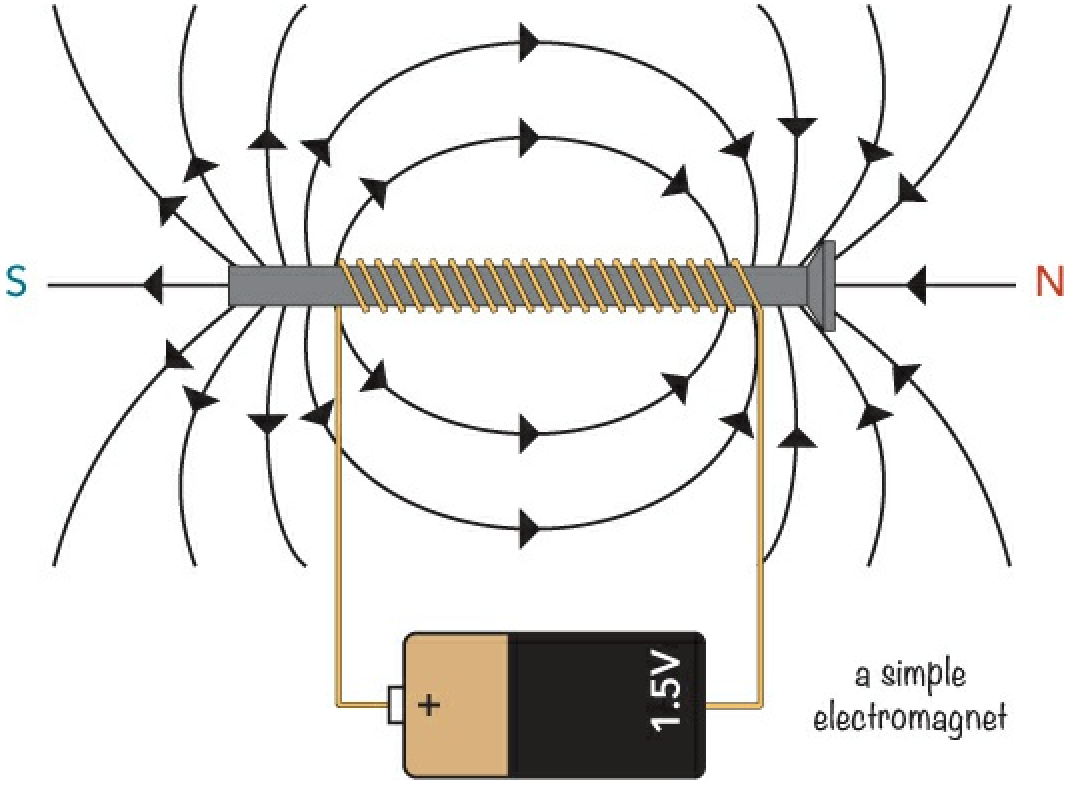
When current flows through a wire, something strange happens: the current creates a magnetic field around the wire.



The magnetic field of one wire, however, is very weak. To make a stronger magnetic field, you need to run current through lots of wires placed next to each other. But you still need only a single wire: you can just wind that wire into many loops to make a coil, and then send a current through it. The magnetic fields from each loop in the coil overlap and combine to create a stronger magnetic field. If you wind your wire around a piece of iron—like a nail, a bolt, or a screw—you'll get an even stronger magnetic field.

All you have to do to create an electromagnet is connect a battery to the ends of the coiled wire, making a closed circuit. When current flows through the wire, the piece of iron it's wrapped around starts to behave like a magnet, with the south pole at one end and the north pole at the other end. Which pole is which depends on the direction of the current, as well as the direction of the coil windings. When you disconnect the battery, the current stops and the magnetic field disappears.

Building an electromagnet will help you start to understand how you can use electricity to make things like a loudspeaker in the real world, so let's make one! With enough current, enough wire, and the right circuit, you could build a supermagnet straight out of your favorite cartoon, but for now, we'll start with a small one.



PROJECT #3: CREATE YOUR OWN ELECTROMAGNET

You know the theory behind how to build your own electromagnet. But reading the theory isn't the same as making something in real life, so it's time to have some fun!

You're going to build your own electromagnet with wire and a bolt. All you need to do is to wrap the wire around the bolt several times and connect the battery to the wire. To make it easy to turn the electromagnet on and off, you'll also add a switch to the circuit so that you can control whether or not current flows through the wires.

Step 1: Check Your Bolt

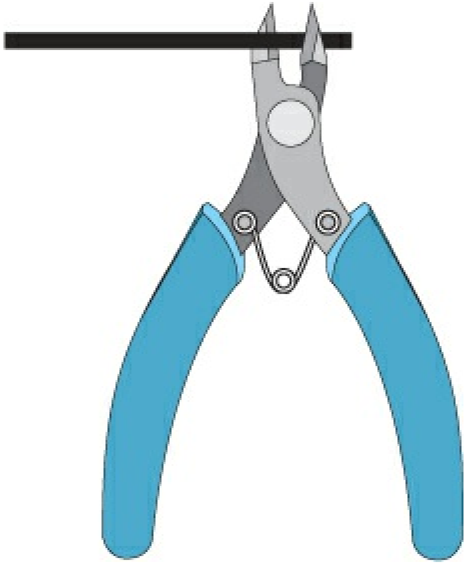
Your bolt is going to be the core of your electromagnet, making it stronger. But not all materials will work as an electromagnet's core! Most metal bolts should work, but if you're unlucky and find one that is made of nonmagnetic material, your electromagnet won't be very effective.

To check whether a bolt is okay to use in this project, just hold it close to any standard magnet. If the magnet attracts the bolt, then the bolt is a good one.

Step 2: Remove Insulation from One End of the Coil Wire

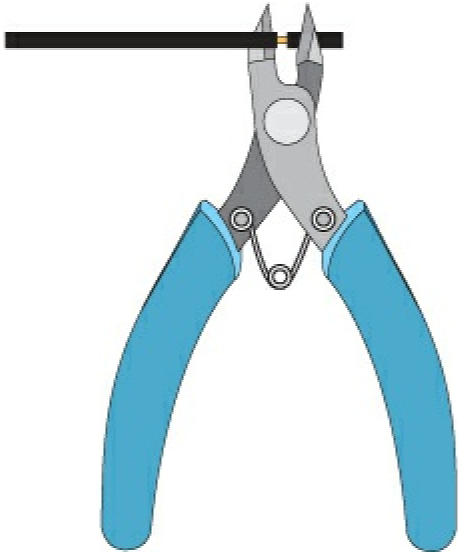
To connect the coil wire to the battery and the switch, you need to expose the metal of the wire at both ends. You'll use a wire cutter to strip away about 0.5 inches of insulation from the beginning of your wire. After you've wound the coil, you'll do the same with the end of your wire. Stripping wires can be a bit difficult if you've never done it before, so ask a parent or teacher for help to get started.

First, gently grasp the end of the wire with the cutters.



Apply just enough pressure with the wire cutter to cut the plastic around the wire, but not the wire itself. When you've cut through the insulation, your wire should look something like this:

Then, place the wire cutter in the cut you made. Squeeze the wire cutter enough to grip the loose plastic with the blades. Use the wire cutter to gently pull off the plastic without cutting into the metal of the wire.



Now, you should have a wire with some exposed metal at the end, like this:

If stripping wires seems tricky in the beginning, don't worry: it becomes much easier with practice.

Step 3: Wind the Wire

Take the wire and wrap it around your bolt 50 to 100 times. Leave about 3 inches of each end of the wire hanging loose. Make sure you don't use all the wire; you'll need a piece of wire about 4 inches long in a later step.

Wrap the wire as tight as possible and tape the end to make sure the turns stay in place. We call this wound wire the *coil* of the electromagnet.

Repeat Step 2 to strip the insulation off the other end of your coil.

Step 4: Connect the Negative Battery Terminal to the Coil

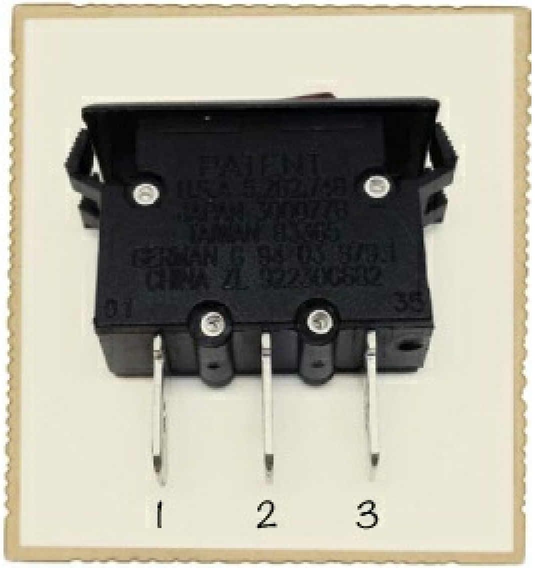
Connect one end of the coil—it doesn't matter which—to the negative terminal of the battery. Fasten it to the battery with tape.

WARNING

Be sure you're using the recommended 1.5 V battery! Anything more powerful could send too much current through your coil, which could make both the battery and the coil hot enough to burn you.

Step 5: Connect the Switch

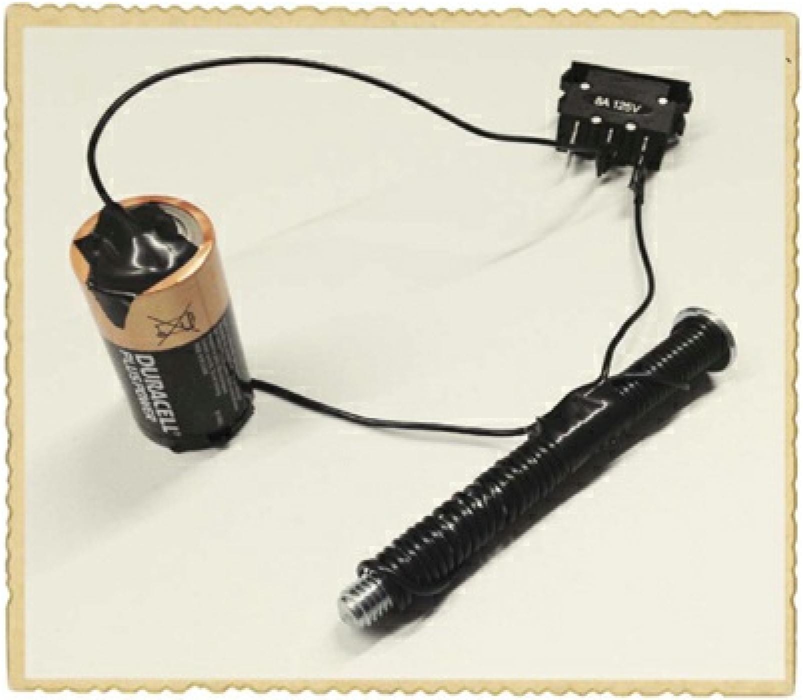
In Chapter 1, I showed you how to build your own switch and described how you can use one to turn something on and off. Now, you’re going to connect a prebuilt switch to your electromagnet to turn it on and off. A switch often has three *pins* that you can connect to.



On the switch in this project’s Shopping List (page 24), pin 2 is the *common pin*, which is connected to either pin 1 or pin 3, depending on the position of the button. If the button is pushed toward pin 1, then pins 2 and 1 are connected. If the button is pushed toward pin 3, then pins 2 and 3 are connected.

Some switches have only two pins. In that case, the two pins are connected when the button is in one position, and not connected in the other—just like the switch you built in “Project #2: Intruder Alarm” on page 11.

Fasten the other end of the coil wire to pin 1 of the switch and make sure the button of the switch is pushed toward pin 3. Then, cut a brand-new piece of wire from your spool, about 4 inches long, and strip some insulation from both ends to expose the metal. Connect one end of the new wire to the positive battery terminal and one end to the middle pin of the switch. Use tape to make sure the wires are properly connected and stay in place.

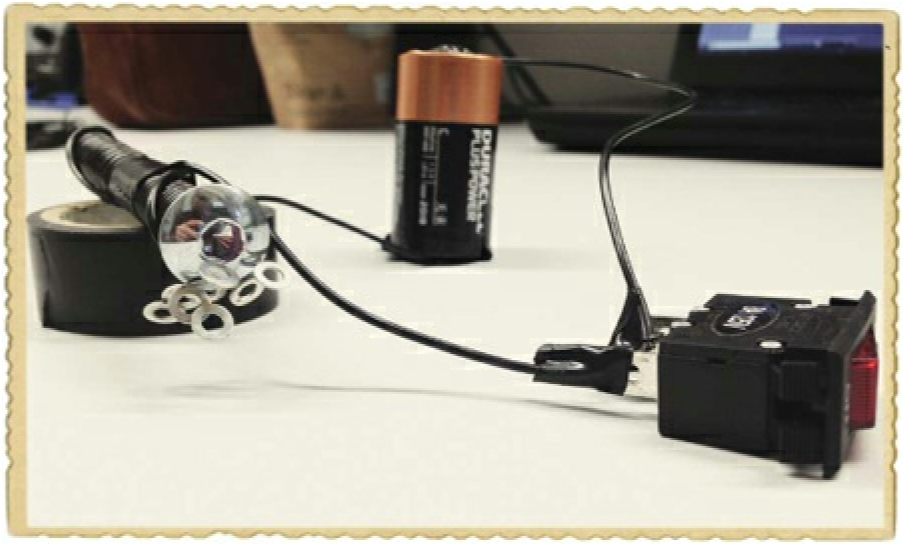


Step 6: Test Your Super Electromagnet

That's it for building the circuit! Now, let's test it. If you've connected everything correctly, your electromagnet should be off now.

First, find a good piece of metal to attract with your electromagnet. A small metal paper clip should do the trick, though I used a little pile of steel washers. Magnets won't attract all metals—for example, aluminum foil is not magnetic—so hold a regular magnet next to the metal you want to attract first to make sure it's magnetic.

Then, flip your switch and place your electromagnet close to your paper clip or whatever other metal object you're using. If you've found the *on* position, the bolt should pull the metal object toward it.



If nothing happens, press your switch into the other position; the bolt should start to pull the metal object now.

The electromagnet consumes a lot of power, so if you keep the switch flipped on for too long, your battery will drain quickly. You might also notice that the battery and the coil become hot. Try to limit the time your electromagnet is on to only a few seconds, and always disconnect the battery before you leave your circuit.

Step 7: What If the Electromagnet Isn't Working?

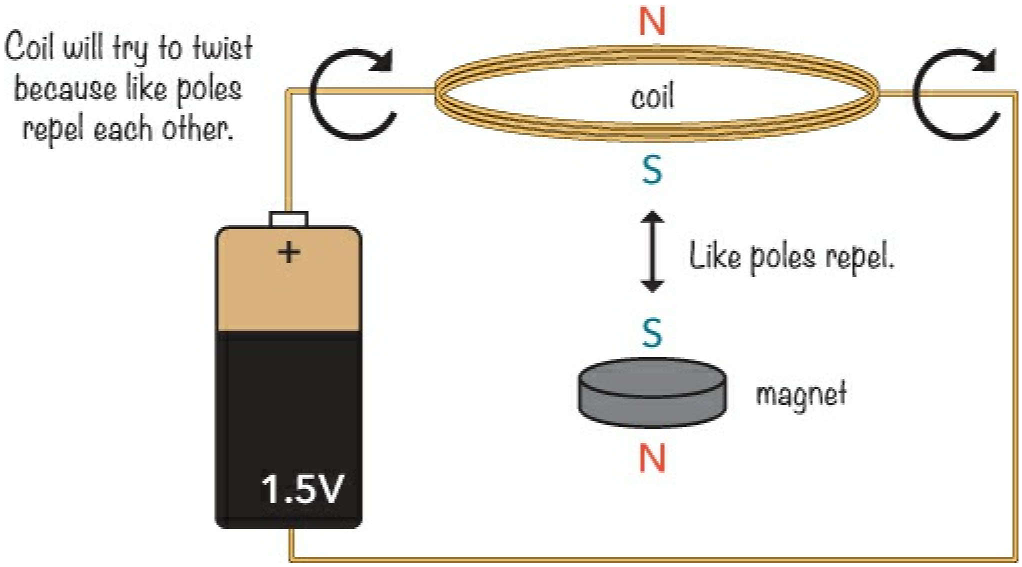
Make sure you used insulated wire to make the loops around the bolt. The wire must have some kind of insulating layer on the outside of the metal; otherwise, it won't work. The reason for this is that without the insulating layer, the current won't follow the wire loops around the bolt. Instead, they'll go through the bolt if the bolt is conductive or through to the neighboring wire if the loops of wire are touching. In either case, the current will function as if you had one thick wire.

Another possible problem is that your battery is dead. Try switching to a different battery that you're sure is working.

If you're sure you're using insulated wire and that the battery has power, check that the connections on the switch and battery are connected, as I described in Steps 4 and 5. If you're unsure, it might be a good idea to redo the connections.

MEET THE MOTOR

A wire with flowing current creates a magnetic field, as I described in "Meet the Electromagnet" on page 22. When powered, the coil from Project #3 will have a magnetic field with south and north poles, just like any other magnet. Like poles repel each other and opposite poles attract each other. So, if you put a magnetized coil of wire over a regular magnet with the same poles close to each other, the coil will try to twist itself around.



If you placed the wire coil on some kind of stand so that it could rotate freely over the magnet, it would flip back and forth without making a full spin. This is because when the coil has made a half spin, the opposite poles face and attract each other, which will force the coil in the opposite direction.

How can you make the coil continue to spin in one direction? You just need to find a way to disconnect the battery halfway around and turn the battery back on when the coil is back in its starting position. Then, here's what happens. The coil starts moving when it's powered and pushes the wire coil halfway through one round. Because you disconnect the battery halfway through, the existing motion keeps the coil moving forward. When it comes back to its original position, the battery gets reconnected and gives the coil another push forward, and it continues the same way.

Electric motors are based on this basic principle of magnetic poles attracting and repelling each other.

PROJECT #4: CREATE A MOTOR

In this chapter, you've built your own electromagnet, and you've learned how motors work. Now, it's time to combine these two concepts. In this project, you'll build your very own motor from scratch!

You'll use a magnet together with a coil of wire. The coil will spin, and this spinning coil is called the *rotor* of the motor. You're going to build the motor so that the rotor coil has current through it for only half of the spin. The magnet should push the electromagnet for half of the spin, and the rotor coil should continue around the second half of its spin with the energy it gets from the first push.

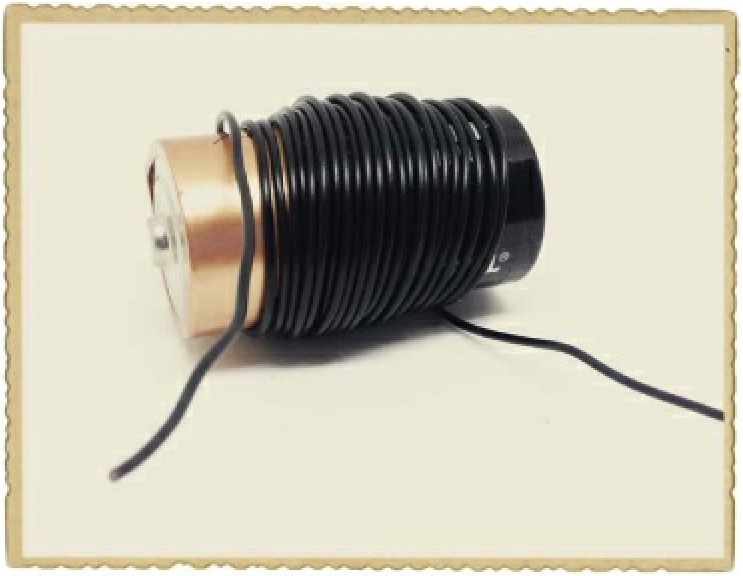
Tools

wire cutter

▸ **A wire cutter** (Jameco #35482, Bitsbox #TL008) to cut or remove the insulation from wire.

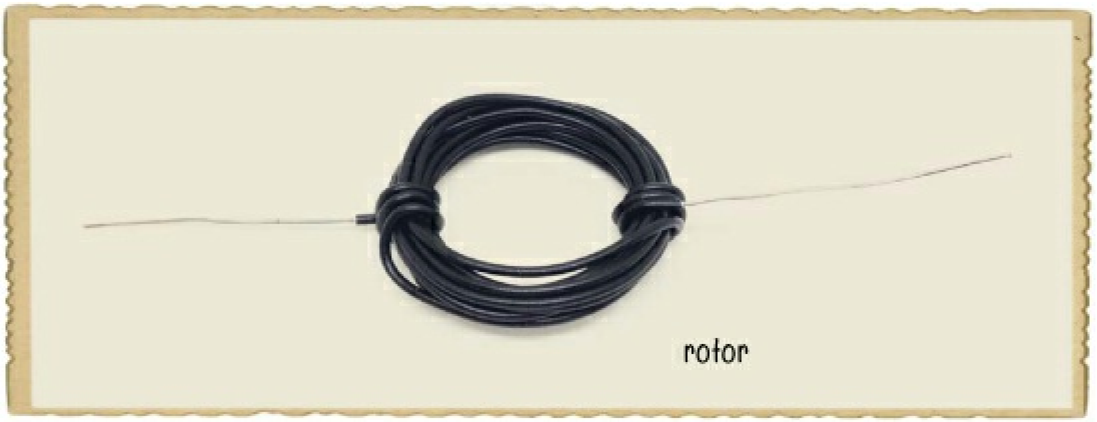
Step 1: Create the Rotor

First, we'll create a new coil of wire; this coil will be the rotor, or spinning part, of your motor. To create the rotor, first take your spool of wire and strip the insulation from about 1.5 inches of the free end. Then, wind the wire around the battery.



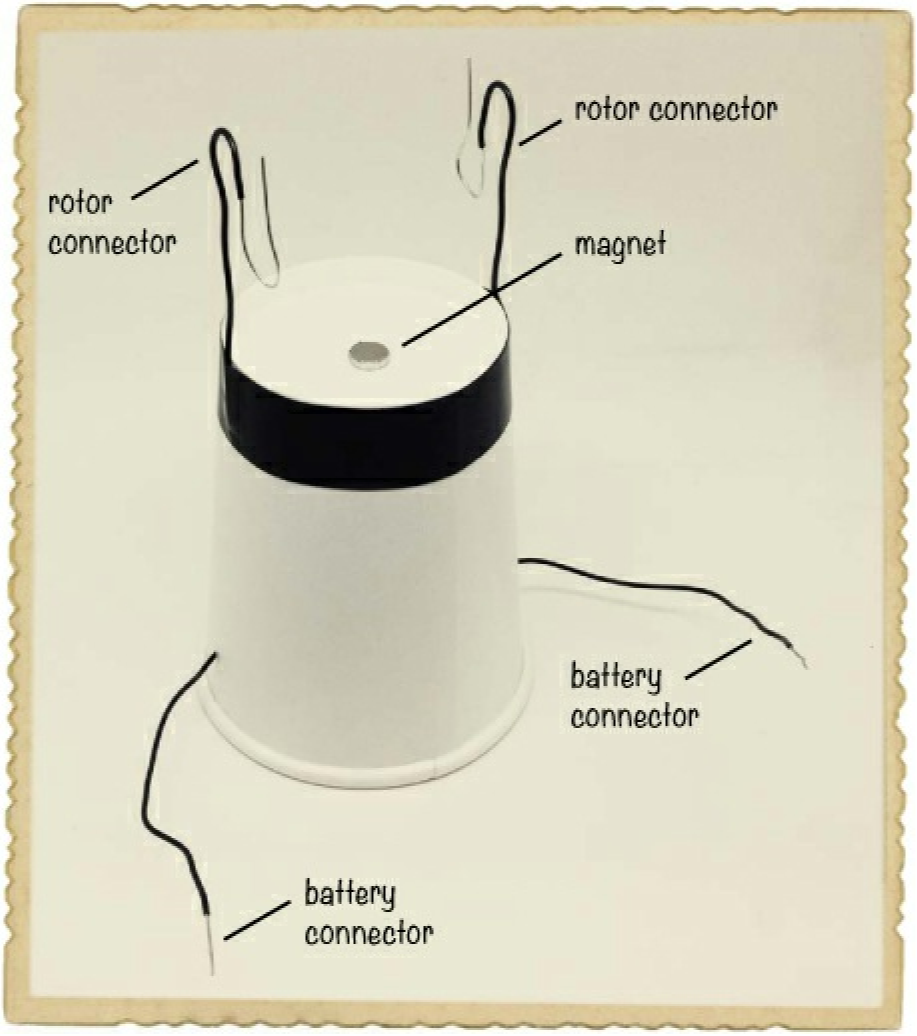
If you buy the wire I recommend in this project's Shopping List (page 34), try making around 30 windings; if you use thinner wire, wind it more. The point is to make the coil as magnetic as possible, without making it too heavy. More windings make the rotor more magnetic, but also heavier.

Carefully slide your coiled wire off the battery. Gather the windings into a loop and wrap the ends of the wire around your loop a few times on each side so that the coils stay together. Cut your loop from the spool of wire, leaving the other end about 1.5 inches long. Then, remove the insulation from this end, too, so that the metal inside is exposed. If you're using wires with plastic insulation, you can use a wire cutter, as described in Step 2 of Project #3 (page 26).



Step 2: Build the Motor's Structure

Set your coil aside for now and take out your paper cup. Punch a hole in one side of the cup about 0.4 inches from the top and another one about 0.4 inches from the bottom. Pull a piece of the stiff wire around 8 inches long through these two holes. Then, do the same on the other side of the cup. Turn the cup upside down, remove the insulation from the ends of both wires, and tape the wires to the cup to ensure they stay in place.



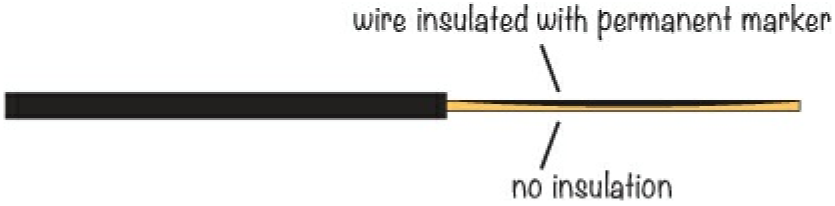
The ends that are now on the bottom will connect to the battery, and the top ends are going to make up the connection to the rotor and support it. Bend the top ends of the two wires into two U-shapes that can hold the rotor. Make sure the bottom part of each U has exposed metal so that it will touch the exposed wires of the rotor. This U-structure will be the battery's connection to the rotor.

Step 3: Place the Magnets

Place one magnet on top of the cup. Then place one magnet inside the cup so that the two magnets stick to each other through the cup. Place your rotor into the U-structure and adjust the position of the magnets to make sure they are at the center, just under the coil.

Step 4: Reinsulate Part of the Coil

If you connected the battery now, the motor wouldn't work. With your coil rotor attached, you'd see movement, but the rotor would just be pushed back and forth in opposite directions because it's always connected to the battery. You need a way to disconnect the coil from the battery halfway through so that it's first pushed away from the magnet and then released until it has spun the rest of the way around. Then, it can reconnect with the magnet and get pushed again, and so on. You can make this happen by insulating the wire on one side with a permanent marker. Do this on only one arm of the rotor.



Lay your coil flat on the table and use a permanent marker to draw along the wire on one side to make it non-conductive. Draw your line so that the rotor disconnects from the battery when the loop lies horizontally above the magnet.

Step 5: Rev Up Your Motor

Let's get that motor running! Connect the battery by taping the two wires to the positive and negative terminals.

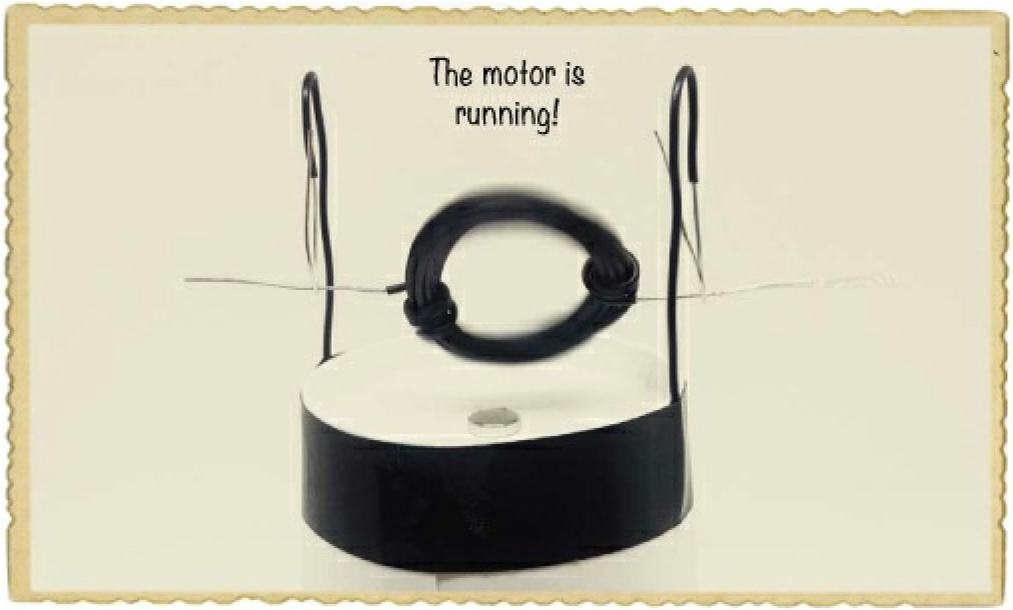
Now, place the rotor into the U-structure. The motor should start spinning. You might need to give it a little push. It won't run any cars, but if it works, then you definitely just made something move with electricity. Congratulations!



The motor is
running!

Step 6: What If the Motor Doesn't Work?

Can you see any movement? If you're very lucky, it'll work right away, but you'll most likely need to make some adjustments. Here are some places to start:

1. Make sure your coil is placed so that it starts with the exposed wire—that is, not the part you covered with the marker—touching the exposed wire of the U-shaped structure. That way, when you connect the battery, the coil becomes magnetic.
2. Figure out which way the battery should be connected. You might find that the rotor spins better

in one direction than the other, so try to connect the battery the other way around to see what's best for your motor.

3. If your coil is a bit too heavy, the magnetism won't be enough to push the coil all the way around the loop. Try unwinding a few loops to make the coil lighter.
4. You might need to adjust the position of the magnets under your rotor. They should be as centered as possible.

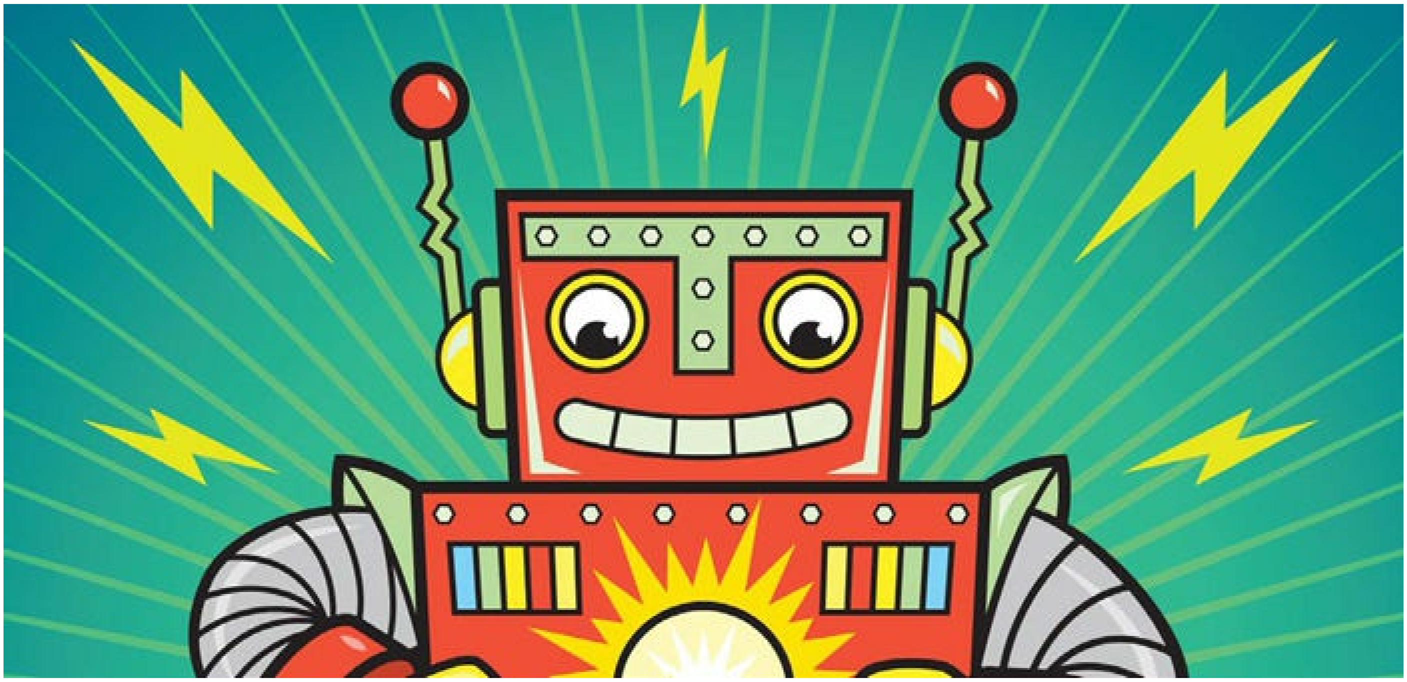
If your motor still doesn't run, your rotor may just need a little push to get started. Try tapping it lightly with your finger to see whether that unleashes a speed demon.

WHAT'S NEXT?

In this chapter, you've learned that magnets can be created by winding a wire around a bolt and connecting it to a battery, and you've tested this by building your own electromagnet. At the end, you learned how electric motors work, and you even built one for yourself. You really got things moving!

Now, take that knowledge and explore electricity a little further. Try adding even more magnets under the rotor of your motor. Then, wind a rotor coil that is twice as big or even bigger. You can create a much larger structure for the motor. How fast can you make your motor go?

So far, you've only used electricity, but you can actually generate it, too. In the next chapter, you'll learn a couple of different ways to generate electricity, and you'll be playing around a bit more with magnets.



3

HOW TO GENERATE ELECTRICITY

Chapter 1 described why you need a closed loop to get current flowing through a circuit, and Chapter 2 showed you how to build your own electromagnet and motor. The projects in those chapters used electricity from a battery, but in this chapter, you'll make your own electricity sources!

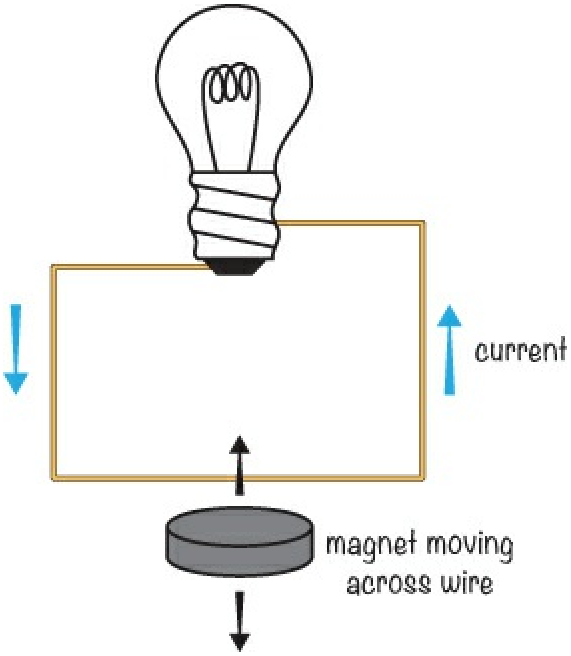
Specifically, you'll learn how to build your own generator, which creates electricity from movement, and your own battery, which creates electricity through chemical reactions. These are two of the most common ways to obtain electricity.

GENERATING ELECTRICITY WITH MAGNETS

When you run current through a wire, it creates a magnetic field around the wire, but there's another connection between electricity and magnetism. You can also create electricity using a wire and a magnet!

A Changing Magnetic Field Creates Electricity

If you move a magnet back and forth over a wire connected in a closed loop, you'll create a current in the wire. Moving the magnet changes the magnetic field around the wire, and the changing magnetic field pushes the electrons through the wire.

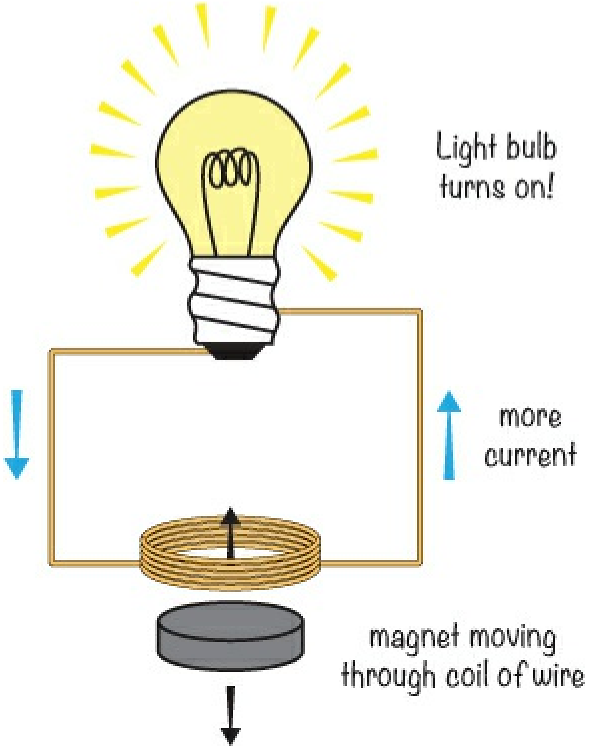


If you stop moving the magnet, the current also stops—even if the wire is still within the magnetic field—because the magnetic field is no longer changing.

If you connect the two ends of the wire to a light bulb and create a closed loop, then the current can flow. Unfortunately, however, the current created by moving a magnet over a single wire doesn't provide enough energy quickly enough to actually light the bulb. To light a bulb, or to power anything else, you need to find a way to generate more *power*, which is the amount of energy produced in a certain time.

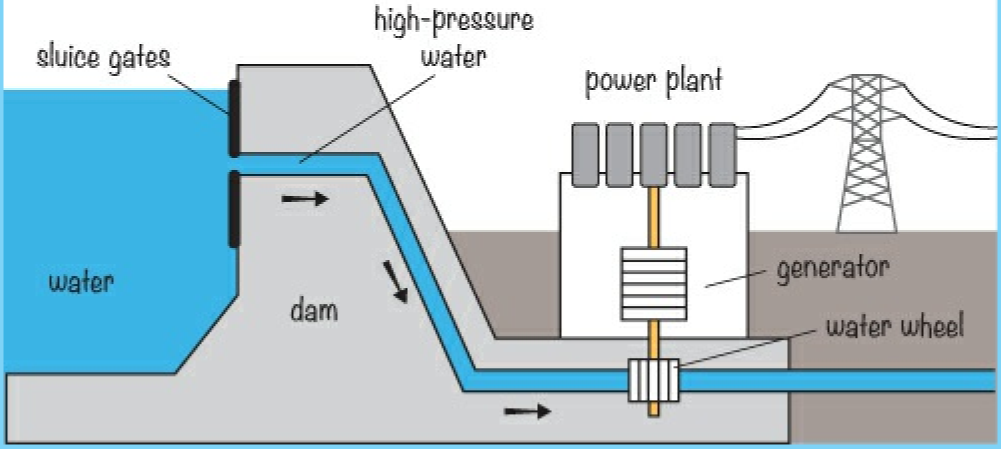
How Does a Generator Work?

A *generator* is a device that turns movement—such as the movement of a magnet over a wire—into electricity. To create more power with a wire and a magnet, you can wind that wire into a coil. The coiled wire acts like a group of wires, and when the magnetic field passes through it, a current flows through each coil, creating more power than you could with a straight wire.



CREATING ELECTRICITY FROM WATER OR WIND

If you place a coil in a magnetic field and rotate the coil with a handle, you're converting your own movement into electricity. If you replaced the handle with a water wheel and placed it into a stream of water, the water would push the wheel so that the coil would rotate in the magnetic field and create a current. This is how some power plants generate electricity! The power plant just lets water run through a wheel that's connected to a generator. Then this electricity is transferred, through power lines, to the power outlets in people's houses.



sluice gates
high-pressure water
power plant
water
dam

You can make electricity out of other natural forces in the same way. For example, to create electricity out of wind, you can connect the coil to a windmill so that when the wind blows, it rotates the coil.

MEET THE MULTIMETER

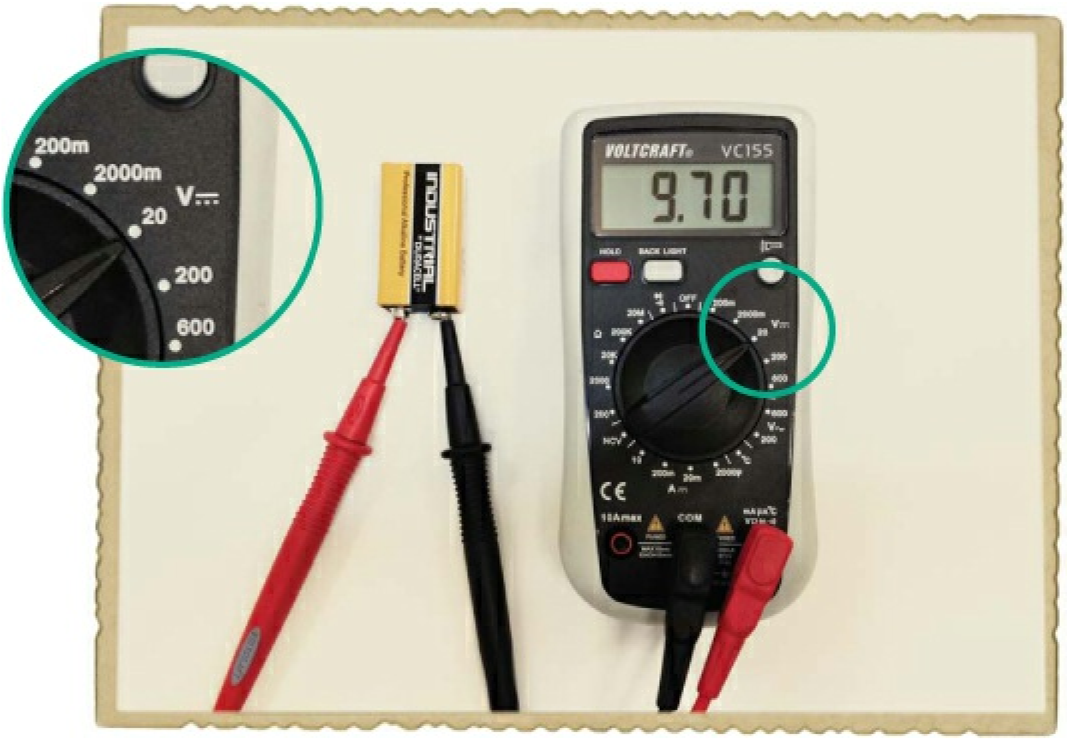
You can measure exactly how much energy a simple generator creates with a basic *multimeter*. Multimeters are handy when building any circuit because they can measure a lot of different values, including resistance, current, and voltage.

VOLTCRAFT
VC155

The red lead is the positive lead, the black lead is the negative lead, and the big dial in the middle lets you tell the multimeter what to measure. If you're having problems with a circuit, measuring the voltage at key points in your circuit is one practical way to figure out what's wrong.

How to Measure Voltage

To measure voltage with a multimeter, first turn the dial to one of the V options. (In this book, I'll tell you which setting to choose, but in your own projects, pick one that has a number higher than the highest voltage you expect to see in your circuit.) Then, at the bottom of the multimeter, connect the black lead to the COM socket and the red lead to the V socket. Finally, place one lead on each side of the part you want to measure the voltage across.

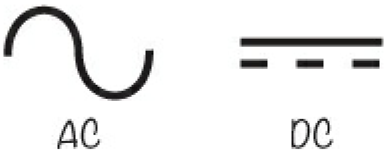


In this example, the meter is measuring the voltage between the positive and negative terminals of a 9 V battery. Notice that my dial is turned to 20 V, in the range showing a V with a straight-line symbol. But there's another V on the multimeter with a wavy line next to it. Let's look at what these symbols mean.

What Are AC and DC?

How you set your multimeter depends on whether you want to measure the voltage from a battery or a generator. A battery has a positive and a negative side, but a generator doesn't! A generator has two wires that alternate between being positive and negative. This is because when one side of the magnet moves past the coil, current in the coil flows in one direction, and when the other side of the magnet moves past the coil, current flows in the other direction.

When the current direction switches like that, we call it *alternating current (AC)*; when the direction of the current stays the same all the time, we call it *direct current (DC)*. Usually, you'll find these symbols on your multimeter to indicate the AC and DC ranges of measurement:



You need to set the multimeter to measure either AC or DC to get the correct reading. For example, batteries have a DC voltage.

PROJECT #5: MAKE A SHAKE GENERATOR

Grab your multimeter—this project will show you how to make a generator and measure its voltage. One quick way to create a simple generator is to manually move a magnet back and forth inside a coil. In this project, you'll put a magnet inside a tube and wind a coil around the tube. When you shake the tube, the magnet should move back and forth inside the coil and create a voltage.

- **Insulated solid-core wire** (Jameco #36792, Bitsbox #W106BK), about 9 feet. Standard hookup wire works fine.
- **A small plastic tube**, such as an old pen.
- **Five disc magnets** (Jameco #2181319, Bitsbox #HW145) stacked to form a magnet rod.
- **Two alligator clips** (Jameco #256525, Bitsbox #CN262) to connect the multimeter to the coil.

Tools

- **A multimeter** to measure the voltage of your generator. The multimeter should be able to measure very low AC voltages, down to 0.01 V or less. Suitable multimeters are Jameco #2206061, Bitsbox #TL057, or Rapid Electronics #55-6662. These multimeters are a bit more expensive than the cheapest ones, but they will serve you for many years to come.

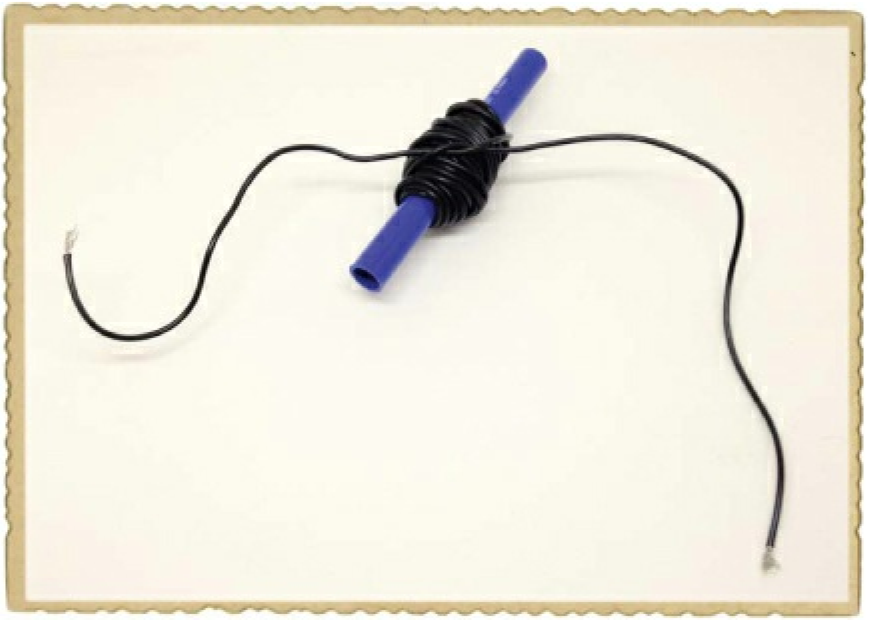
multimeter

Step 1: Prepare Your Tube

Find a tube that's big enough to let the magnets slide easily back and forth. If you're using a pen, disassemble the pen and make sure your magnets fit inside the tube.

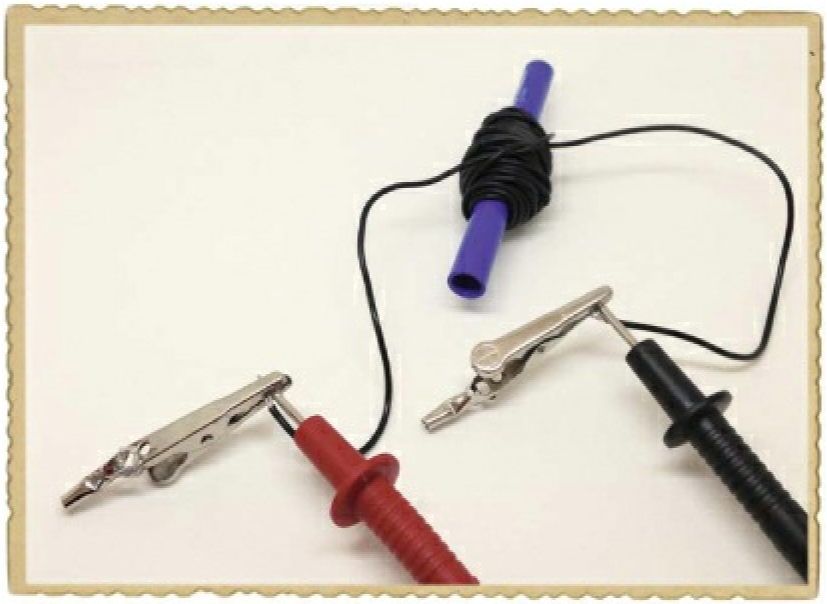
Step 2: Wind Your Coil

Wind about 50 turns of wire around the middle of your tube. After winding, make a simple knot with the two ends to keep your coil together. Then, strip the insulation from the two wire ends, as shown.



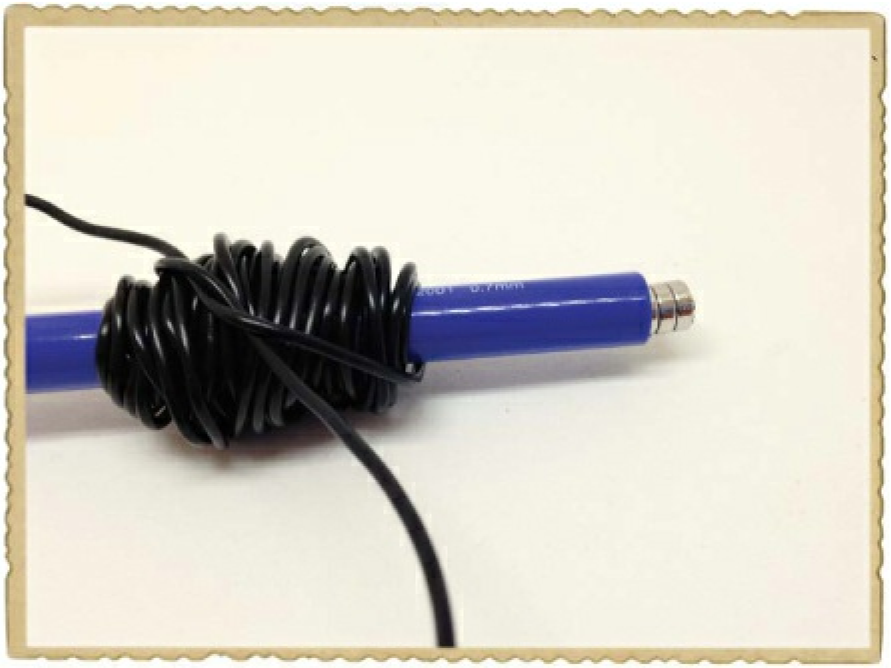
Step 3: Connect the Multimeter

Connect the multimeter to both ends of the coil using alligator clips and set the multimeter to measure AC. Choose the lowest AC voltage setting available.

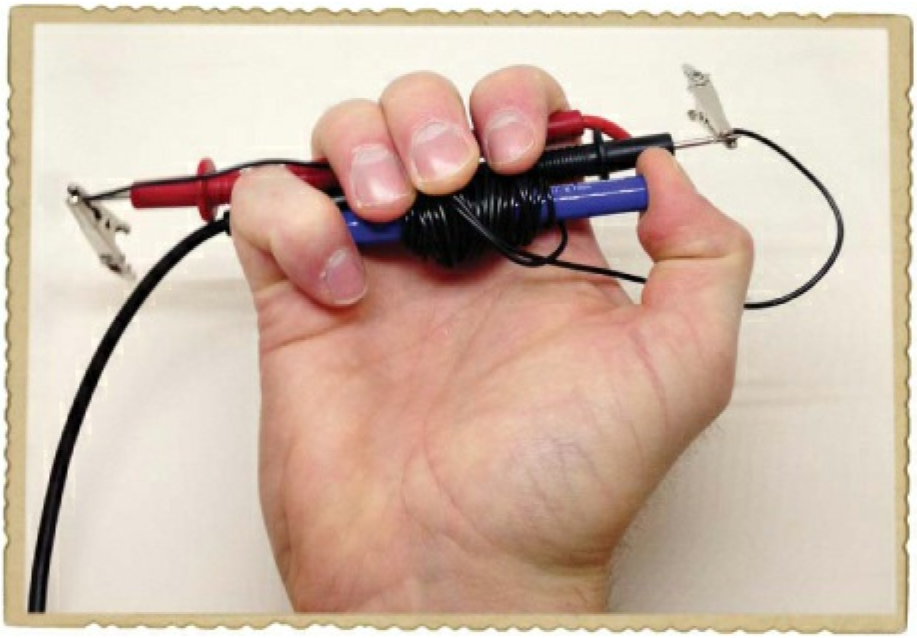


Step 4: Shake That Thing!

Next, put the magnets inside the tube. They should fit inside without coming apart.



Holding the tube and multimeter leads in your hand, place one finger on each side of the tube so that the magnets don’t fall out. Then, shake it like you mean it!



Observe the voltage value on the multimeter. How much voltage do you get? I was able to get only 0.02 V from my generator, so it's not very powerful.

Step 5: What If There's No Voltage?

If you can't measure any voltage from your generator, first check that your multimeter leads are connected well to the exposed coil wires. If you still don't see a voltage higher than 0 V, make sure your multimeter is set to measure really low voltages; my dial was turned to 2 V AC. You won't get a high voltage from this simple generator, so if the multimeter isn't on the lowest setting possible, it will keep reading 0 V. Note that not all multimeters are able to measure such low voltages.

This generator isn't very powerful right now. How can you make it more powerful? Try to increase the voltage from the generator by shaking it faster, adding more loops of wire to the coil, or using a more powerful magnet.

NOTE

Standard hookup wire is a bit bulky; even 50 turns take up a lot of space! If you want to get a lot more turns, try using magnet wire *instead. It's really thin wire with a thin layer of insulating coating.*

TRY IT OUT: USING A MOTOR AS A GENERATOR

A motor already has a magnet and a coil of wire that can rotate in the magnet's magnetic field. If you rotate the rotor with your hand, you can generate a voltage on the motor's wires.

You could create a generator by reversing the motor you built in Chapter 2, but the power you'd get from it would be too small to measure. Instead, try to find an old motor from a computer fan or a radio-controlled toy car that you don't want to play with anymore. Then, set your multimeter to a low-voltage DC range, such as 2 V DC. Attach the multimeter leads to the motor wires, just as you did with the shake generator, and turn the rotor with your fingers. Some motors have internal circuits that control the motor, and those circuits can prevent the electricity generated inside the motor from going out to the wires. But if you're lucky and find a motor that doesn't have such circuits, you should see a reading on the multimeter. Try a low-voltage AC range on your multimeter if you see nothing with DC.

HOW DO BATTERIES WORK?

I've shown you how to generate electricity manually, but that doesn't explain how you've powered circuits up to this point in the book. You've been using batteries, and in this section, we'll look at what lets those batteries create electricity.

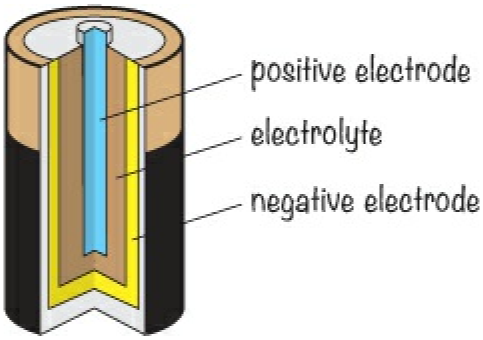
What's Inside a Battery?

To create a battery, you need three things:

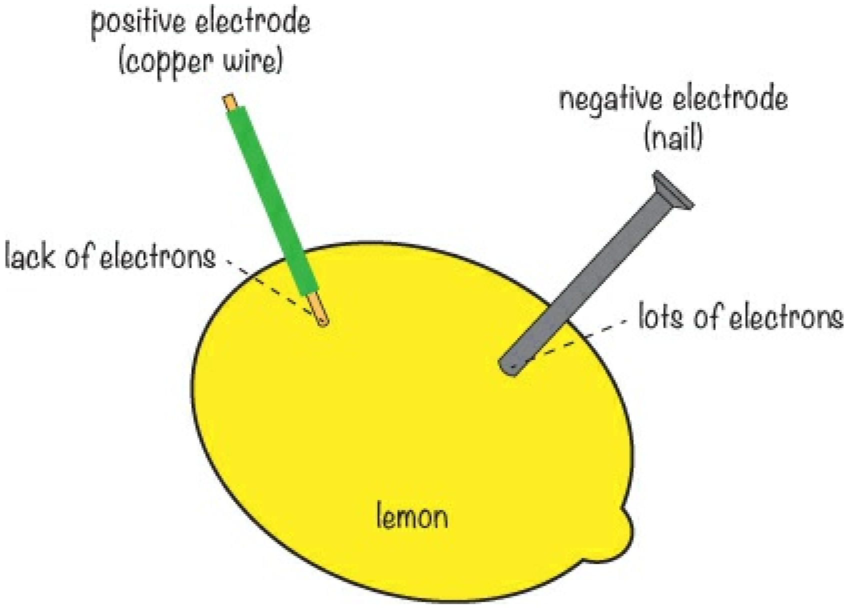
- A positive electrode
- A negative electrode
- An electrolyte

An *electrode* is a wire that is used to make contact with something nonmetallic, like the inside of a battery. An *electrolyte* is a substance that can release or gain electrons.

Here's how these three pieces fit inside a typical battery:



You can actually make your own battery by using a simple nail for one electrode and a copper wire for the other. Stick both into a lemon, and the lemon juice is your electrolyte.



The copper wire becomes the positive terminal of the battery, and the nail becomes the negative terminal.

The Chemistry Behind Batteries

When you combine the lemon, the copper wire, and the nail, two chemical reactions happen: one between the lemon juice and the nail, and another between the lemon juice and the copper wire. In the first reaction, electrons build up on the nail; in the second, electrons leave the copper wire. The nail gets too crowded with electrons, and the copper wire ends up with too few. Electrons don't like to be in crowded places, so the electrons on the nail want to go over to the copper wire to even things out. But the chemical reactions with the lemon juice are pushing the electrons the other way.

Now, what do you think will happen if you connect a light bulb between the nail and the copper wire? The electrons on the nail really want to get to the copper wire, so they'll take the easiest path they can find, and when you create this closed-loop circuit, they flow from the nail to the copper wire through the light bulb. Recall that current is just electrons flowing in a wire; if you have enough current flowing through the light bulb, it lights up!

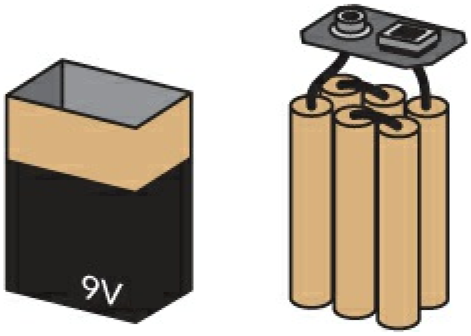
After a while, the chemical reactions in the battery stop. When this happens, the battery is dead. Some batteries can be recharged when they die, while others must be thrown away. The materials chosen for the electrodes and electrolyte determine whether the battery can be recharged or not.

The batteries you buy in the store are not made of lemons, of course! Modern batteries are made from different materials, and scientists are always looking for new ways to create batteries that have more energy, while being small and lightweight.

What Determines a Battery's Voltage?

The materials used for the electrodes and electrolyte determine the voltage you get from a battery, but the size of the electrodes and the amount of electrolyte don't matter when it comes to voltage.

To create higher battery voltages, several battery cells are connected in *series*. Connecting two battery cells in series means that you connect the positive side of one battery to the negative side of the other. The two unconnected terminals become the bigger battery's new positive and negative terminals, and the resulting voltage is the sum of the voltages from the two batteries. For example, in a standard 9 V battery, you have six 1.5 V battery cells, as shown. Notice that the connectors on the outside are attached to just two terminals.



PROJECT #6: TURN ON A LIGHT WITH LEMON POWER

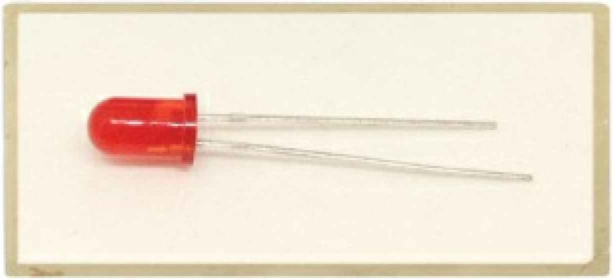
You can make a battery out of many different things; for example, in "What's Inside a Battery?" on page 55, I showed you how a lemon battery might work. In this project, you'll learn how to build a lemon battery of your own and power a light with it.

WARNING

When you're finished with this project, throw the lemons away. The chemical reactions that happen with the nail and copper wire will leave the lemons unsuitable for eating.

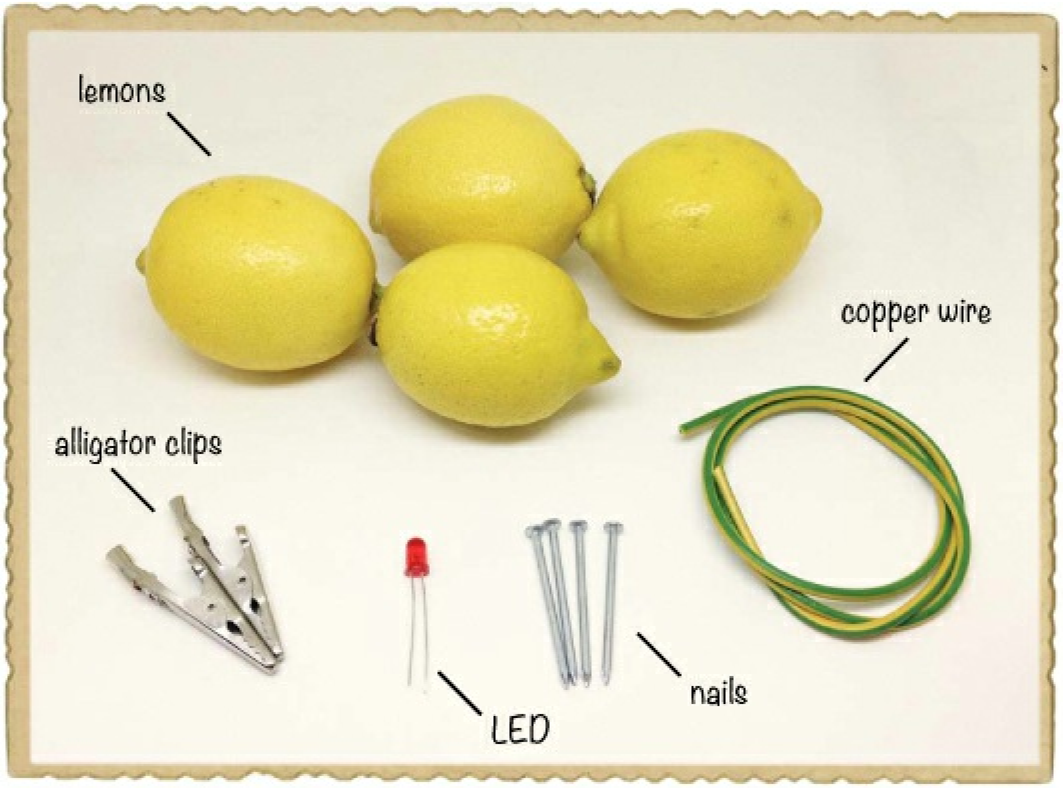
Meet the LED

A lemon battery can't create a lot of electricity, so you need to connect the battery to something that needs very little power to see the effect. Most light bulbs need more power than you'll generate in this project, so let me introduce a component called a *light-emitting diode*, or *LED*.



This little electronic component gives off, or *emits*, light when you apply a little bit of power to it. LEDs come in many colors: red, green, yellow, blue, and more. You'll learn more about this component in Chapter 4, and you'll use LEDs a lot in this book. For now, you're just going to use an LED to see the power generated by your lemon battery.

Shopping List



- **Four lemons** or one lemon cut into four pieces.
- **24 inches of copper wire** (any copper wire will do, but it's important that the wire be copper).
- **Four galvanized nails** (most common nails for outdoor projects are galvanized).
- **Two alligator clips** (Jameco #256525, Bitsbox #CN262) for connecting the LED.
- **A standard LED** (Jameco #333973, Bitsbox #OP002 for just this one, or Jameco #18041, Bitsbox #K033 for a variety pack). You'll need several LEDs for the projects in this book, so order at least 10 or a variety pack.

Tools

multimeter and leads
wire cutter

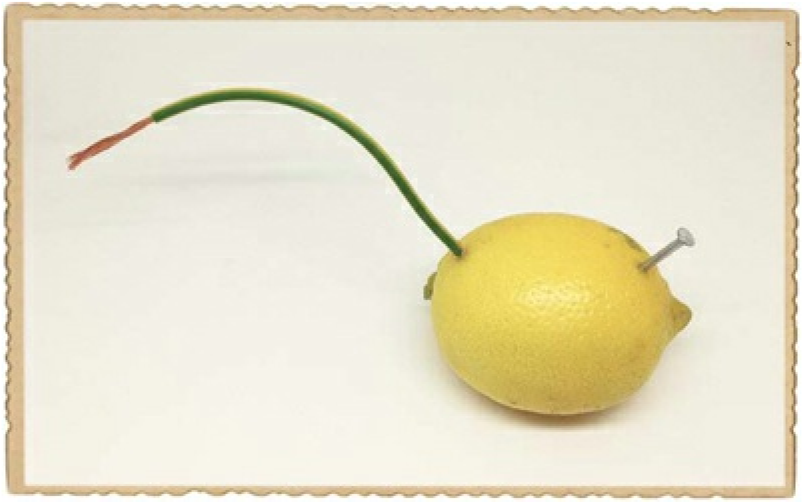
- **A wire cutter** (Jameco #35482, Bitsbox #TL008) to prepare the copper wire.
- **A multimeter** (Jameco #2206061, Bitsbox #TL057, Rapid Electronics #55-6662) to see whether your battery is working correctly.

Step 1: Prepare Your Wires

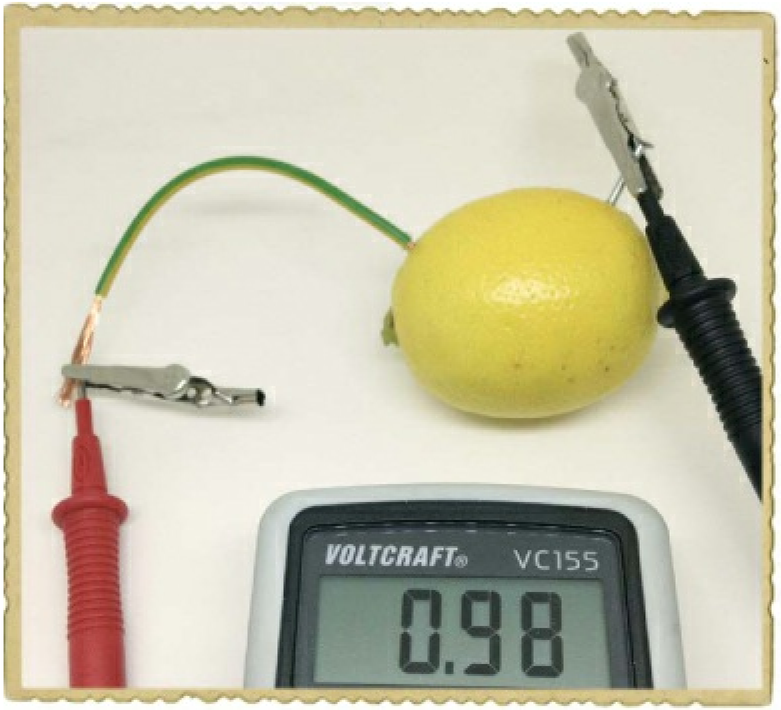
First, cut your copper wire into four 6-inch lengths. Strip about 1 inch of insulation from both ends of each wire. These will become the electrodes.

Step 2: Insert Electrodes into a Lemon

Roll and squeeze a lemon so that you break up the small juice packets inside it, but not enough to break the skin. Then, use a nail to make one hole in one end, push a copper wire into that hole, and push the nail into the other end, as shown. This is the first lemon battery!



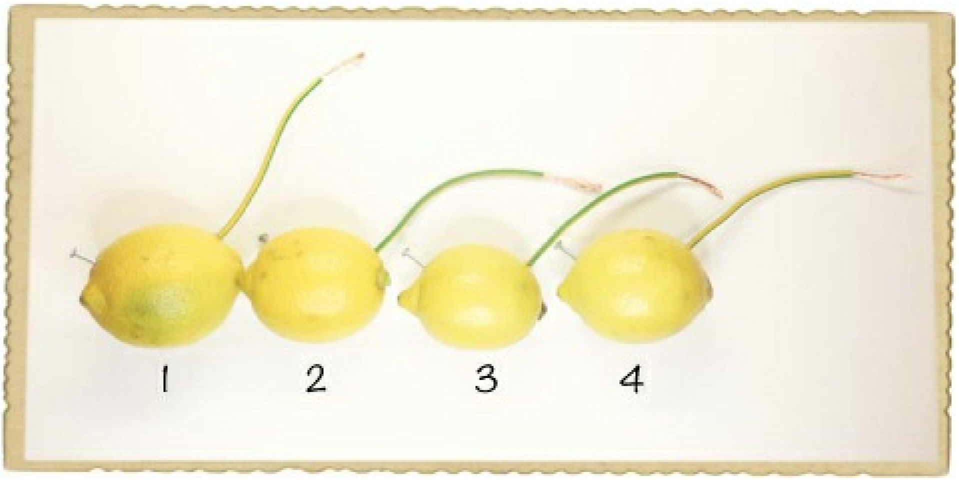
Get your multimeter, set it for DC voltage measurement, and test your lemon battery now. Place the positive test lead on the copper wire and the negative test lead on the nail. If everything works correctly, you should see a voltage of around 1 V on your multimeter.



Step 3: Create Four Lemon Batteries

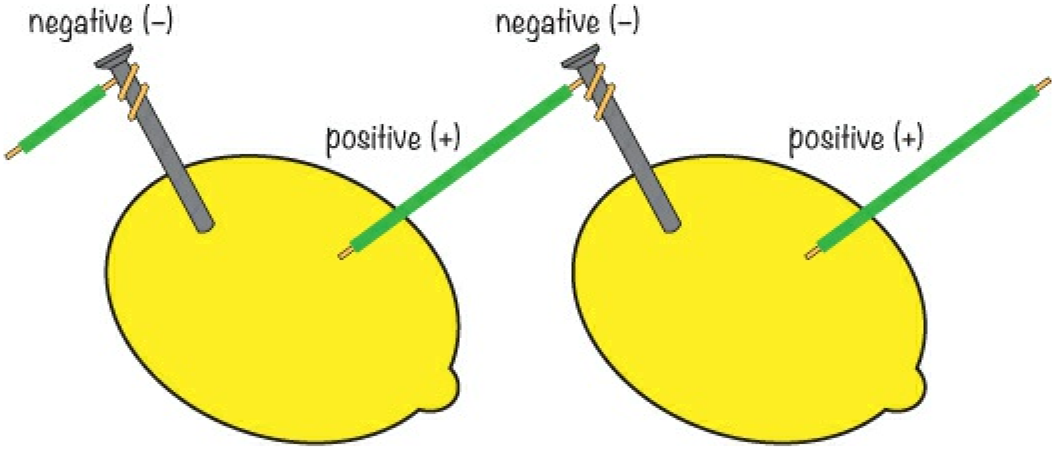
Even if you get 1 V out of your lemon, that's not enough to light an LED. Let's create several lemon batteries so we can get more electricity!

Just repeat the process described in Step 2 for the other lemons; each will become a battery. (If you don't have four lemons to spare, you can cut one lemon into four pieces.) Now you should have four lemon batteries.



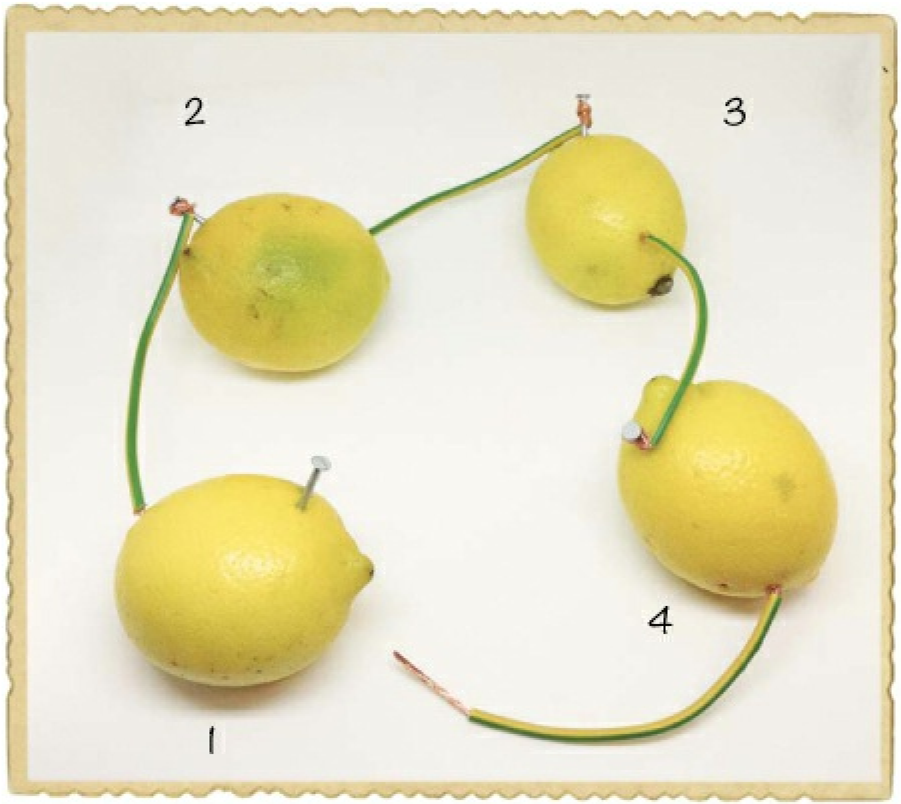
Step 4: Connect the Lemons in Series

To get a higher voltage with your lemon batteries, you'll need to connect them in series. To connect two lemons in series, you just connect the positive side of one lemon to the negative side of another. Remember, the copper wire is positive, and the nail is negative.

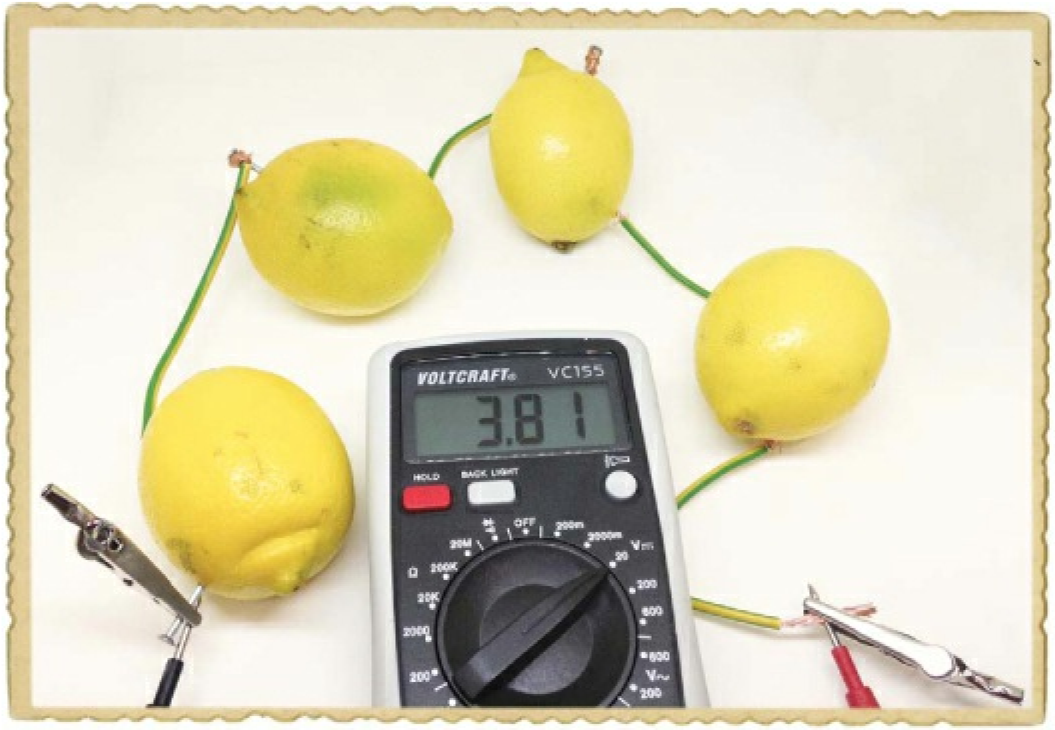


To wire four lemons in series, just repeat that process a couple more times. Line your lemons up in a row with the copper wires pointing to the right and number the lemons from 1 to 4, beginning from the left. Connect the copper wire from lemon 1 to the nail in lemon 2. Twist the wire onto the nail so that the metals connect without coming apart.

Connect the copper wire of lemon 2 to the nail in lemon 3, and connect the copper wire from lemon 3 to the nail in lemon 4. This should give you a row of four lemons, with an unconnected nail on lemon 1 and an unconnected copper wire on lemon 4. These are the positive and negative terminals for your big lemon battery, respectively.

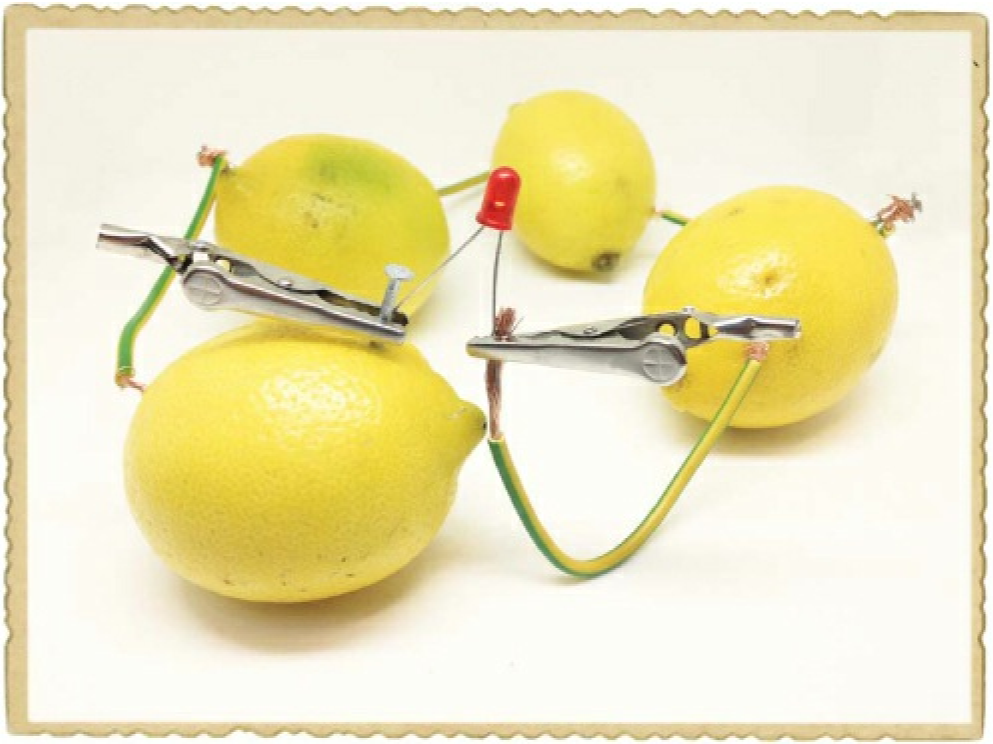


When you connect batteries in series, you can add their voltages to find your total. Four 1 V lemon batteries should give you 4 V. If you have a multimeter, measure the voltage between the two ends to see whether everything is connected. You should get a voltage of around 3.5 to 4 V.



Step 5: Test Your Lemon Battery

Let’s connect the LED to the lemons! Connect the long leg from the LED to the copper wire, and connect the short leg to the nail, as shown. The LED should now light up.



Lemons aren't super powerful batteries (you'd never see anyone with a lemon connected to their computer, for example), so your LED will probably be very dim. After you finish building your lemon-powered circuit, turn off the light in your room, and you should see the LED glow.

Remember, when you're finished with your lemon battery, throw the lemons away—don't eat them!

TRY IT OUT: MORE FOOD BATTERIES!

When you're done making lemon batteries, test to see whether you can make batteries out of other fruits or vegetables. For example, what about a potato battery? Are you able to get more voltage, or is it the same as the voltage from the lemon?

Step 6: What If Your Lemon Light Doesn't Work?

If you can't see light from your LED, even in a dark room, check to see whether your LED is connected the right way. The long leg should be connected to the positive side of the battery, which is the copper wire.

Make sure the lemons are connected to each other only through the wires and nails. For example, if your lemons are sitting in a puddle of lemon juice, they could be connected through that. Just dry them off and move them somewhere else. Next, check that the copper wires are properly connected to the nails and that the nails and copper wires are actually touching the juice inside the lemons. Also, check that the nails and copper wires are not touching each other inside any of the lemons.

If the circuit still doesn't work, disconnect all the lemon batteries from each other. Then, use a multimeter to check that each lemon battery has some voltage. Connect two lemons in series, and check that you see a higher voltage. Connect the third lemon, and check that the voltage has increased again. Then, connect the fourth lemon and check that you have even more voltage.

If you see a voltage but the LED doesn’t light, then you probably just need some more power. Get another lemon or two, create some more batteries, and connect them in series with the rest.

WHAT’S NEXT?

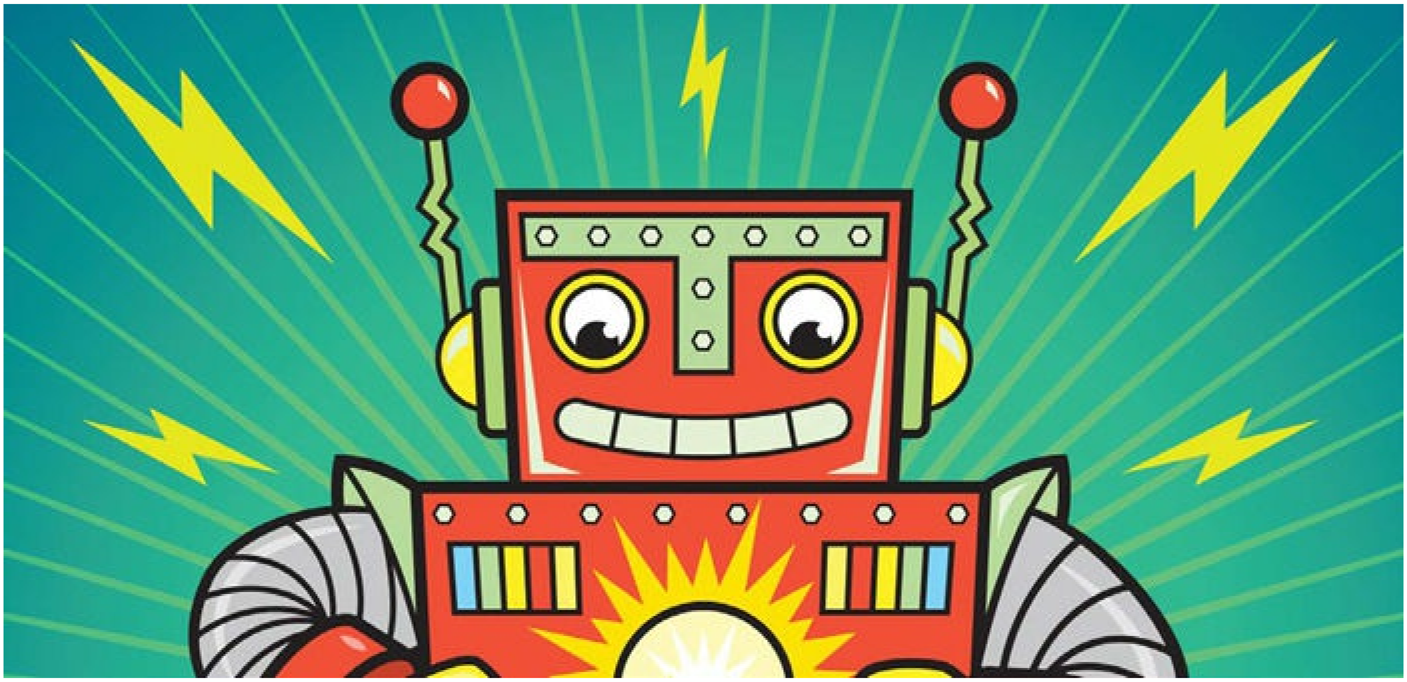
In this chapter, you learned how to create your own electricity from magnetism and chemical reactions. You made your own shake generator, and you built a lemon battery to power an LED.

If you want to explore generators even more, I suggest trying to find a *dynamo* from an old bike. Unlike the generator you built in this chapter, a dynamo is a generator that gives you a DC voltage, like a battery, and dynamos are commonly used to power headlights on bikes. Cut some windmill blades out of some stiff cardboard or plastic, connect them to the dynamo, and see whether you can harvest energy from the wind.

You’ve now met a few electronic components, including switches, LEDs, and motors. In the following chapters, you’ll learn about even more components and graduate to building some real electronic circuits, like lights that blink, a touch-sensitive switch, and even your own electronic musical instrument!

PART 2

BUILDING CIRCUITS



4

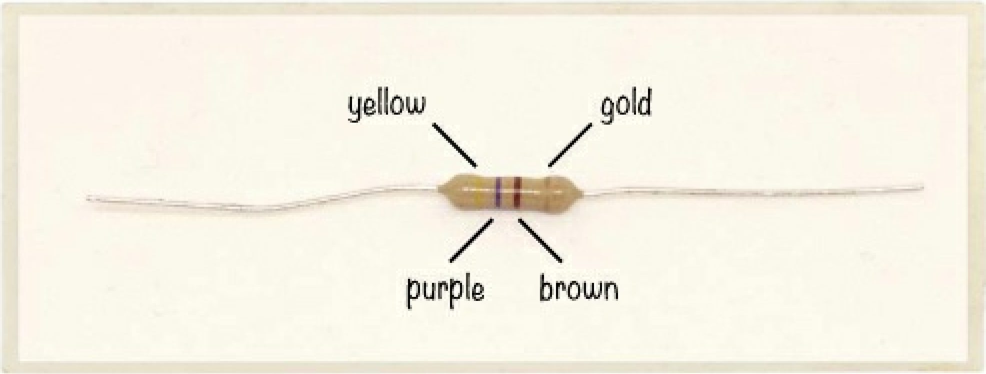
CREATING LIGHT WITH LEDS

Lights, especially LEDs, are used all the time in electronics. Sometimes, they're just simple indicators that show whether a device is on or not, but they can also be part of more complicated devices, like computer displays. In fact, some displays are actually made up of thousands of tiny LEDs.

In this chapter, you'll learn how two of the most common basic components in electronics work: the resistor and the LED. I'll show you how to kill an LED, but don't worry: you'll learn how to use resistors to keep LEDs alive, too. In this chapter's projects, you're also going to start using a new tool, called a *breadboard*, to connect circuits. Many projects in this book use breadboards, and you can also use them to build a lot of cool projects on your own.

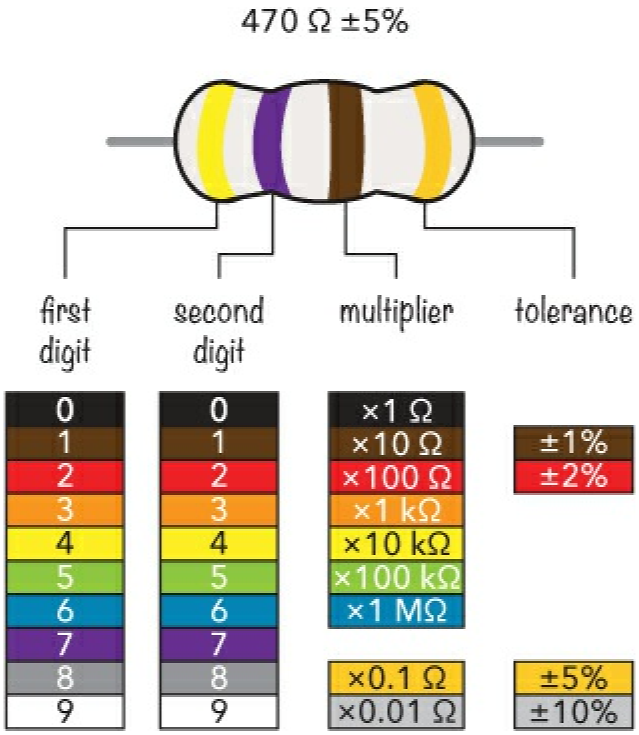
MEET THE RESISTOR

Recall that resistance restricts current from flowing freely in a circuit. A *resistor* is a component that adds resistance to a circuit. The more resistance your circuit has, the less current will flow through it.



Resistor Color Codes

When you look at a resistor, you'll notice that it has several colored bands. These colors tell you the value of the resistor. Resistance is measured in *ohms*, but when we write about it, we'll use an *omega* symbol, *Ω*, for short. More ohms means more resistance.



Most resistors have four color bands. From the left, the first band gives the first digit of the resistance value. In this example, the first band is yellow, so the first digit is 4. The second digit is given by the second band, which is purple for 7. Together, this gives us the base value of 47. Next we multiply 47 by the value of the third band—the *multiplier*. In this example, the brown band stands for 10 Ω, so we multiply 47 by 10:

$$47 \times 10\ \Omega = 470\ \Omega$$

NOTE

If a resistor has five bands instead of four, then the first three bands are digits, and the fourth is the multiplier.

But the actual resistance of a resistor usually won't match the value written on it! That sounds a bit crazy, right? It's hard for manufacturers to create resistors with a very exact resistance value, so instead, they make sure the resistors are somewhere around that value and tell you how far off the real value could be.

This is where *tolerance* comes in. Our example resistor is labeled 470 Ω with a tolerance of 5 percent. This means that the resistor's real resistance could be any value 5 percent higher or 5 percent lower than 470 Ω. Because 5 percent of 470 is around 24, the real resistance could be anywhere between 446 Ω and 494 Ω.

Usually, the three bands that tell you the resistance value are grouped together, and the band that tells you the tolerance is spaced a bit farther away. But sometimes the bands are so close that it's hard to see which three bands give the resistance. Fortunately, the fourth band is typically gold or silver, so if you see a gold or silver band, it's safe to assume this is the tolerance band.

HOW TO WRITE LARGE VALUES

Our resistance color chart shows some resistance values written with *k* and *M* in front of the Ω symbol. These are part of a shorthand that makes it easier to write really large values. If you have a resistor that's 300,000 Ω, it's common to shorten that to 300 kΩ instead, where *k* is short for *kilo*, which means one thousand. The *M* stands for *mega*, which means one million. So instead of writing 3,000,000 Ω, you could write 3 MΩ.

What Are Resistors Made Of?

To create a resistor, you could just use a really long piece of standard wire. Wires have a bit of resistance, and the longer your wire is, the more resistance you'll get. But using miles of wire to reduce current isn't very efficient. It's better to use a material that has more resistance, such as carbon. Often the resistors that you buy in stores are made of carbon wrapped inside an insulating material.

Resistors Control Current and Voltage

At first, you might find the resistor a bit boring. If you connect one to a battery, you probably won't see anything happen; the resistor might just get warm, and you might wonder what the big deal is. On the other hand, if you use a resistor with a very low resistance value, such as 10 Ω, then it could get *really* hot—hot enough to give you a burn—and the battery might die pretty quickly.

WARNING

Connecting a low-value resistor directly between positive and negative points can be dangerous on some types of batteries. Some batteries are strong enough to make your resistor burst into flames. Be careful!

But the cool thing about resistors is that you can use them to change the voltages and currents in your circuit! That means that you get to be the master of your circuit and decide how it should behave.

INTRODUCING OHM'S LAW

The key to controlling the current and voltage in your circuit is a formula called *Ohm's law*. Ohm's law relates resistance, voltage, and current as follows:

$$V = I \times R$$

Here's what those letters mean:

V Voltage, measured in volts (V)

I Current, measured in amps (A)

R Resistance, measured in ohms (Ω)

Given these definitions, in English, Ohm's law reads, "Voltage equals current multiplied by resistance." You can also write the Ohm's law formula in the two following forms:

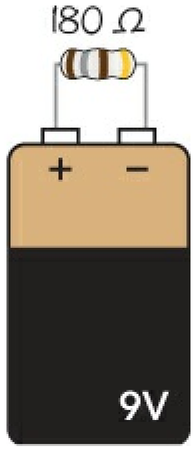
$$R = \frac{V}{I} \qquad I = \frac{V}{R}$$

Let's put Ohm's law to work. Imagine you have a resistor and a 9 V battery, and you want 0.05 A of current to flow in the resistor. How much resistance do you need in the resistor to get the right amount of current flowing? Use Ohm's law to find out:

$$R = \frac{V}{I}$$

$$R = \frac{9\text{ V}}{0.05\text{ A}}$$

$$R = 180\ \Omega$$



After dividing the voltage by the current, you'll find that to get 0.05 A of current flowing in the resistor, you need a 180 Ω resistor.

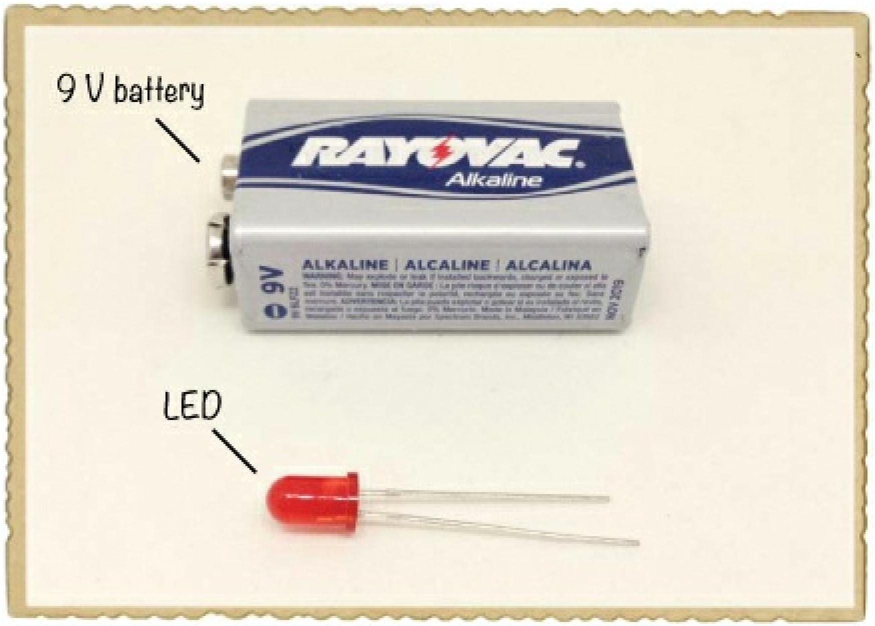
PROJECT #7: LET'S DESTROY AN LED!

Almost all electronics have some LEDs, which I introduced in Chapter 3. Where there are LEDs, there are also resistors. Look around a house, and there's a big chance you'll see a few. For example, check a computer, a washing machine, a television, or a Wi-Fi router. Do you see some blinking lights when you push buttons? Those are very likely LEDs in series with resistors.

In "Project #6: Turn On a Light with Lemon Power" on page 58, you just connected an LED to your homemade lemon battery, and that was it. In most circuits, however, you need to take a bit more care to make sure you don't break your LED. If too much current flows through an LED, it becomes really hot and burns out. The lemon battery was too weak to provide enough current to break the LED.

Of course, I could tell you all this forever, but trying things in real life is the best way to learn! I had to break a few LEDs myself before I accepted that I couldn't connect them directly to a battery without a resistor, and I want you to see what that's like, too. That's why in this project, you're going to destroy an LED!

Shopping List

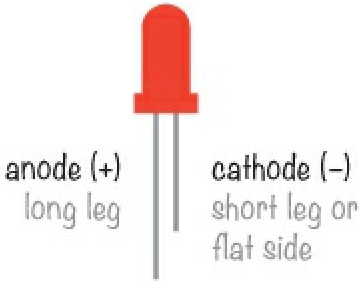


- **A standard LED** (Jameco #333973, Bitsbox #OP002).
- **A standard 9 V battery** to power the circuit.

Step 1: Identify Which LED Leg Is Which

Look at your LED closely, and you should see that one leg is longer than the other. LEDs are *polarized*, which means that current flows through them only if you connect them a certain way in your circuit. The longer leg is called the *anode*; it's the leg that you connect to the positive side of the battery. The shorter leg is called the *cathode*, and you connect it to the negative side of the battery.

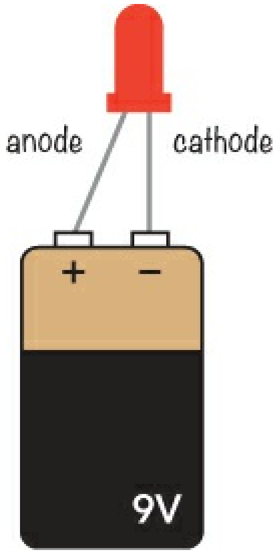
On some LEDs, the legs are the same length. In that case, find the flat side on the bottom of the LED itself. The leg on the flat side is the cathode.



Step 2: Break That LED!

To avoid burning your fingers, hold your LED by one of the legs. Then, place the 9 V battery on the table and touch the legs of the LED directly to the battery terminals.

The LED should glow brightly for a short moment, become hot, and then go dark. Parts of it may actually turn black. Congratulations: You just broke your first LED!



NOTE

Some LEDs stop working after a second when connected directly to a battery. Others may give a bit of light for a few seconds.

Step 3: What If Nothing Happens to the LED?

If nothing happens, there are three likely causes:

- You connected the LED backward.
- Your LED is already broken.
- Your battery is dead.

First, try connecting your LED to the battery the other way around. If you're sure it's connected the right way, then either your LED is already broken or your battery is dead. Try replacing the battery first; if that doesn't work, replace the LED. Now, you should be able to break your LED.

HOW TO USE AN LED CORRECTLY

Even though it's pretty fun to destroy LEDs, it's better to know how to *avoid* destroying an LED. Your LED burned because it had too much current running through it, but you can prevent that with your trusted friend the resistor. Resistors resist the flow of current, and if you choose the right resistance value, they'll resist the current enough to get just the right amount of current for your LED.

HOW TO WRITE SMALL VALUES

In electronics projects, you often need to deal with very small values, especially when measuring or calculating current. For example, most current values in the circuits in this book are less than 0.1 A, and many are closer to 0.02 A. To simplify writing these values, I typically use the prefix *milli*, which is written as a lowercase *m*. It means one thousandth, so 1 mA is 0.001 A. Because

1,000 mA is the same as 1 A, 0.02 A becomes 20 mA, and 0.1 A becomes 100 mA.

Protecting Your LED with a Resistor

An LED in a circuit should always have a resistor in series with it. Of course, resistors come in many different values, and to figure out the right one for your circuit, you need to do a little math.

Most standard LEDs need a voltage of about 2 V and a current of about 20 mA, or 0.02 A, to light up. These two values, together with the voltage of your battery, are all you need to figure out the correct resistance. Just put these two values into the following formula:

$$R = \frac{V_{\text{BAT}} - V_{\text{LED}}}{I_{\text{LED}}}$$

If this formula looks familiar, that's because it's actually just another version of Ohm's law. The two Vs and the I are still voltage and current, but V_{BAT} is the battery voltage, V_{LED} is the voltage your LED needs to light up (often 2 V), and I_{LED} is the current your LED needs (often 20 mA). You'd read this formula as "To find the resistance, subtract the LED voltage from the battery voltage and divide the result by the LED current."

Calculating the Resistance You Need

Imagine you have a 9 V battery, a resistor, and a standard LED. What resistance value should the resistor be? Using the formula from the previous section, you should get:

❶ $$R = \frac{V_{\text{BAT}} - V_{\text{LED}}}{I_{\text{LED}}}$$

❷ $$R = \frac{9\text{ V} - 2\text{ V}}{20\text{ mA}}$$

❸ $$R = \frac{7\text{ V}}{0.02\text{ A}}$$

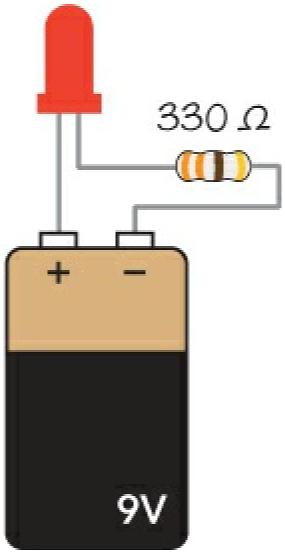
❹ $$R = 350\ \Omega$$

That means you need a resistor of 350 Ω to get the right amount of current flowing through the circuit.

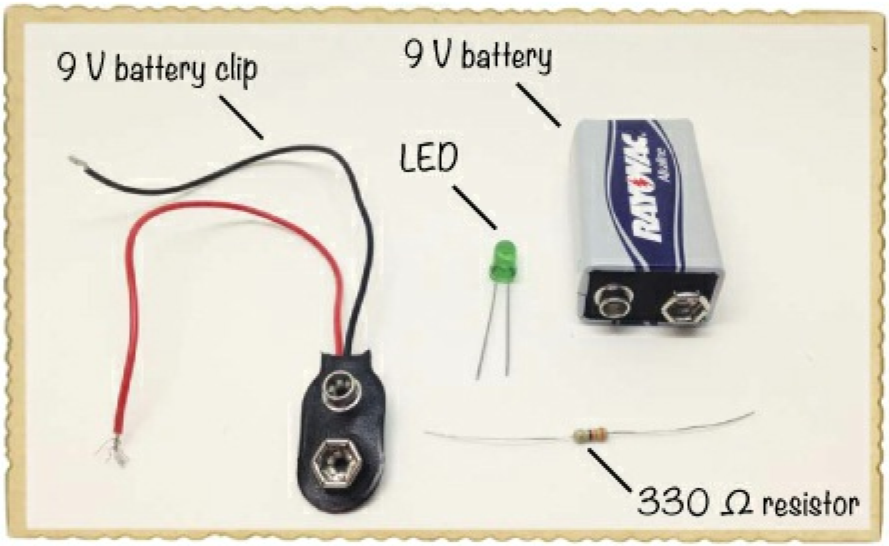
PROJECT #8: POWERING AN LED

Now let's power a standard LED with a protective resistor so the LED doesn't burn out. We just calculated that to power an LED with a 9 V battery, you need a resistor of 350 Ω.

But as I explained in "Resistor Color Codes" on page 70, standard resistor values aren't always exactly the resistance you need. If you buy a 350 Ω resistor, it isn't necessarily 350 Ω, but maybe 370 Ω. And not all resistance values are even available. For a resistor in an LED circuit, having the exact value isn't important. That's fortunate because you won't find any 350 Ω resistors in standard resistor packs. Instead, you can use a 330 Ω resistor, which is a standard value that's easier to find.



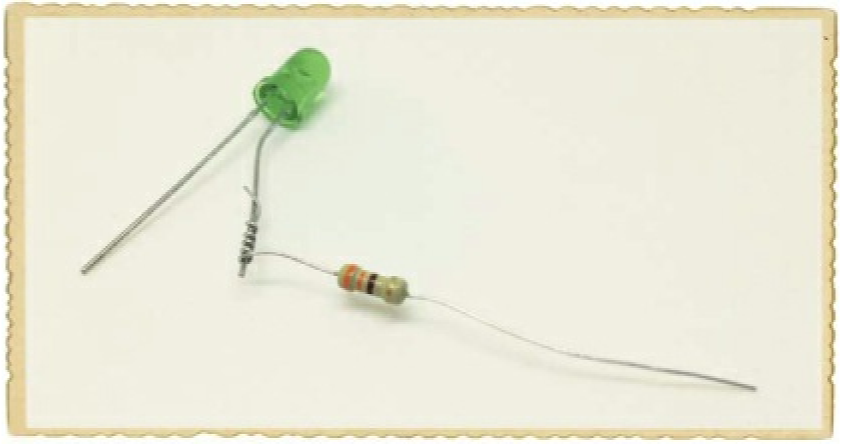
Shopping List



- **A standard 9 V battery** to power the circuit.
- **A 9 V battery clip** (Jameco #11280, Bitsbox #BAT033) to connect the battery to the circuit.
- **A standard LED** (Jameco #333973, Bitsbox #OP002)
- **A 330 Ω resistor** (Jameco #661386, Bitsbox #CR25330R for just this value or Jameco #2217511, Bitsbox #K017 for a variety pack) for limiting the current to the LED.

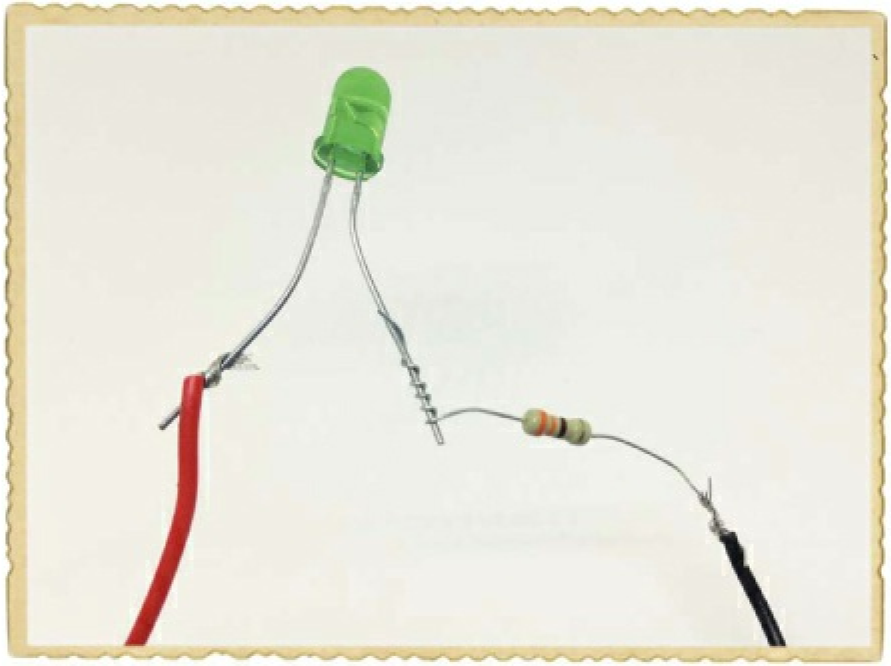
Step 1: Twist the Resistor and LED

First, connect the short leg, or the cathode, of the LED to one side of the resistor. It doesn’t matter which side of the resistor you connect; just twist the resistor leg around the LED leg.



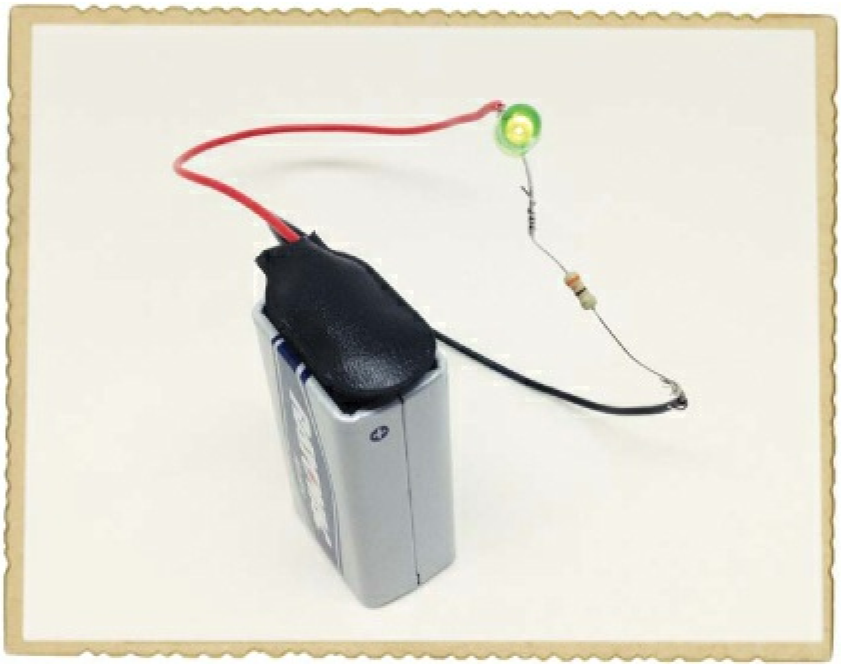
Step 2: Wire the Battery Clip

Twist the battery clip's red wire onto the long leg of the LED. Then twist the black wire to the unconnected side of the resistor.



Step 3: Let There Be Light!

Now, plug your battery into the clip, and your LED should glow!



Step 4: What If the LED Doesn't Work?

If your LED doesn't turn on, first disconnect the battery and make sure you've connected the components exactly as I described in Steps 1 through 3. Having someone else review your wiring can be helpful, too; ask a parent, sibling, or friend to look it over.

If your connections look right and the LED is still dark, then double-check the LED's orientation; just about anyone who's ever built an electronics project has connected an LED backward at least once. The long leg is the anode, and in this project, it should connect to the positive side of the battery.

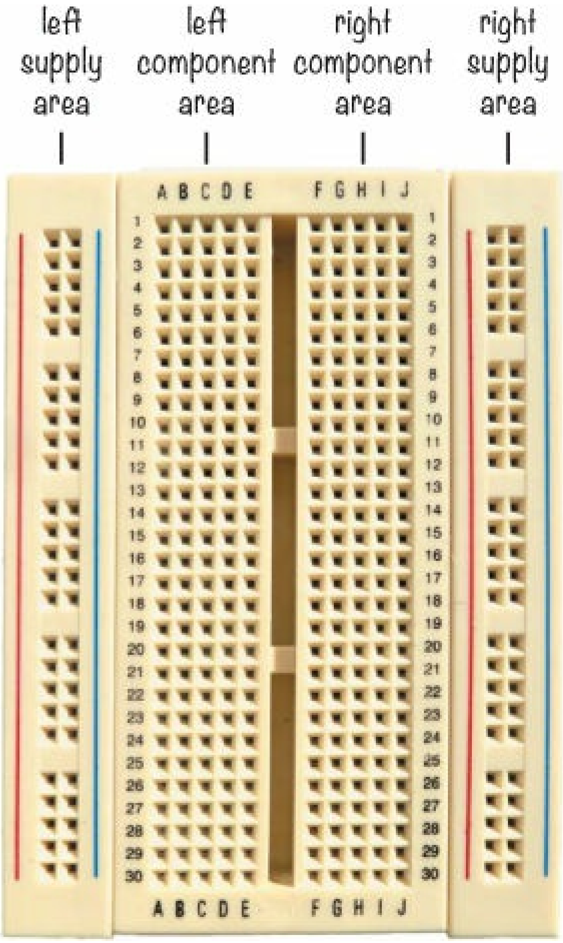
BUILDING CIRCUITS ON A BREADBOARD

Up to now, you've connected circuits with tape or by twisting component legs together, but this isn't very practical when a circuit has more than a few components. Fortunately, a *breadboard* can make connecting components easier. Breadboards have holes that you can stick component leads into to create circuits. When you're done, you can just unplug all the components and reuse them in different projects!

How to Connect Components and Wires

Inside a breadboard, metal plates connect the holes you see on the outside in a certain pattern. Let's look at a breadboard with four connection areas—two supply areas and two component areas.

In the supply areas on both sides, all the holes in each *column* are connected. You'll typically plug the positive side of your circuit's *power supply*—like the batteries you've used so far—into the red columns, and you'll typically plug the negative side of the power supply into the blue columns. Throughout this book, I'll refer to the supply column marked with a red line as the *positive supply column*, and I'll refer to the supply column marked with a blue line as the *negative supply column*.



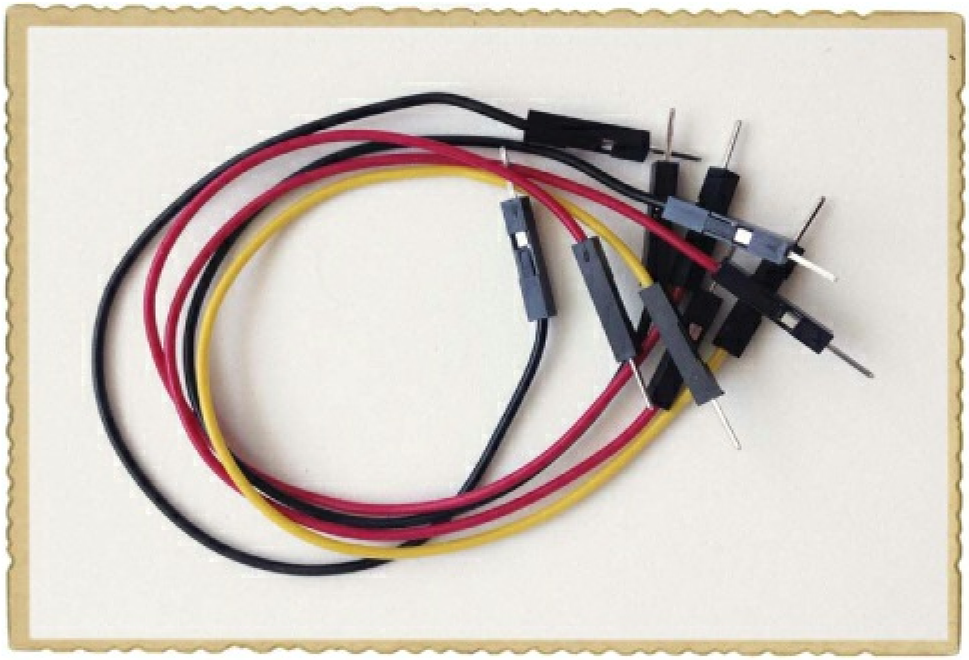
In the component areas, all the holes in each *row* are connected, and the columns are not connected. The left and right component areas are separated so that there's no connection between them. For example, holes A, B, C, D, and E in row 1 are connected, and holes F, G, H, I, and J in row 1 are connected, but holes E and F in row 1 are not connected.

To plug a component into a breadboard, simply push it into the hole where you want the connection. For example, if you wanted to connect one side of a resistor to the positive side of an LED, you'd just insert both the leg from the resistor and the leg from the LED into two holes on the same row in the left or right component area. If you have two component legs or wires that shouldn't connect, just make sure they are either on different rows in the component area or on opposite sides of the component area.

Wires to Use on a Breadboard

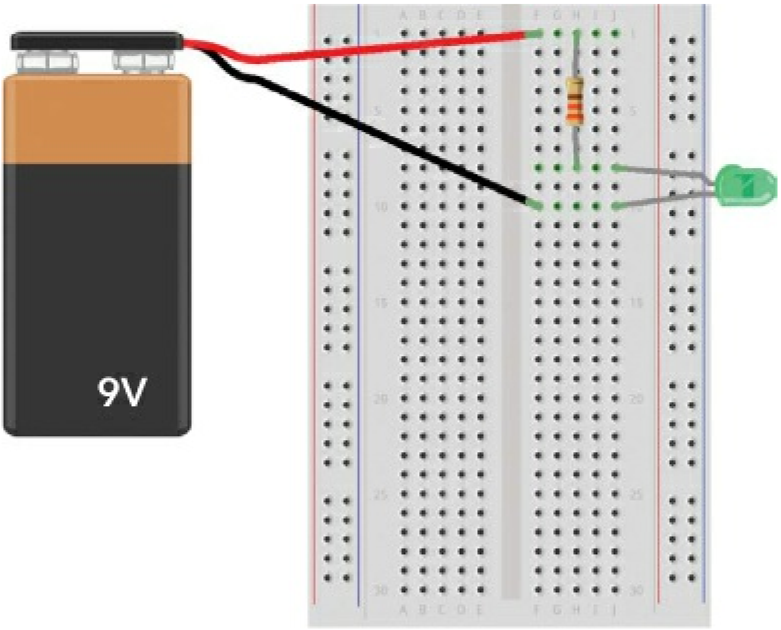
Eventually, you want to connect one row on your breadboard with a different row. You can use a wire to make that connection, but not all wires work well on a breadboard. The wire has to be stiff enough that you can push it into the hole without it bending, and it has to be thick enough to fit all the way inside the breadboard hole without falling out. *Single-strand* wires are the best wires for building circuits on a breadboard because they have one solid core inside, instead of many tiny wires wrapped together. The thickness of wire you need depends on your breadboard, but wires with 0.016- to 0.028-inch diameters should work. Wire thickness is often given in *American wire gauge (AWG)*, and I recommend using wire that is 21 to 26 AWG. You can buy wires that are cut and stripped for simple use with breadboards, or you can cut and strip your own wires using a wire cutter.

Another option is to use breadboard *jumper wires*. These wires have stiff ends that are very easy to connect to a breadboard. If you plan to connect a lot of circuits on a breadboard (you should!), keep a bunch of breadboard jumper wires on hand to make your life easier.



PROJECT #9: YOUR FIRST BREADBOARD CIRCUIT

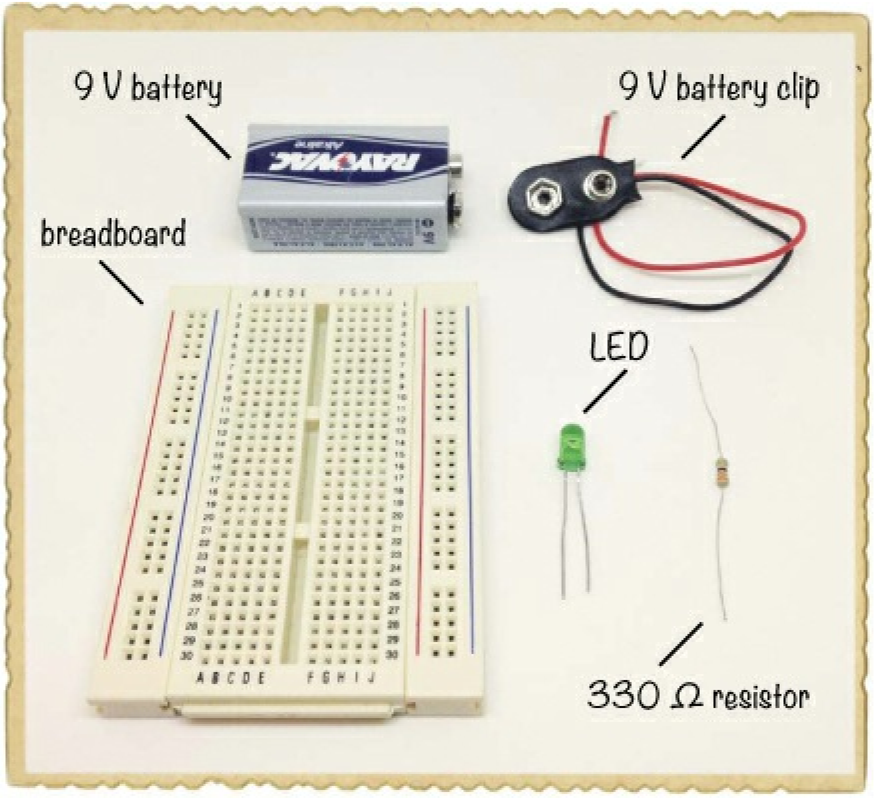
Let's connect a simple circuit on a breadboard! Just as in "Project #8: Powering an LED" on page 78, this circuit lights up an LED, but this time we'll build the circuit on a breadboard. In this project, we're not going to use the supply rails on the side because the circuit is so simple that it makes more sense just to connect it all on the component area.



Shopping List

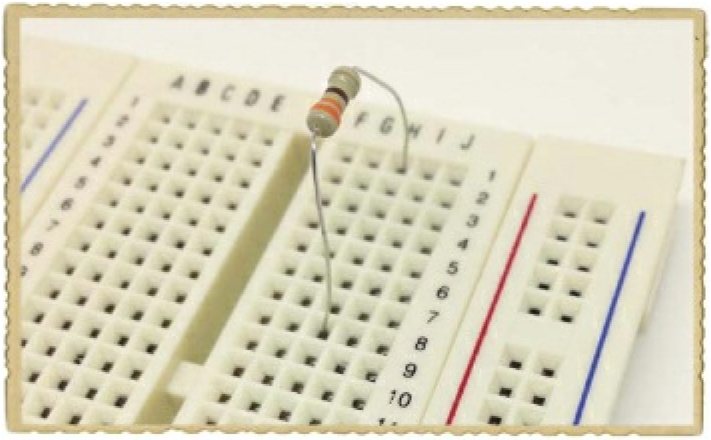
- **A breadboard** (Jameco #20601, Bitsbox #CN329) with at least 30 rows.

- **A standard 9 V battery** to power the circuit.
- **A 9 V battery clip** (Jameco #11280, Bitsbox #BAT033) to connect the battery to the circuit.
- **A standard LED** (Jameco #34761, Bitsbox #OP003).
- **A 330 Ω resistor** (Jameco #661386, Bitsbox #CR25330R for just this value or Jameco #2217511, Bitsbox #K017 for a variety pack) for limiting the current to the LED.



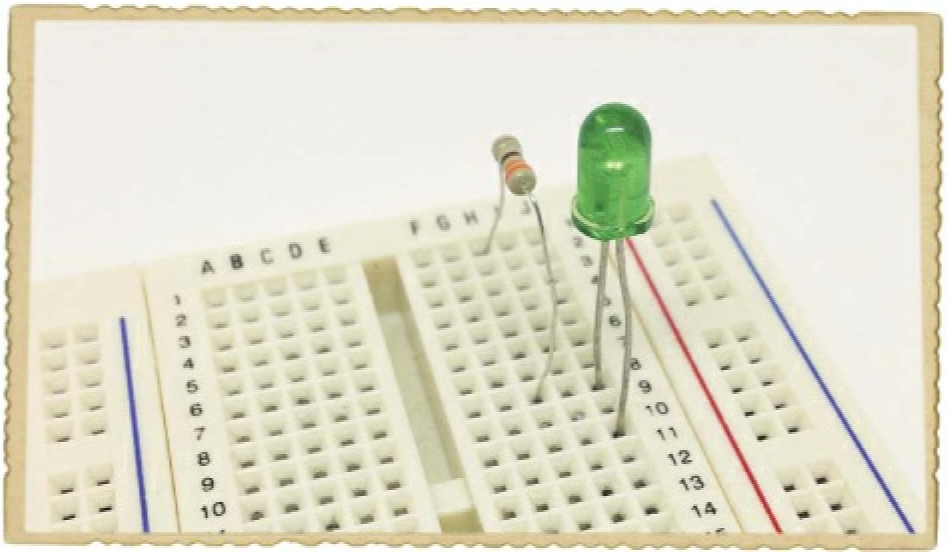
Step 1: Place the Resistor

First, place one leg of the resistor in row 1 and the other in row 8.



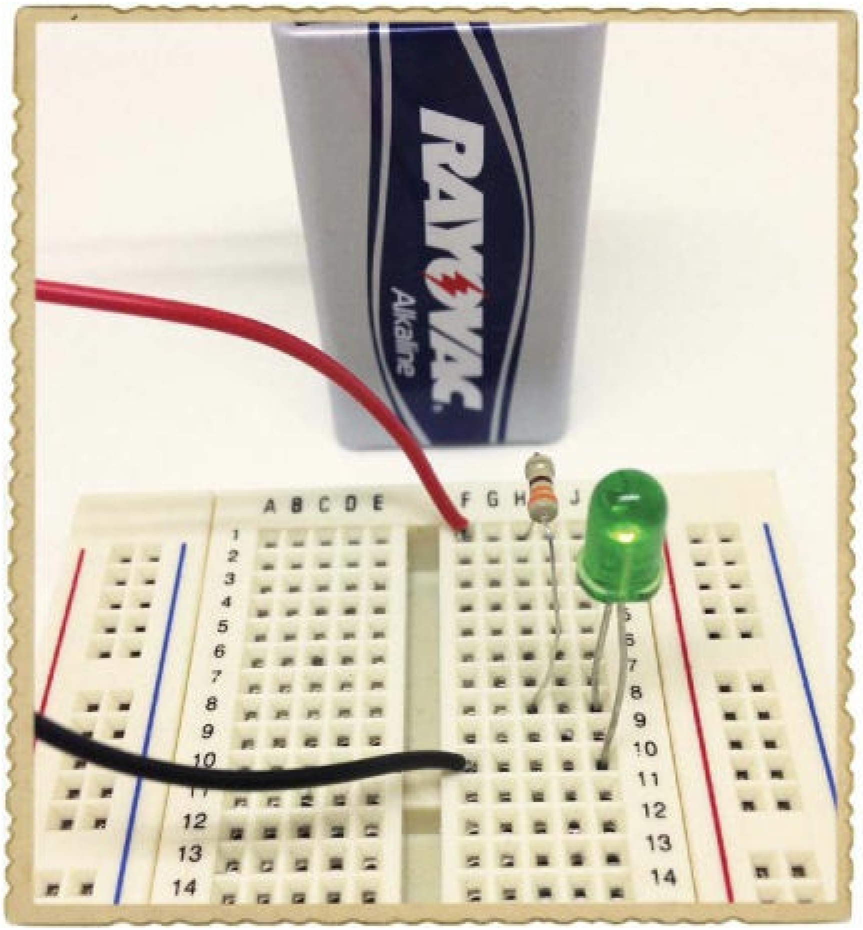
Step 2: Place the LED

Remember, LEDs are polarized, and they must be connected the right way to work. Connect the long leg of the LED to row 8, where the resistor leg is connected. Because the resistor and LED legs are on the same row, they're now connected. Connect the other leg of the LED to row 10.



Step 3: Place the Battery Clip

Now, connect the battery to the LED and resistor. Connect the battery clip with the red wire at row 1 and the black wire at row 10. Plug your battery into the clip, and your LED should light up!



Step 4: What If the LED Doesn't Work?

If your LED doesn't glow, first disconnect the battery. You should always disconnect the battery when making changes to your circuit. Then, check whether the short leg of the LED is connected to the negative side of the battery.

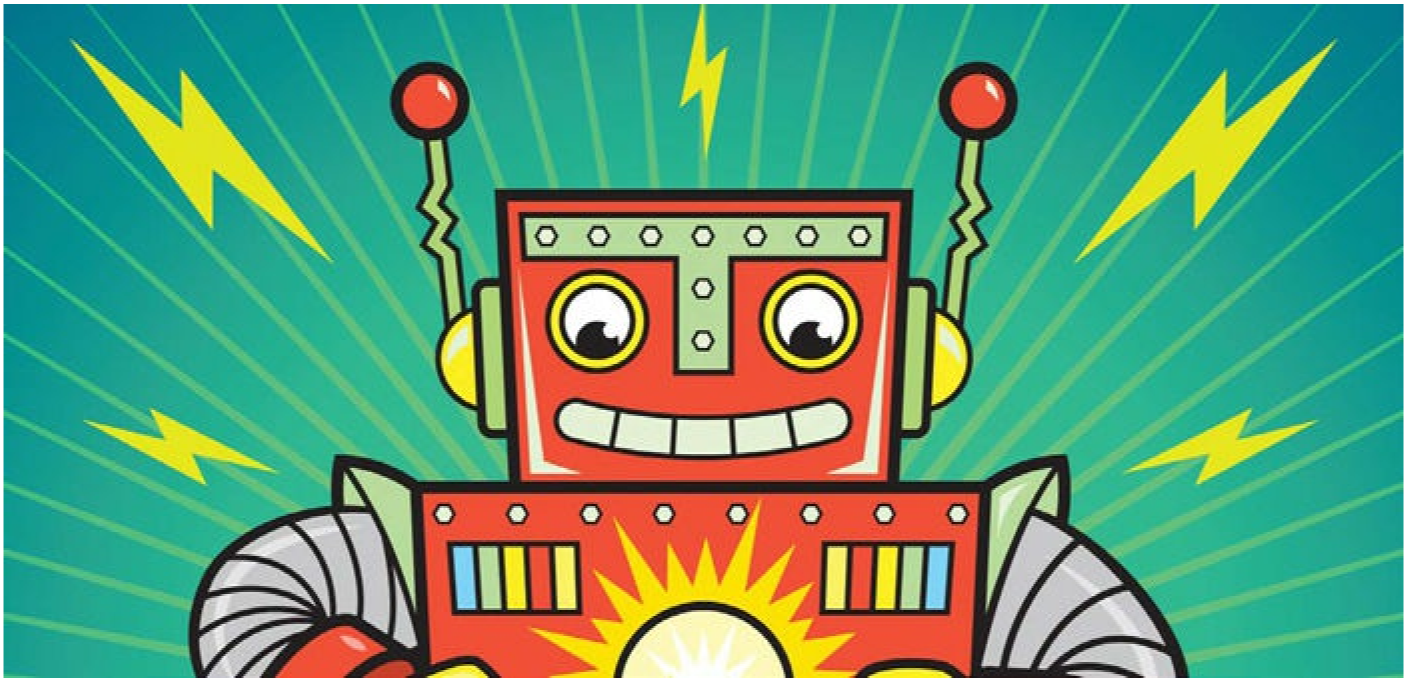
If your LED is still not working once it's oriented correctly, check that your components are connected exactly as described in Steps 1 through 3. Are the long leg of the LED and one of your resistor's legs in row 8? Is the positive battery lead in the same row as the other resistor leg? Is the negative battery lead in row 10 with the short LED leg? Ask someone else to have a look at your circuit, too; maybe they can help you find the problem.

WHAT'S NEXT?

In this chapter, you've learned about two very common components: the resistor and the LED. You also learned how to use Ohm's law to calculate resistance, current, and voltage values. This knowledge will form the foundation for many aspects of electronics that you'll explore throughout this book.

You also learned to use a breadboard, which is a useful skill. To practice placing circuits on a breadboard, try building one of the projects you did earlier in this book without tape! How would you re-create "Project #2: Intruder Alarm" on page 11 on a breadboard?

In the next chapter, you'll learn about two more components: the capacitor and the relay. Then, I'll show you how to build one of my favorite circuits—a circuit that blinks a light!



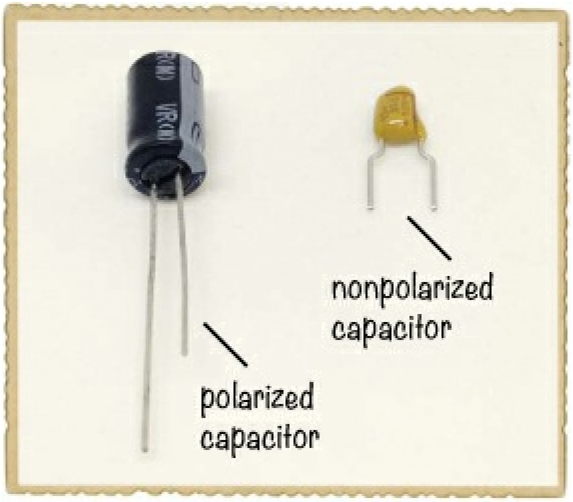
5

BLINKING A LIGHT FOR THE FIRST TIME

When I was a kid, one of my very first electronics projects was making a light blink. It was amazing to see the circuit work for the first time, and now I want to share that experience with you. In this chapter, you'll learn how the capacitor and the relay work. These are two common and very interesting electronics components, and I'll show you how to have some fun with them. At the end, you'll build your very own blinking light!

MEET THE CAPACITOR

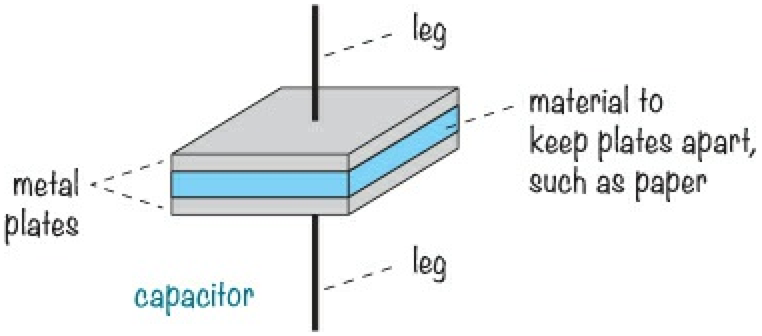
The *capacitor* is like a rechargeable battery; you can charge a capacitor and use its energy to power something. But a battery can hold much more energy than a capacitor. A battery can power an LED for days without recharging, while most capacitors can power one for only a few seconds at most.



Capacitors are often used to introduce time delays in a circuit. For example, because a capacitor stores energy, it could be used to keep an LED on for a bit more time, even after the power is shut off. This little trick can be used with other components, too, to create interesting results.

How Capacitors Work

On the inside, capacitors are very simple devices. They're made of two metal plates placed very close together, with a material such as paper in between. To save space, the metal plates and the material between them are folded or rolled into a compact package.



When you connect a battery to the two sides of a capacitor, a current flows as the battery tries to push electrons through the capacitor. But electrons can't flow across the gap between the plates, so instead, electrons build up on one plate and leave the other plate. Eventually, one plate can't hold anymore electrons, and the current stops flowing; at that point, we say that the capacitor is *fully charged*.

But just like the electrons in a battery, the electrons in the capacitor don't like being crowded together on the one plate. They want to go over to the side with fewer electrons. This means you have stored potential energy in your capacitor. If you disconnect the battery and connect, for example, a resistor between both sides of the capacitor, the stored electrons on one plate will start flowing the other way around, through the resistor, in order to reach the plate with few electrons.

Polarized and Nonpolarized Capacitors

Capacitors can be either *polarized* or *nonpolarized*. Like an LED, a polarized capacitor has a positive and a negative leg, and its positive leg must always face the positive terminal of the battery. The black capacitor shown in the photo is polarized, and its negative leg is marked with a stripe and minus signs down the side. The yellow capacitor isn't polarized, so it doesn't matter which leg goes where.

WARNING

Take care when you use polarized capacitors for the projects in this book and in your own projects. You must connect them the correct way to prevent them from being damaged.

In all circuits that call for a capacitor, you can use a nonpolarized capacitor as long as you can find one with the right *capacitance*. Capacitance is measured in farads (F), and the more capacitance a capacitor has, the more energy it can store. Nonpolarized capacitors with large capacitances aren't made because they'd have to be physically very large. Polarized capacitors are able to hold more energy in a smaller space, but they have the disadvantage of needing to be connected the correct way around.

When building circuits with high capacitance values, you'll be using polarized capacitors. Always make sure the positive leg of any polarized capacitor is connected closest to the positive side of the battery.

Capacitor Values

The capacitors you’ll use in this book will have capacitances in the µF (microfarad), nF (nanofarad), or pF (picofarad) range. Capacitances tend to be very small, and they’re often written with the *micro*, *nano*, and *pico* prefixes, which are defined as follows:

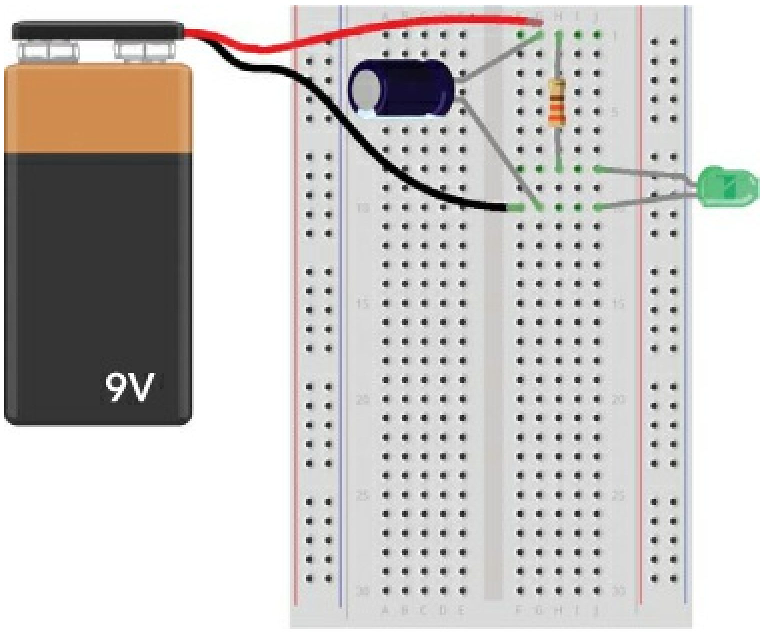
- µ (micro) means *millionth*, so 1,000,000 µF = 1F
- n (nano) means *billionth*, so 1,000,000,000 nF = 1F
- p (pico) means *trillionth*, so 1,000,000,000,000 pF = 1F

Polarized capacitors are big enough to have their values written on them. Nonpolarized capacitors, on the other hand, are a bit trickier. They’re usually really small, so they tend to have cryptic codes like *104* or *202*. I always forget what they mean, so when I need to figure out what a certain code means, I just look it up in a table. You can find a table of common codes in “Capacitor Codes” on page 283.

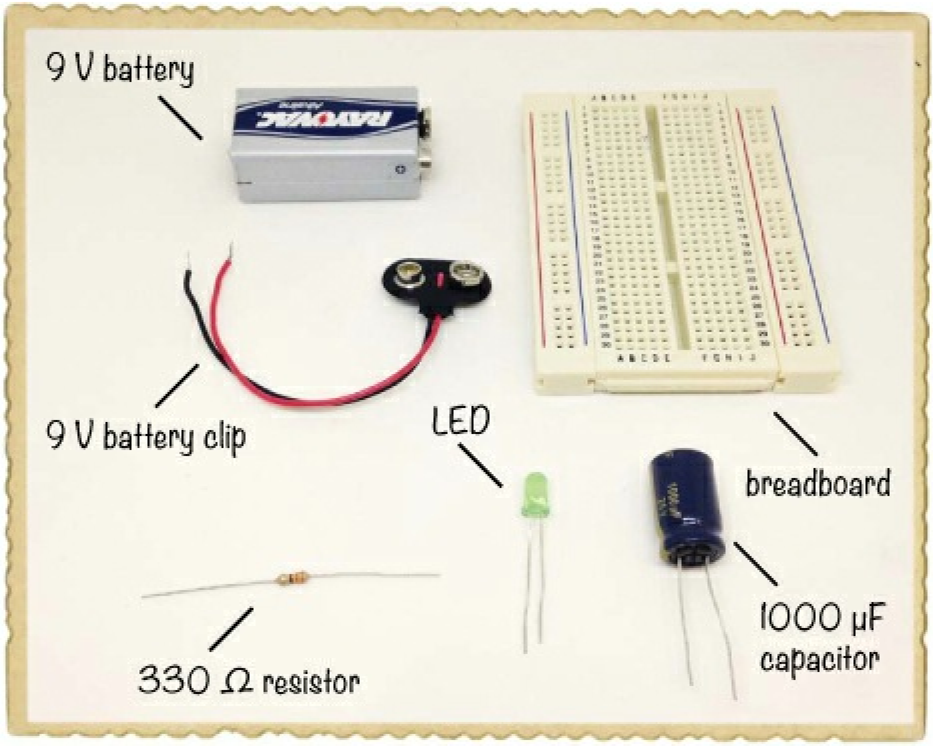
But like most things, capacitors are much more interesting to play with than to read about. Build the next project, and you’ll see for yourself how a capacitor works.

PROJECT #10: TEST A CAPACITOR

This project demonstrates that a capacitor stores energy. It’s nearly the same circuit you built in “Project #9: Your First Breadboard Circuit” on page 84, but this time, you’re going to add a capacitor. When you remove the battery from the circuit, as shown here, you’ll see that the LED remains lit for a second or two. That’s because the capacitor is powering the LED using its stored energy.



Shopping List



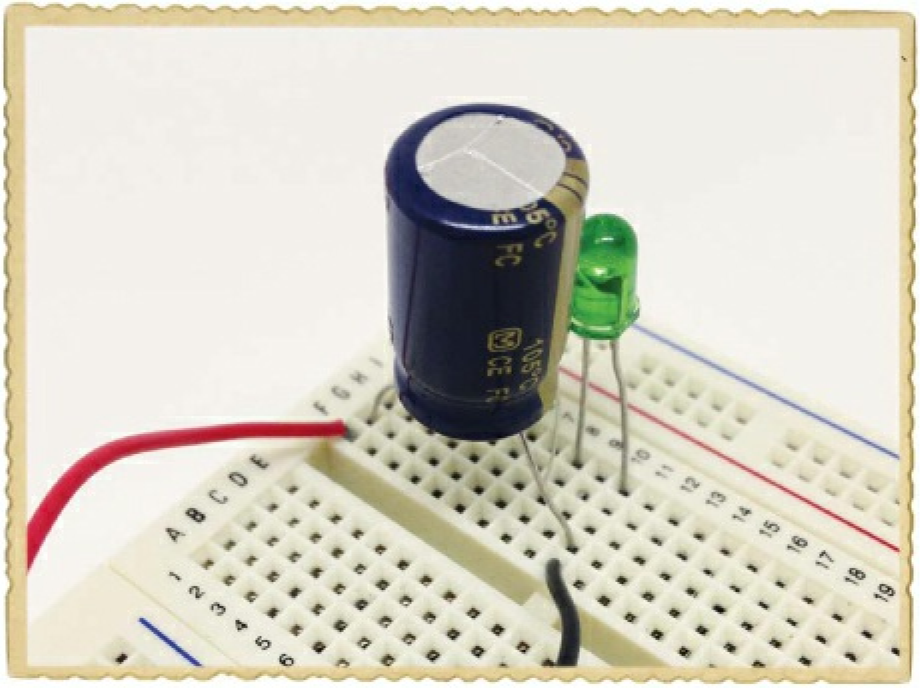
- **A breadboard** (Jameco #20601, Bitsbox #CN329) with at least 30 rows.
- **A standard 9 V battery** to power the circuit.
- **A 9 V battery clip** (Jameco #11280, Bitsbox #BAT033) to connect the battery to the circuit.
- **A standard LED** (Jameco #34761, Bitsbox #OP003)
- **A 330 Ω resistor** (Jameco #661386, Bitsbox #CR25330R) for limiting the current to the LED.
- **A polarized 1000 µF capacitor** (Jameco #158298, Bitsbox #EC1KU25)

Step 1: Start with the LED Circuit

Follow the instructions from "Project #9: Your First Breadboard Circuit" on page 84, making sure you end up with a working circuit that lights an LED. Then, disconnect the battery and move on to the next step.

Step 2: Add the Capacitor

Connect your capacitor to the battery. Because the capacitor is polarized, place the pin marked with a minus sign or a zero in the same breadboard row as the battery's negative leg. Connect the other leg to the same row as the battery's positive leg, as shown.



Step 3: Charge the Capacitor

Connect the battery to the clip, and the LED should light up. At the same time, the battery should have very quickly charged the capacitor.

Step 4: Use the Capacitor to Light the LED

Watch the LED while removing the battery. The LED shouldn't turn off right away when you disconnect the battery. Instead, it should stay lit for a second or so and then fade out slowly until there's no more energy left in the capacitor.

Step 5: What If the Circuit Doesn't Work?

First, check whether the circuit works without the capacitor. If not, then go back to Step 1 and get the LED circuit working before you move forward.

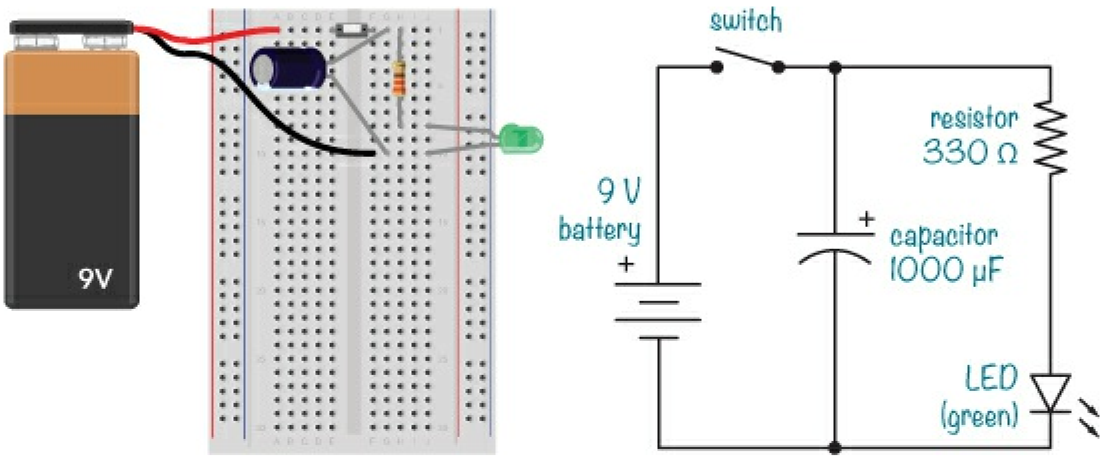
If the LED lights up with the battery connected but turns off the instant you remove the battery, then something is wrong with the capacitor part of your circuit. Check that the capacitor's positive leg is connected to the positive battery leg (row 1 in the photo) and that the other leg is connected to the negative battery leg (row 10 in the photo).

If the circuit looks correct, confirm that the capacitor value is at least 1000 µF; the value should be written on the capacitor. If it's less than 1000 µF, try a bigger capacitor.

DESCRIBING CIRCUITS WITH SYMBOLS

So far, you've built circuits with only a few components. To build more interesting electronics projects, you usually need more components. But drawing out every component in a big circuit exactly as it looks in real life can be messy and time-consuming. This is where *circuit diagrams*, also called *schematics*, come to the rescue.

In a circuit diagram, each component has its own simple symbol, which lets you draw the whole circuit quickly. As with words and books, until you know what the different symbols mean, a circuit diagram might look a bit complex. Let's jump right in and learn a few symbols! Here's a circuit with an LED, a resistor, and a battery, alongside its circuit diagram:



The battery symbol has a + sign to tell you where the positive leg goes. Sometimes you'll see the battery symbol without the plus sign; in that case, the positive side is the one with the longest line.

NOTE

The battery symbol may be drawn with two lines, with four lines, and sometimes with even more lines. Regardless of the number of lines, just look for the specified voltage and use a battery with the same voltage.

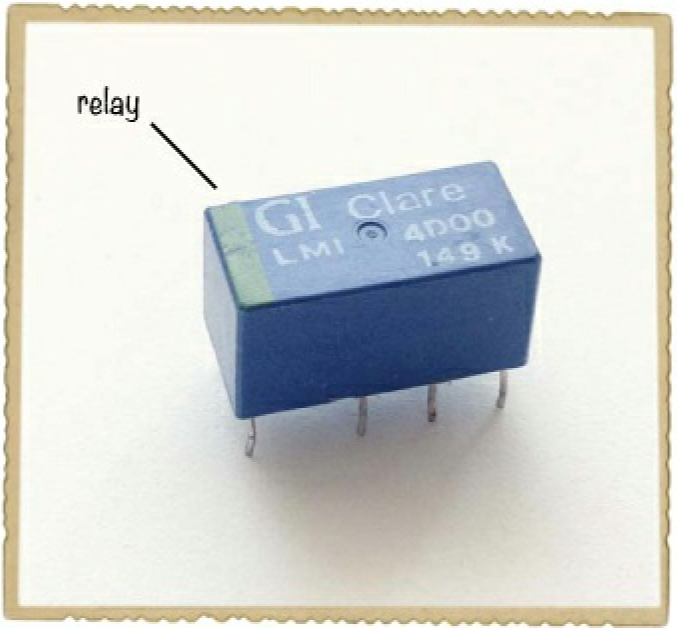
The switch symbol is very simple, and it doesn't matter which way you draw it. In the LED symbol, the line on the point of the triangle indicates the negative side of the LED, or the cathode. Check that against the "real-life" version, and you can see that the LED's positive leg is indeed connected to the resistor in both diagrams. The resistor, on the other hand, isn't polarized, so its symbol doesn't have any directional markers. There are both polarized and nonpolarized capacitor symbols, but our example shows the polarized version, which has the positive side marked with a + sign. Look at both the circuit and the circuit diagram again—do you agree that they are the same?

Once you learn how to build something just by looking at a circuit diagram, a whole new world will open up for you. You can find circuit diagrams for almost anything on the Internet these days, like radios, MP3 players, walkie-talkies, or whatever you want to build! I'll teach you more circuit symbols throughout this book as we use more components.

MEET THE RELAY

I was a very curious child, and I always wondered how things worked. To me, electronics devices like the radio or the television were just magical. I had no idea how they worked, and I didn't believe I'd ever understand how to make one.

But one day, I asked my dad how it was possible to blink a light automatically. I thought that if I could only understand that, I'd be able to understand more. Fortunately, my dad was an engineer, and he was also good at explaining things in a practical way. When I asked him how to blink a light, he introduced me to a *relay*, like the one shown here.



relay

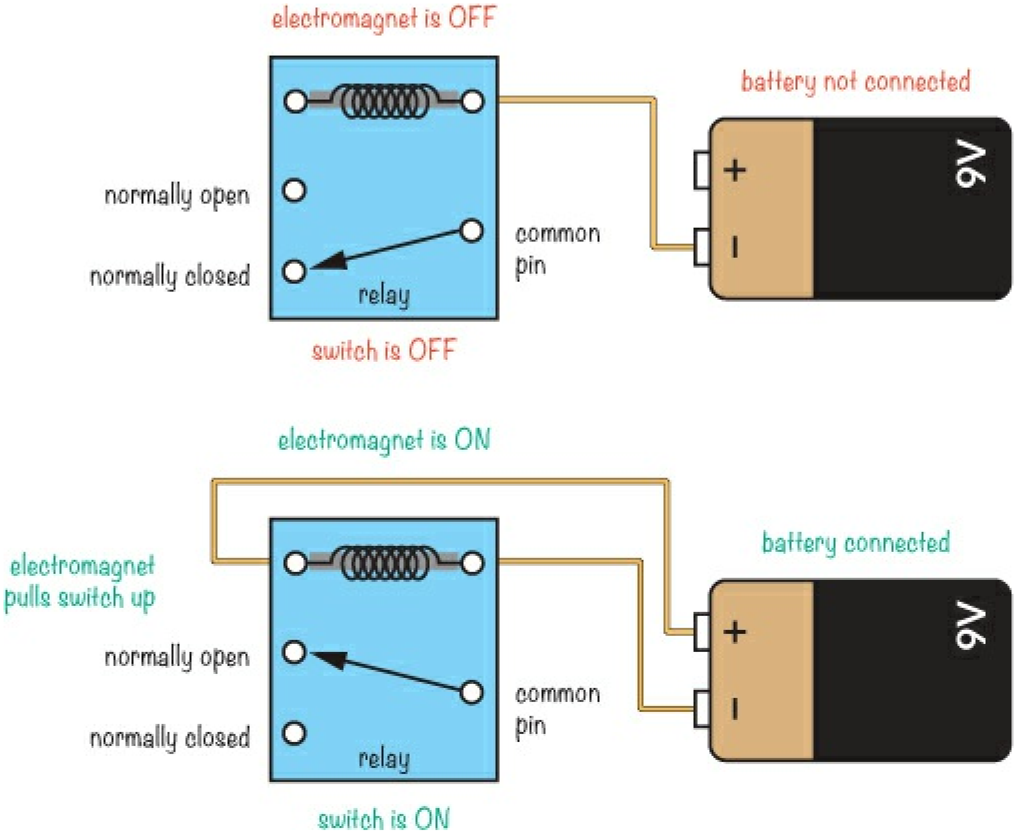
Chapter 1 described how you can use switches to turn things on and off. Chapter 2 showed you how to use an electromagnet to move things. Imagine combining the electromagnet with a switch: instead of pushing a button to change the switch's position, you add an electromagnet that can change the switch position for you. That's the idea behind the relay, and this illustration shows how it works:



electromagnet is OFF
battery not connected
normally open
normally closed
common pin
relay
switch is OFF
+
-
9V
electromagnet is ON
battery connected
electromagnet pulls switch up
normally open
normally closed
common pin
relay
switch is ON
+
-
9V

The white dots represent the relay's pins. Notice that the connections are labeled *common pin*, *normally closed*, and *normally open*. These labels are defined as follows:

Common pin (COM) Connected to either NC or NO

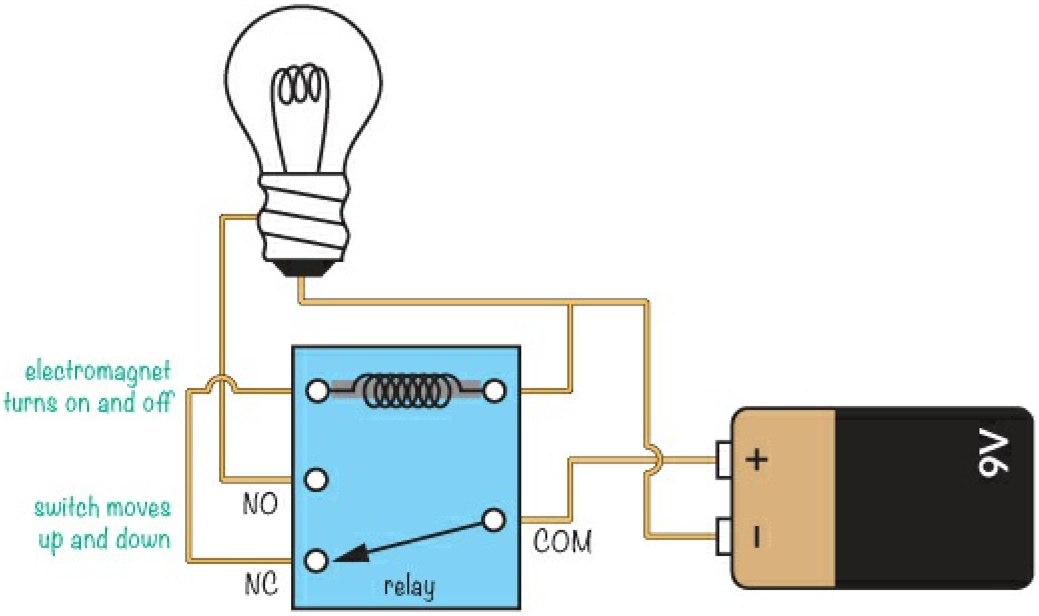
Normally closed (NC) Connected to COM when coil is off

Normally open (NO) Connected to COM when coil is on

When the battery isn't connected to the relay coil, the electromagnet doesn't pull, and COM from the switch is connected to NC. But when you connect the battery to the relay coil, the electromagnet turns on, and the switch is pulled so that COM gets connected to NO instead. You can connect or disconnect a battery from the electromagnet to change the position of the switch!

Using the Relay to Blink a Light

If you were to connect a relay to a battery so that the electromagnet connects to the battery through the relay's COM and NC switch contacts, the electromagnet would turn on and off continuously. Here's an example relay circuit that's also connected to a light bulb:



Before you connect the battery in this circuit, the electromagnet would be off, leaving the COM and NC switch contacts connected. With the battery connected to the circuit, the electromagnet would receive power from the battery through the switch. This means it'd pull the switch and connect COM and NO instead, giving the light bulb power from the battery.

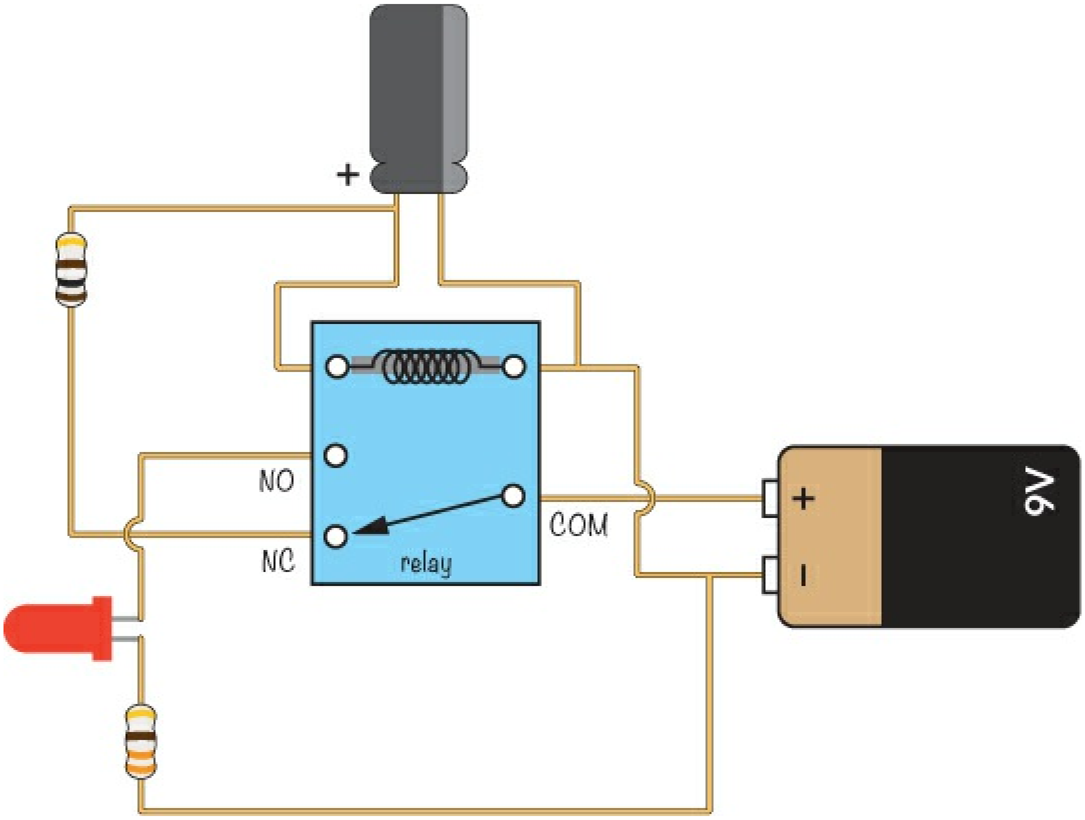
But with the switch in this position, the battery would no longer be connected to the coil, and the electromagnet would lose its power. When the electromagnet has no power, the switch falls back to its original position, disconnecting the battery from the light bulb. The battery would power the electromagnet again, and the process I just described would repeat.

In this example, it seems like you'd get a blinking light, right? In theory, yes. But the relay would switch on and off so fast you wouldn't see the light turn on and off properly! Instead, you'd hear a really fast ticking sound as the relay switched back and forth, but the light would appear to stay dark.

Slowing Down the Blinking

To build a circuit that lets you actually see the light blink, you need to slow down the relay. The capacitor can help with this. In "Project #10: Test a Capacitor" on page 92, adding a capacitor to the LED circuit made the LED stay on for a short time after the battery was disconnected. If you connected a capacitor across the electromagnet in our too-fast blinking-light circuit, the electromagnet would stay on for a bit, too.

But the electromagnet wouldn't stay off for long, so in this case, the light would appear to be on all the time. To make it stay off longer, you'd need to slow down the charging of the capacitor so it wouldn't jump back to fully charged as soon as it discharged. To do this, you could reduce the amount of current flowing into the capacitor. And how do you reduce the amount of current? With a resistor! To blink an LED light with a relay, you'd use a circuit like this one, which we're going to build next:



PROJECT #11: BLINK A LIGHT!

It's time for you to build your first blinking light by flashing an LED. Here's the complete circuit diagram—do you recognize the components?

When connecting a circuit, it's helpful to connect it in a way that looks like the circuit diagram. That makes it easier to find out what's wrong if your circuit isn't working later—and you'll often find that your circuit doesn't work on the first try. Tracking down errors and figuring out how to fix them is part of the game!

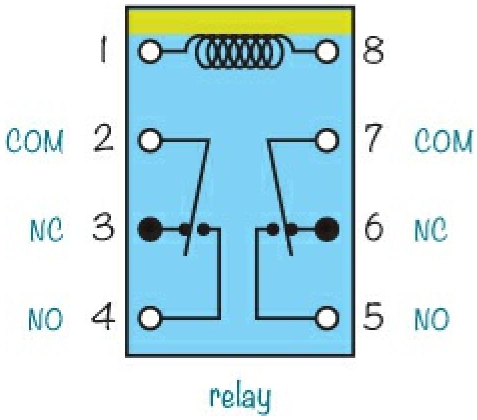
- **A DPDT or SPDT relay** (Jameco #842996, Bitsbox #SW073) with a 5 V, 6 V, or 9 V coil.
- **A standard LED** (Jameco #34761, Bitsbox #OP003)
- **A polarized 1000 µF capacitor** (Jameco #158298, Bitsbox #EC1KU25)
- **A 100 Ω resistor** (Jameco #690620, Bitsbox #CR25100R) for limiting the current to the capacitor.
- **A 330 Ω resistor** (Jameco #661386, Bitsbox #CR25330R) for limiting the current to the LED.

Step 1: Identify the Relay Pins

Not knowing which pin on the relay is which is the biggest source of error when building this circuit, so let's look at these pins now. To find the function of each pin, look up the *datasheet* for your relay. A datasheet is a document that tells you how an electrical component works. For a relay, it should say what voltage you need for the electromagnet coil, how much current you can run through the contacts, and so on. You should be able to find a link to the datasheet on the product page where you bought your relay.

For the relay I recommend, the pins are placed as shown here:



This type of diagram is called a *pinout*, and it shows the function of each pin. The view is from above with the pins out of sight below the plastic case of the relay. I suggest drawing the pinout on a piece of paper and keeping it on your desk while you connect the circuit so you can check it repeatedly and make sure you're connecting it the right way.

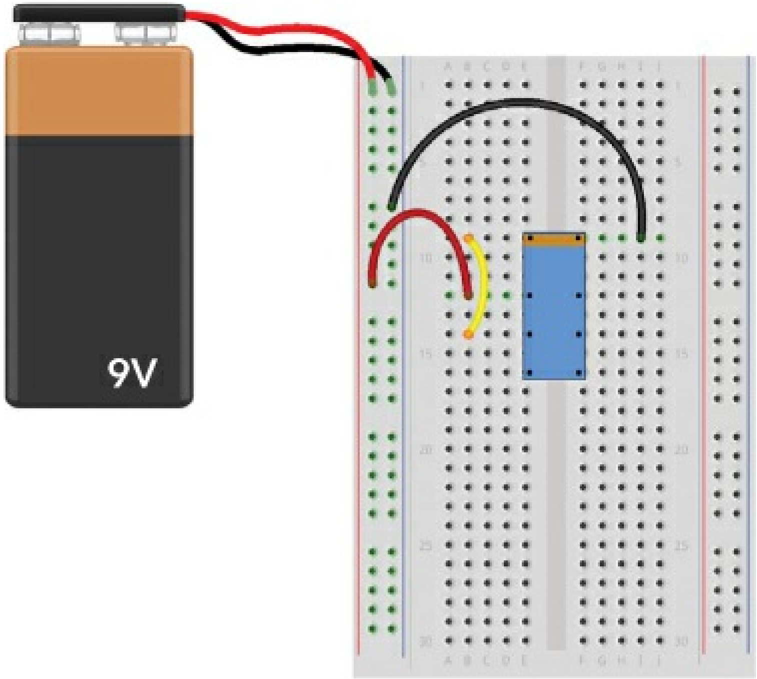
In this relay, pins 1 and 8 are for the electromagnet coil—you can identify these pins by the line at the top. When you look at the real relay with the line at the top, the pins should be in the same places as in the pinout.

The pinout also shows that there are two switches inside. Pins 2 to 4 make up one switch, and pins 5 to 7 make up the other. Don't worry about memorizing the relay pins, though. You can always refer to the pinout if you get stuck, and I encourage you to do so whenever you need to. Also, different relay types can have different pinouts.

Step 2: Make the Relay Switch Fast

First, let's connect the relay so that it switches on and off automatically. Place the relay in the middle of your breadboard, centered over the notch, with one side in each component area. This way, no pin should be connected to any other pins.

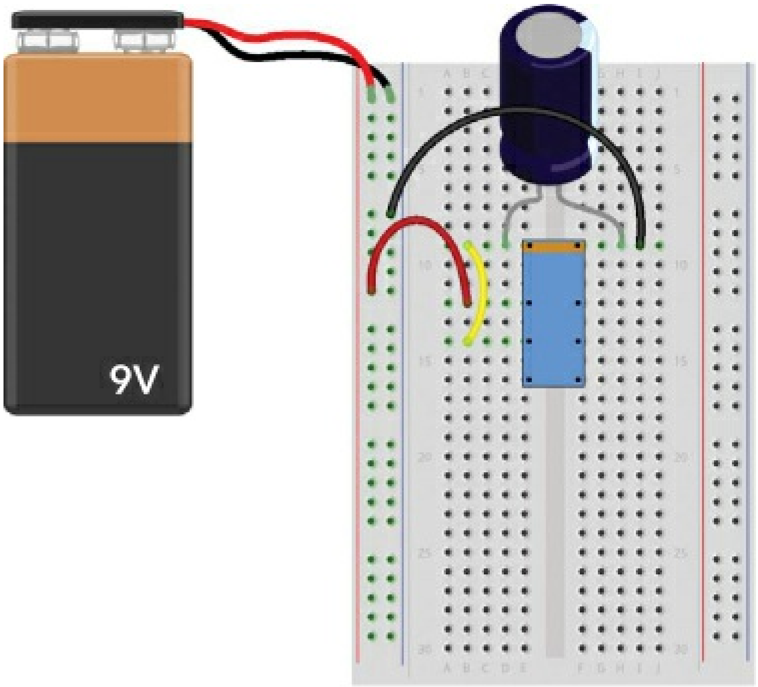
Plug your battery clip's positive leg into the positive supply column on the left, and plug the negative leg into the negative supply column on the same side. Connect a jumper wire from the negative supply column to the same row as the right coil pin (pin 8), shown as row 9 this diagram:



Next, connect a wire from the plus column on the left to the relay's common switch pin (pin 2). In this diagram, the common pin is in row 12, column B. Then, connect a wire from pin 3 on the relay (the NC pin) to the coil pin (pin 1); this is the yellow wire going from row 14 to row 9 in column B in the diagram. Connect the 9 V battery, and you should hear a really fast ticking. This is the relay turning on and off. Disconnect the battery for now.

Step 3: Make the Relay Stay On Longer

The next step is to slow down the relay by placing a capacitor across the coil of the electromagnet. Connect the capacitor as shown here:

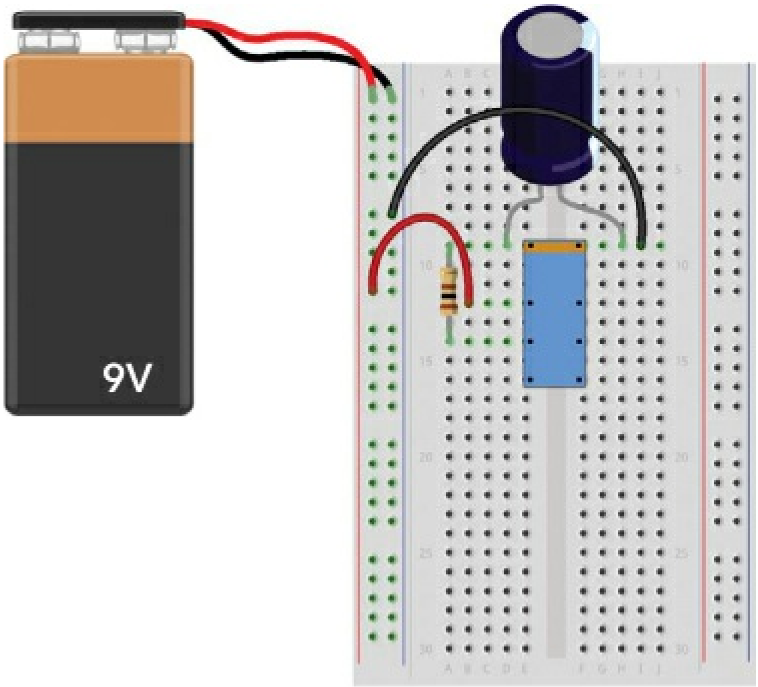


In the diagram, I’ve connected the negative capacitor leg to pin 8 on the relay by plugging it into row 9, column H and connecting the positive leg to pin 1 on the relay at row 9, column D. Whichever holes you use, just make sure you connect the capacitor’s negative leg to the same relay pin as the one you connected the negative supply to. The negative capacitor leg is usually marked with a stripe, a zero, or a minus sign.

Connect the battery to test your circuit. You’ll know it’s working if you hear the telltale ticking sound. The ticking should be much slower now, which means that the relay is staying on for a longer time. But in the instant the relay is turned off, the capacitor should charge again, leaving the relay off for only a fraction of a second. You’ll fix that in the next step, so disconnect the battery again now.

Step 4: Make the Relay Stay Off Longer

Let’s add a resistor before the capacitor to reduce the amount of current that flows and force the capacitor to take more time to charge. To do this, simply replace the wire between pins 1 and 3 on the relay (the yellow wire connected to rows 9 and 14 in my diagrams) with a resistor of about 100 Ω as shown here:

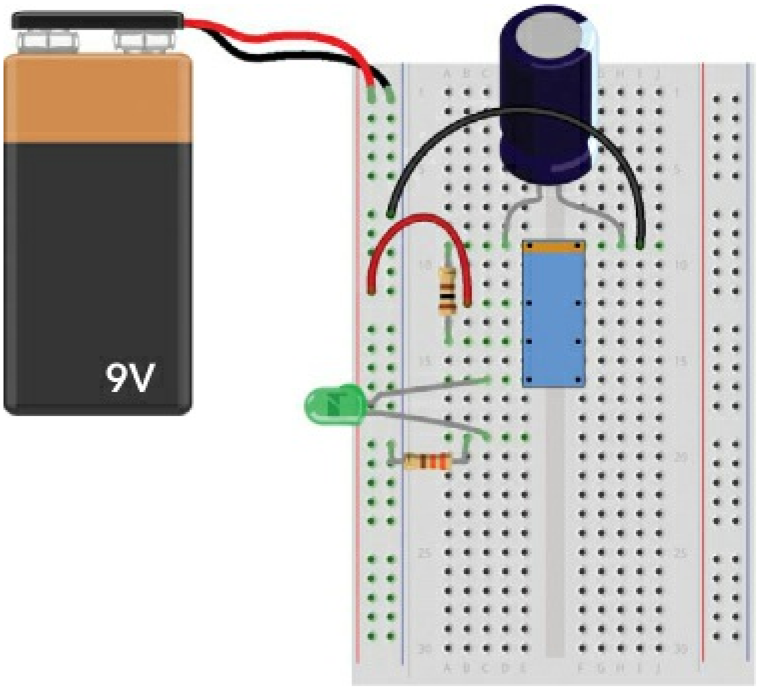


Connect the battery to test it. The relay should stay off a bit longer now, and you’ll recognize this by the “tick-tock” sound of the relay.

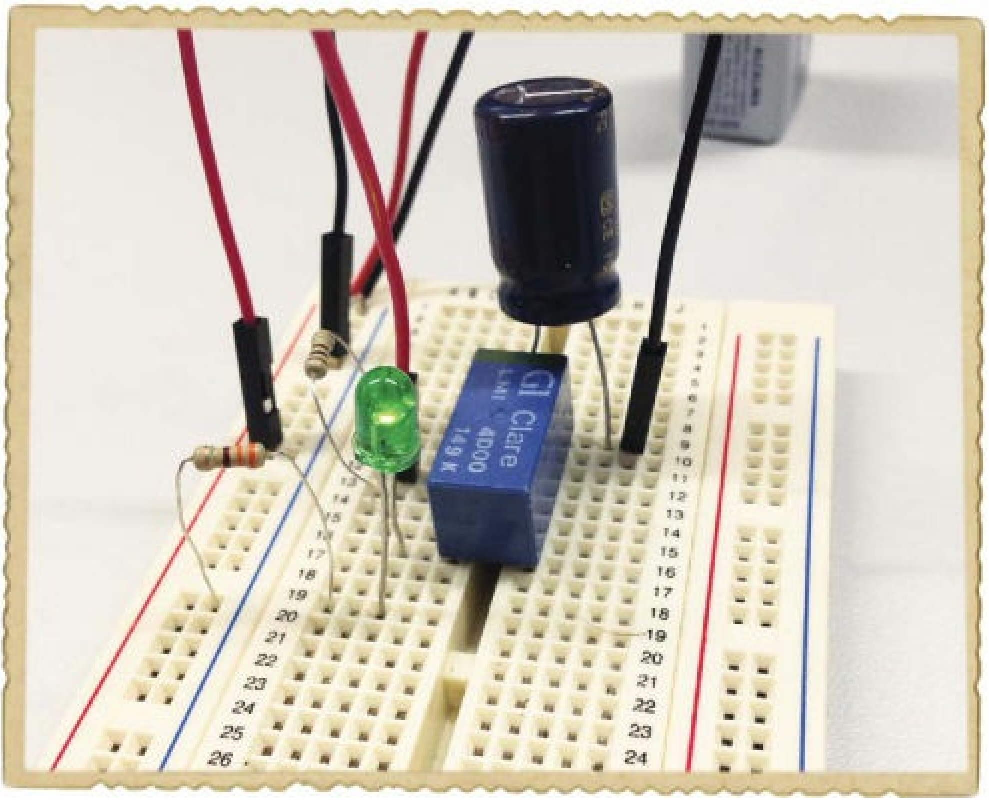
Step 5: Add the LED and Resistor

Disconnect the battery and add the LED and the 330 Ω resistor to the circuit. Connect the long leg of the LED to the NO pin of the relay (pin 4). My LED’s long leg is connected to row 16, because the NO pin is plugged into that row. Connect the other leg to an unconnected row below, such as row 19. Connect the resistor from the same row to the negative column on the supply side.

Your breadboard should look something like this:



Compare this to the circuit diagram at the beginning of the project to see how the symbols match. Now, connect the battery and watch the light blink!



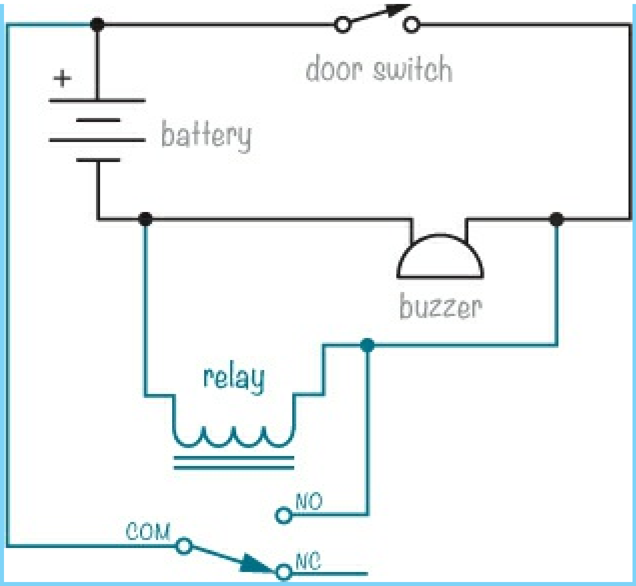
Step 6: What If the LED Won't Blink?

If you can't get the LED to blink, go back to Step 1 and check your work through to Step 4. This should give you a relay that turns on and off automatically. If that works, then you should be able to connect the LED and resistor to have a working circuit.

If the LED still doesn't blink, confirm you've connected it according to the diagrams. Still no luck? Remove the LED and the resistor from the circuit, and then connect only these two to the battery until you can make the LED light up. (Follow the instructions in "Project #9: Your First Breadboard Circuit" on page 84.) If you can't make the LED light, then your LED may be broken or your resistor may be the wrong value.

TRY IT OUT: MAKE YOUR INTRUDER ALARM MORE EFFECTIVE

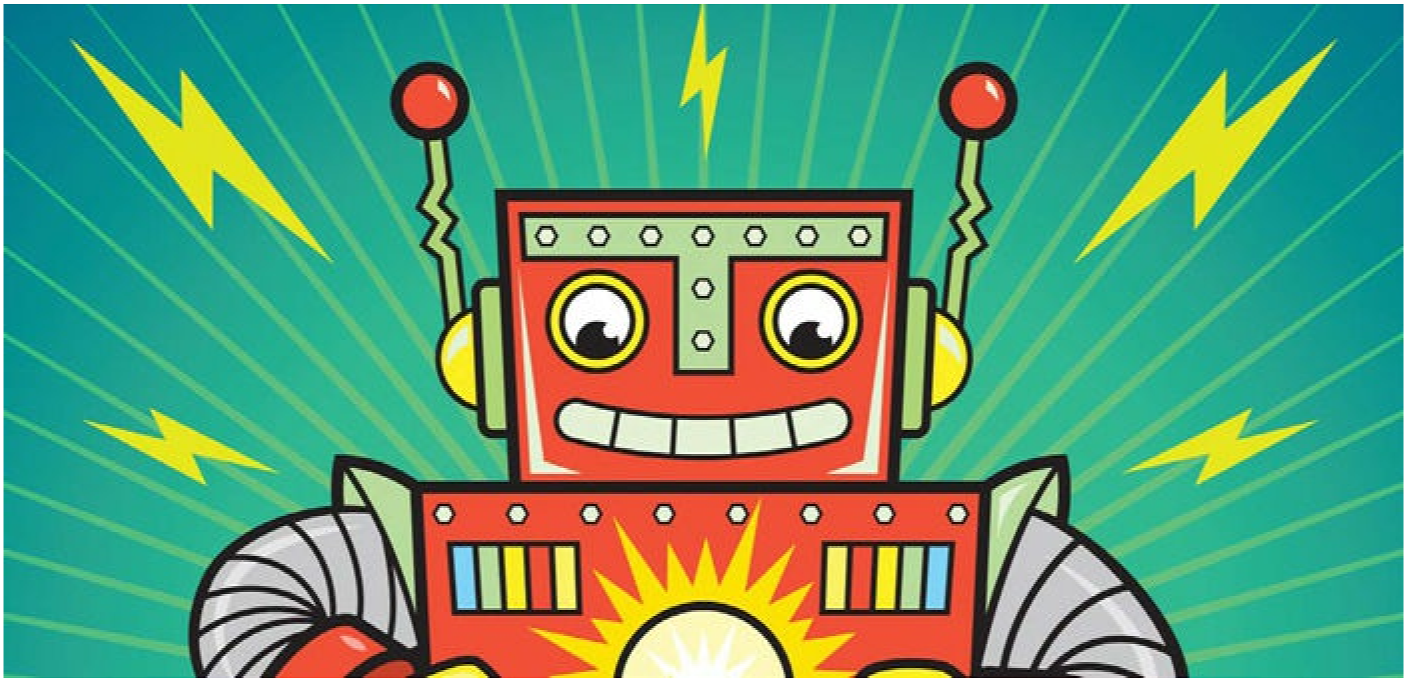
Try connecting a relay to the Intruder Alarm you built in Project #2 on page 11 so that when someone tries to enter a room, they can't turn off the alarm by closing the door. When your relay is triggered by a switch, it should stay on. This diagram shows how you can connect the relay (shown in blue) to the rest of the circuit (shown in black). When the alarm is triggered, the beep will continue to sound until you disconnect the battery.



WHAT'S NEXT?

You've come a long way in this chapter! So far, you've learned how four common components in electronics work (resistors, LEDs, capacitors, and relays), you've connected a few circuits on a breadboard, and you've even made your own project that blinks a light. Hopefully, you understand why the light blinks, too.

You've already connected a few circuits on a breadboard, which is a useful skill when you want to test a circuit or build simple prototypes. But when you want a circuit's components to stick together forever, you need to solder them, and I'll show you how in the next chapter.



6

LET'S SOLDER!

In Chapter 5, you used a breadboard to build new circuits. A breadboard lets you quickly test new ideas and experiment with different components to see the result, but it isn't a permanent solution. Components can easily fall out, and there can be loose wires all over the breadboard. When you want to use a circuit for a long time without changing it, it's better to solder the circuit to a *circuit board*. Soldering is kind of like gluing: you melt a material called *solder* onto the component legs so the components stick to the circuit board. A circuit board has holes like a breadboard, and when you solder components to it, they become connected by plates of copper.

This chapter will teach you how to solder, starting with a simple LED circuit. This will give you the foundation you need to solder your own circuits later. After you've practiced the basics in this chapter, you'll continue soldering in Chapter 7 to build a touch-enabled switch and a circuit that wakes you up when the sun rises in the morning.

HOW TO SOLDER

To solder a circuit, you need a few tools:

- Solder
- A soldering iron
- A stand to hold the soldering iron
- A damp sponge
- Safety goggles

Solder is a mix of metals that can easily melt at high temperatures. The most commonly used solder melts at around 360 to 370 degrees Fahrenheit.

A *soldering iron* is a pen-shaped tool that heats up to a temperature high enough to melt solder. If you put solder on the tip of the soldering iron, the solder melts.

soldering iron

Soldering is quite easy once you learn the basics, and one important basic step is to take a few safety precautions.

Soldering Safety Tips

Soldering irons get extremely hot, and you can burn yourself if you touch the metal part of a soldering iron while it's plugged in. Always return the soldering iron to its stand when you're not using it; never lay it directly on a surface. Avoid touching *joints* (soldered connections) and components for a few seconds after you solder them, too. They can get hot enough to burn.

Here are some other important safety tips to keep in mind while soldering:

- Keep the hot parts of the soldering iron away from the power cord.
- If you're soldering on a table, protect the surface with a piece of wood or some thick cardboard.
- Always wash your hands after handling solder.

- If you do get burned, don’t panic. For a minor burn, immediately cool the burn with running cold water, keeping the burned area under water for at least five minutes. Putting ice on a burn is good, too, but make sure to do the initial cooling with water right away.

Ask an adult to supervise your first few attempts at soldering, and remember: soldering is fun, but soldering irons must still be used with great care. With those tips in mind, read the rest of this section for a step-by-step guide to basic soldering.

Heat the Soldering Iron

The first step of soldering is to plug in your soldering iron and place it on your stand. Don’t forget to put on your safety goggles!

After a minute or two, check whether the iron is hot enough by touching some solder to the tip of the iron. If the solder melts, your iron is ready to go.

Clean the Soldering Iron Tip

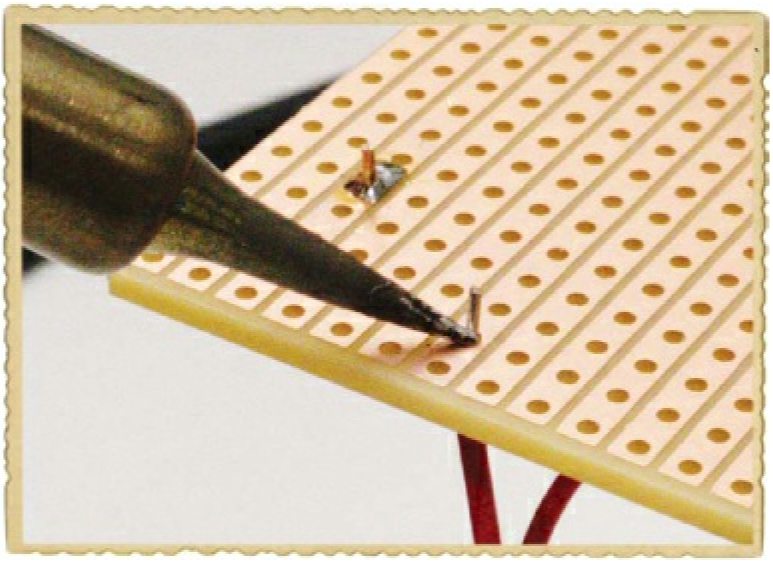
Touch the tip of your soldering iron to a damp sponge to clean it. A clean tip transfers heat much better than a dirty one, so clean the tip often.

Tin the Soldering Iron Tip

Here’s a little trick: to heat the joint faster, add a bit of solder to the tip of the soldering iron just before you start soldering. This is called *tinning*. This must be done just a second or two before soldering to be effective.

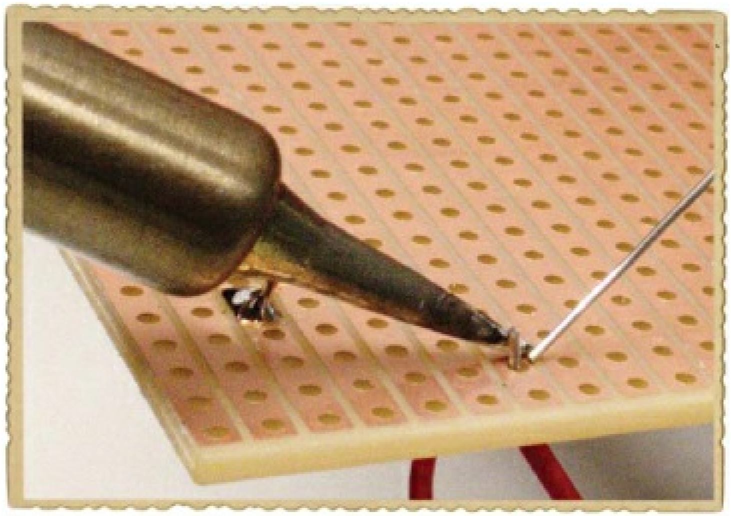
Heat Both the Pin and the Pad

Place the tip of the soldering iron onto both the component leg and the copper strip. Heat the strip and leg for a couple of seconds before you move on to the next step.



Add Solder

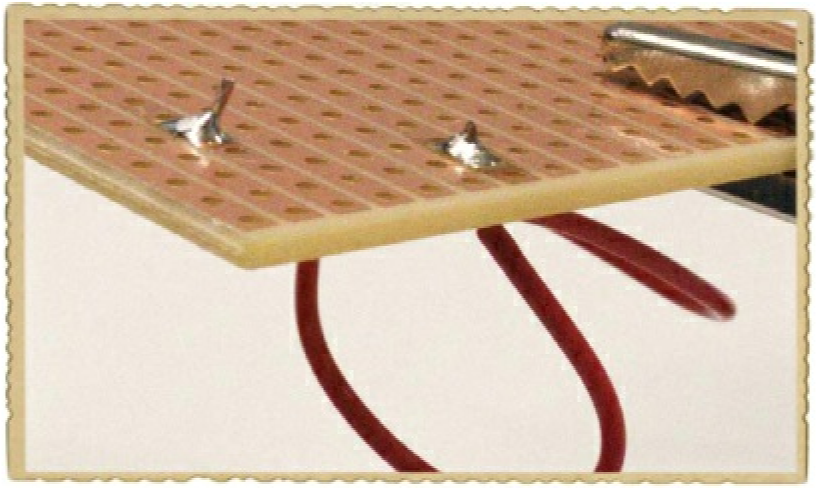
While keeping the soldering iron tip on the joint, touch some solder to the leg and the copper strip. As the solder melts, slowly add more until there’s just enough to coat both the leg you’re soldering and the copper strip you want to connect it to. When you have enough melted solder, remove the solder wire from the joint while still keeping the soldering iron tip on the joint.



Remove the Soldering Iron

Finally, remove the soldering iron tip from the joint and place the iron in its stand. Always do this last. If you remove the iron while the solder wire is touching the solder joint, the solder wire may get stuck to the circuit board when the solder joint hardens.

Your solder joint should have a cone shape.



If you're done soldering, then unplug the iron so it can cool down.

Watch Out for Bad Solder Joints!

It's important to heat both the component leg and the copper strip with the iron before touching solder to either. When you heat only the component leg and not the copper strip, the solder sticks to the leg, but there's no connection between the solder and the copper strip. If only the strip is heated, the solder will stick to the strip, but not the leg. It could look like a good soldering joint from a distance, but the solder probably won't be connected to the leg.

You must also make sure the solder doesn't float over to another copper strip next to it. This will create an unintended connection between the two strips.

If your solder joint doesn't look right, don't worry. Just reheat the joint, the component leg, and the copper strip and add more solder to achieve the cone shape of a good solder joint. Then, you should be good to go.

PROJECT #12: SOLDER YOUR FIRST LED CIRCUIT

Now, let's get soldering! In this project, you'll solder the resistor and LED circuit from "Project #8: Powering an LED" on page 78 to a circuit board. The battery should make current flow in the circuit, the resistor should make sure there isn't too much current, and the LED should light up.

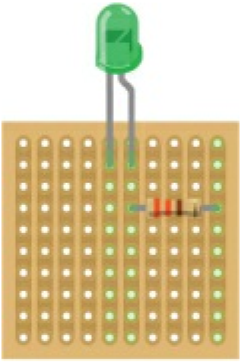
- **A wire cutter** (Jameco #35482, Bitsbox #TL008) to cut off excess legs from components.

Step 1: Place the Components

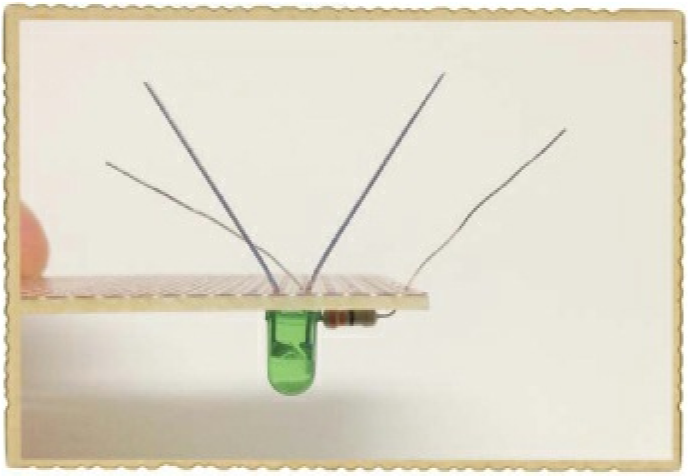
Look at your circuit board and get familiar with the connection pattern on it. The circuit board I recommend is called a *prototyping board*, and it's covered with little straight strips of copper, each with lots of holes. Any component leads that you solder into holes that share a strip of copper will become electrically connected.

Place your resistor and LED legs through the circuit board. The resistor should share a copper strip with the LED's positive lead. Note that the strips shown in the figure are on the bottom side of the board, which is why they're not copper colored in the picture. Anytime a project involves soldering to a circuit board, I'll show shadows of the copper strips so you can see where the connections are underneath.



Step 2: Bend the Component Legs

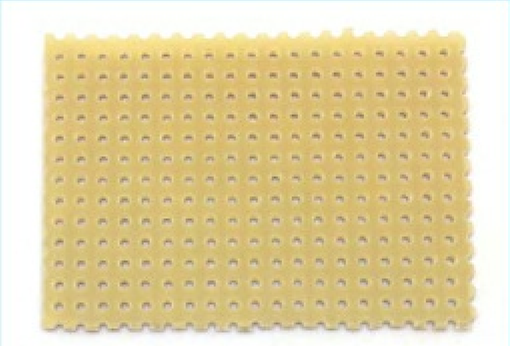
Carefully flip your circuit board over so you can see the copper; hold the LED and resistor in place with a finger if needed so they don't fall out. Then, slightly bend each component's legs outward so that the LED and resistor stay in place even with the copper side up. Keep the board copper-side-up for now.



HOW TO READ THE CIRCUIT BOARD ILLUSTRATIONS

Throughout this book, you'll see circuit board illustrations I created in a program called Fritzing. These illustrations show the top side of the circuit board so you can see how the components look, and they show the bottom side—a slightly darker color than the top—so you can see how the copper strips look.

When following my instructions, always orient your circuit board with the copper strips on the bottom going in the same direction shown in the illustration. If you ever get confused about how you should read the connections in a circuit board illustration, just refer back to this example.



top view photo of real circuit board

If you want to create your own circuit illustrations with Fritzing, you can download the free, open source software from *http://www.fritzing.org/*.

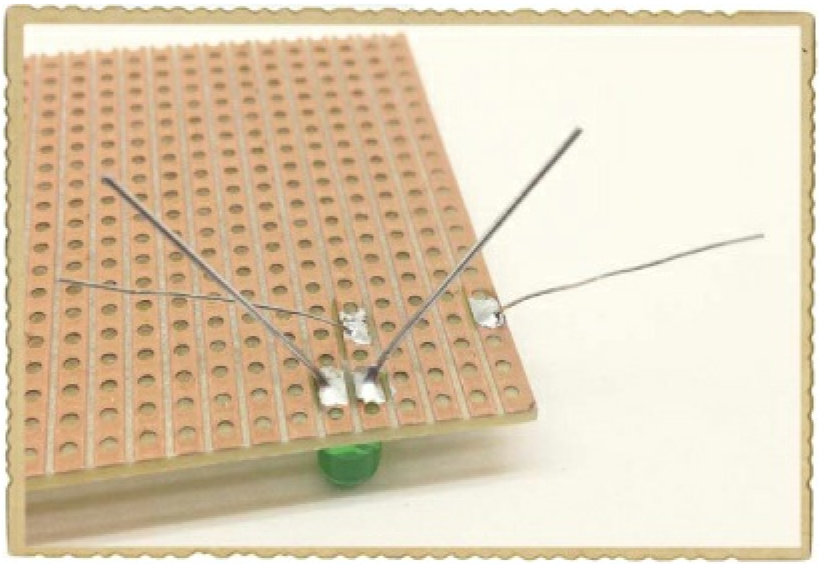
Step 3: Heat and Clean the Soldering Iron

Your components should be in place and ready to solder, so plug in and heat up the iron now. This may take a few minutes. As always, check to see whether the iron is hot enough by touching some solder to the tip to see whether it melts.

Before you start soldering, clean the tip of the soldering iron, too. Wet your sponge just a little bit and wring out any excess water. Then, wipe the tip of the iron on the sponge to remove any old solder.

Step 4: Solder the Resistor and LED

With the copper side of the circuit board facing up, solder each component leg to the board, as described in “How to Solder” on page 112. Your board should look like this:

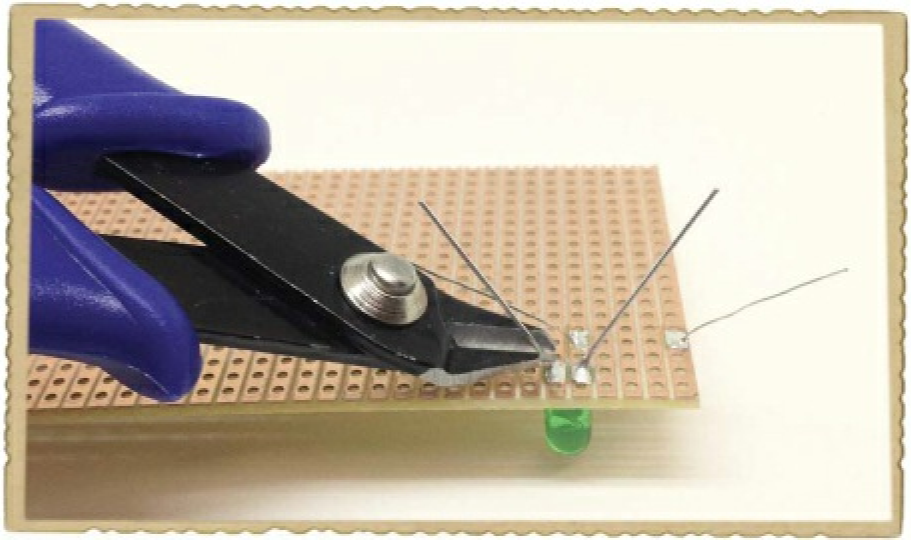


Step 5: Trim the Legs

Right now, your LED and resistor have really long legs. You don’t want to leave them sticking out because stray metal can create unintentional paths between components. At best, that could prevent your circuit from working until you move the leg away from the component it shouldn’t be touching; at worst, an unintended connection could break a component. To prevent accidental connections, cut off each leg just above the solder joint. The legs could go flying when you cut them, so turn the board away from your eyes or wear safety goggles for protection.

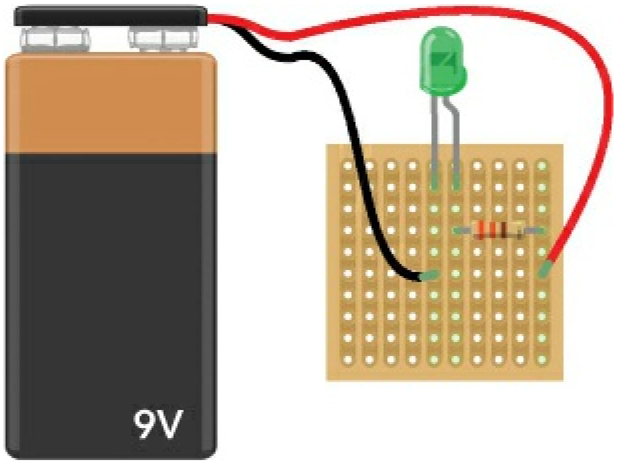
TIP

Hold the circuit board over an empty box while you cut the legs off, to prevent the scraps from getting lost and to make cleanup easier. You could also rest the circuit board on a table and hold the leg with one hand while you clip.

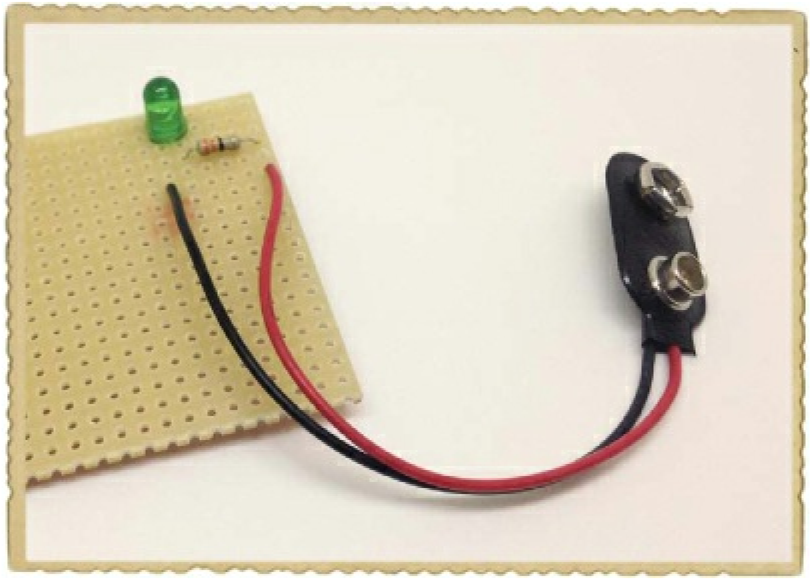


Step 6: Solder the Battery Clip

This circuit also needs a way to connect the battery to the components, so solder the battery clip to the circuit board now.



The red wire from the battery clip is the positive wire; connect it to the copper strip that connects only to the resistor, not the LED. The black wire is the negative lead, so connect it to the negative side of the LED. Your circuit board should now look like this:



Step 7: Let There Be Light!

Now, let's test your circuit. Plug in the battery, and your LED should light up!

Step 8: What If the Soldered LED Circuit Doesn't Work?

If your LED doesn't light, check that you don't have any unintentional connections. Is solder connecting two joints that shouldn't connect? Are extra long component legs making contact?

Next, inspect your solder joints closely. Do any of them look like the examples of bad connections described in "Watch Out for Bad Solder Joints!" on page 117? If so, you might need to flow a little more solder: warm up your iron again and try to make sure your solder joints look like little pyramids.

Check the placement of the LED, too. Did you connect it correctly? Because you've cut off the excess legs, you can't see which leg is longer anymore, but if you look closely at the LED, you should see that one side of the base of the plastic housing is flattened. This is the negative side, which should be connected to the battery clip's black wire. If you've placed it the wrong way, here's one quick fix: use your wire cutters to cut the battery clip leads, removing the clip from the circuit board. Now, solder the positive battery lead where the negative lead used to be, and solder the negative battery lead where the positive lead used to be. This works because it doesn't matter which side of the LED the resistor is on.

OOPS! HOW DO I REMOVE A SOLDERED COMPONENT?

Sometimes, you'll make mistakes when soldering. For example, what if you soldered the battery clip the wrong way or used a 33,000 Ω resistor instead of a 330 Ω one? Well, don't worry: even the most experienced engineers mess up at soldering sometimes, and there's a way to fix your circuit when it happens. In these cases, you need to *desolder*, which just means to remove the solder from a solder joint.

Solder wick is a very useful tool for desoldering, and I suggest keeping some at your side any time you solder. The solder wick is made of braids of copper thread, so it's also called *desoldering braid*.

When you place a piece of solder wick on top of a solder joint and heat both together, the solder should melt as usual, and the solder wick should absorb the liquid solder just as a dry cloth absorbs water. When you remove the solder wick, the solder should be on the wick instead of on the circuit board!

PROJECT #13: DESOLDER THE BATTERY CLIP

Knowing how to desolder is very useful, and not just for fixing soldering mistakes. For example, desoldering will let you exchange a broken component in a circuit for a fresh one—or you can desolder a component to reuse it in another circuit. In this project, I'll show you how to desolder your battery clip from the previous project.

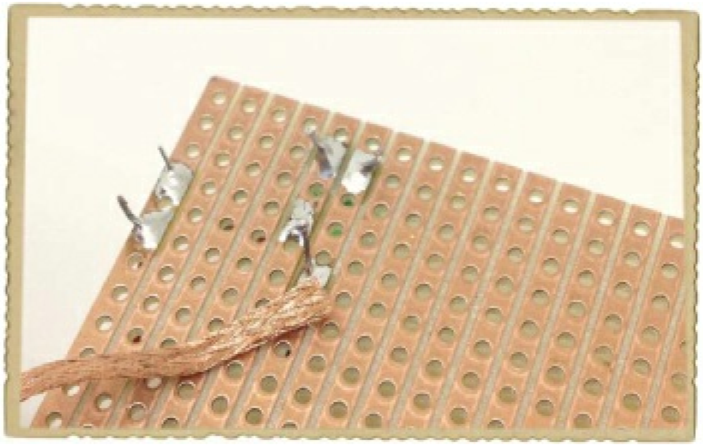
Step 1: Heat the Soldering Iron

Plug in your soldering iron and wait for it to heat. To test the temperature, touch some solder wire to the tip; the solder will melt when the iron is warm enough.

Step 2: Place the Solder Wick on the Solder Joint

Lay the end of your solder wick on top of the solder joint for one battery clip wire.

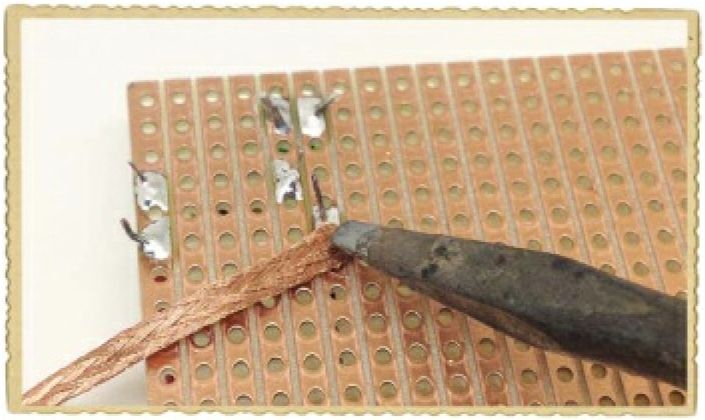


WARNING

Solder wick can get very hot when you heat it with the soldering iron, so don't hold the metal part by your fingers.

Step 3: Heat the Solder Joint and the Solder Wick

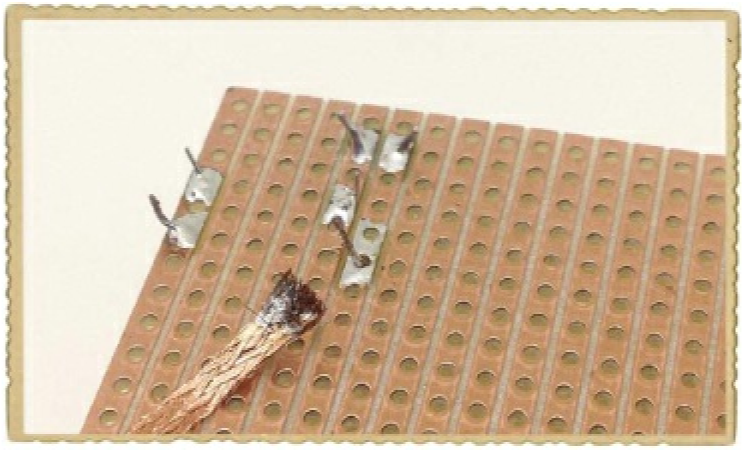
Place the tip of the heated soldering iron on top of the solder wick, directly over the solder joint you want to desolder.



After a few seconds, the solder should melt and flow onto the braid. Lift the braid from the board, together with the soldering iron.

Step 4: Trim the Used Solder Wick

Remove the braid from the joint and look at it. The braid should have solder in it.

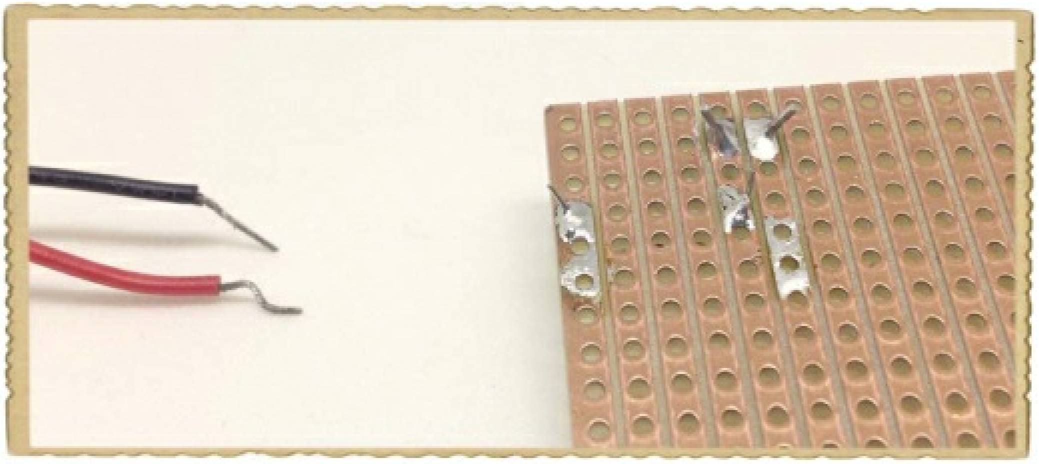


Much like a dirty cloth, this bit of wick is too dirty to use anymore. Use your wire cutter to cut off the piece that has solder inside.

Now, inspect your solder joint. If there's no solder left connecting the component leg to the circuit board, then you should be able to remove the wire from the hole. If not, repeat Steps 2 and 3 with a fresh bit of solder wick, and then repeat Step 3 until you can remove the wire.

Step 5: Remove the Other Battery Clip Wire

Repeat Steps 2 to 4 for the other battery clip wire, and you should be able to completely remove the battery clip from the circuit board. At this point, the copper side of your circuit board should look something like this:



TRY IT OUT: SOLDER MORE STUFF!

Are you itching to get some extra soldering practice? One fun way to practice is to buy and build electronics *kits*, which include components and a circuit board that you can solder. You can also find circuit diagrams online, buy the necessary components, and solder them on a prototyping board, just as you did in this chapter.

Here are some online stores that sell both kits and components:

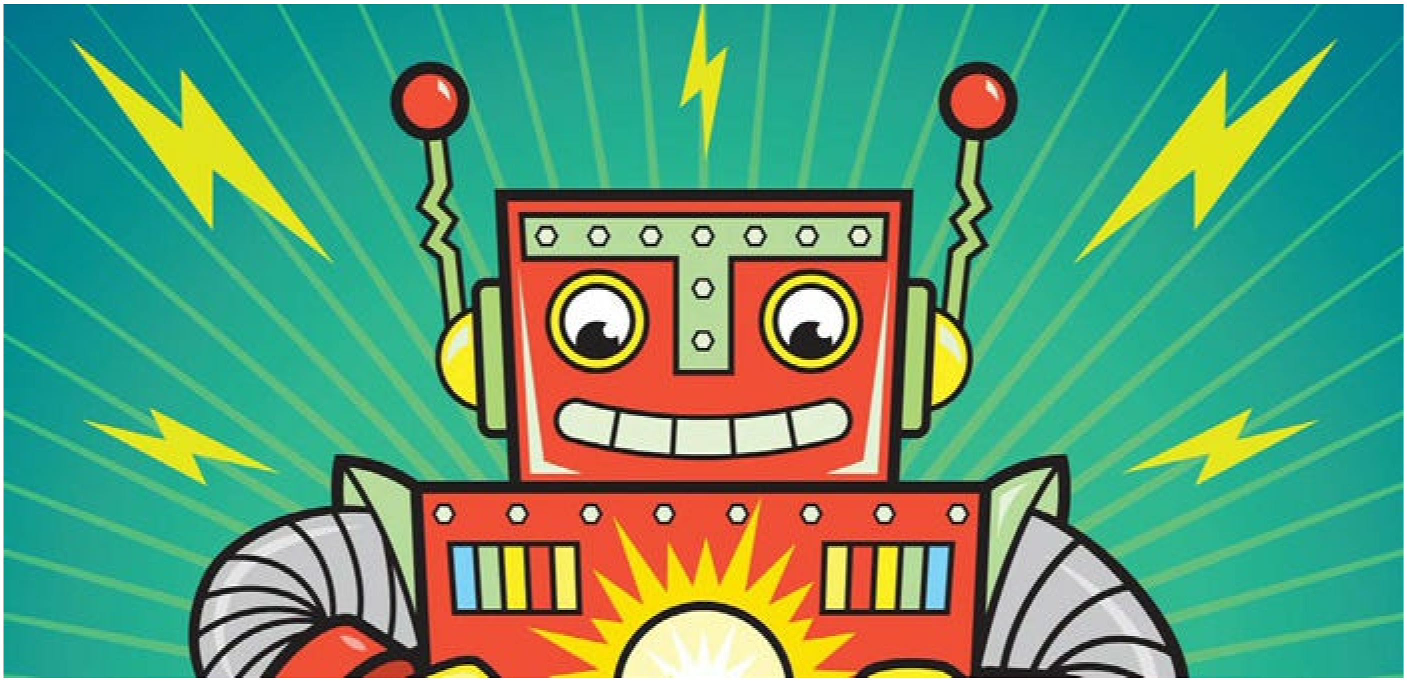
WHAT’S NEXT?

In this chapter, you learned a very useful skill: soldering. This means you can make permanent circuits for your projects without worrying that they’ll fall apart. And with a little practice at desoldering, you can take projects apart on purpose, too.

In Chapter 7, I’ll introduce you to the transistor, the photoresistor, and the potentiometer. These are some really exciting components that you can use to make your circuit come alive and respond to its surroundings. For example, I’ll show you how to create a circuit that tells you when the sun rises in the morning!



7

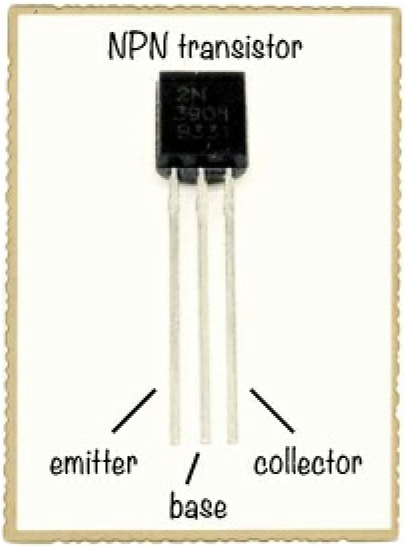
CONTROLLING THINGS WITH ELECTRICITY

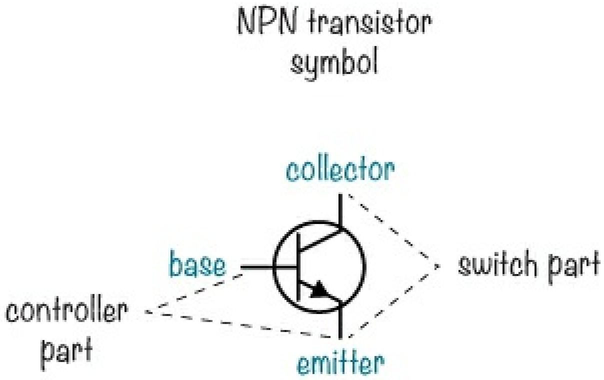
Electronic components let you build smart things, like a lamp that turns on when it gets dark or a door that opens automatically when you approach it. In this chapter, you'll learn about a new component that will help you build such smart objects: the transistor.

The previous chapter showed you how to solder, and this chapter's projects—a touch sensor and an alarm that wakes you up when the sun rises—will give you more chances to practice your soldering skills. All you need for each project is the transistor and a few additional components.

MEET THE TRANSISTOR

The *transistor* is the most important component in electronics, and if you've ever heard experienced hardware enthusiasts talk about it, you've probably noticed that they tend to use a lot of difficult words. But the transistor really isn't hard to understand; in fact, you've already used something that acts a lot like one! Do you remember the relay you learned about in Chapter 5? The transistor is similar to the relay in many ways: it's like a switch that you can open and close with electricity.





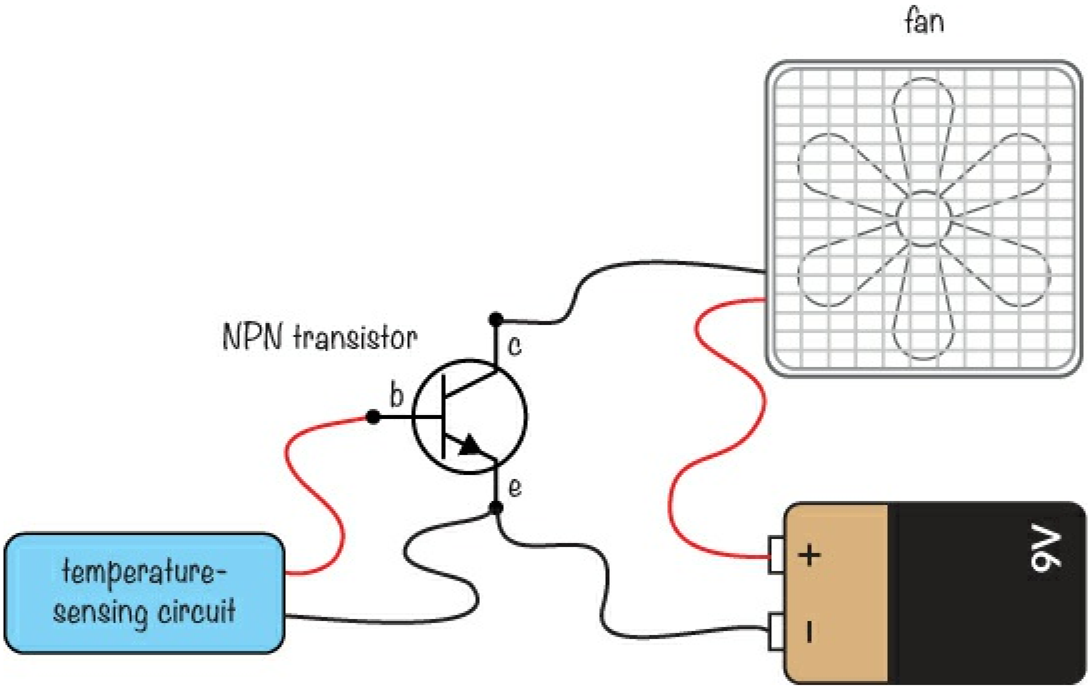
A transistor has three legs. In a standard *NPN transistor*, the three legs are called *emitter*, *base*, and *collector*. You'll often see these labeled *e*, *b*, and *c* in circuit diagrams. You turn the transistor on and off—that is, you open and close the switch—with the base and emitter legs, and you connect a circuit that you want to control between the collector and the emitter legs.

When you look at our example transistor with the flat side facing you, the leftmost leg is the emitter, the middle leg is the base, and the rightmost leg is the collector. But this is not the case for all transistors, so always check the datasheet for your transistor to find out which leg is which.

Why Use a Transistor?

If a transistor acts like a switch, then you might be wondering when you'd want to use a transistor instead of a switch in the first place. Well, think about a fan: if it's hot in your room and you want to turn a fan on, you have to manually flip a switch. But if that fan were part of the right kind of circuit with a transistor and a few other components, you could make the fan turn on automatically when the temperature in your room rises above 75 degrees Fahrenheit. To make this happen, you'd need one circuit that could sense temperature and another circuit that could turn on a fan.

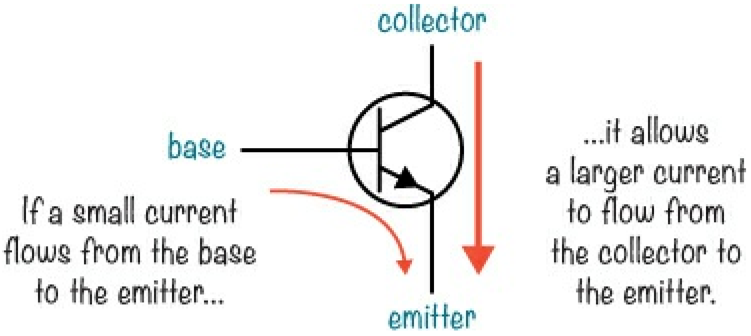
Now, imagine a temperature-sensing circuit that gives a voltage when the temperature is above 75 degrees and no voltage if the temperature is below. If you were to connect one wire from the fan to an NPN transistor's collector, connect the fan's other wire to the positive terminal of the battery, and connect the transistor's emitter to the battery's negative terminal, the transistor would control when the fan is switched on.



Then, you could connect the output of the temperature-sensing circuit to the controlling part of the transistor—that is, the base and emitter. In such a circuit, the fan would turn on when the temperature rises above 75 degrees and turn off when the temperature is less. Let's look at how the transistor's "switch" closes in the first place.

How the Transistor Works

When a little bit of current flows from the base of a transistor to the emitter, the transistor "closes the switch" so that current can also flow from the collector to the emitter.



collector
base
If a small current flows from the base to the emitter...
...it allows a larger current to flow from the collector to the emitter.
emitter

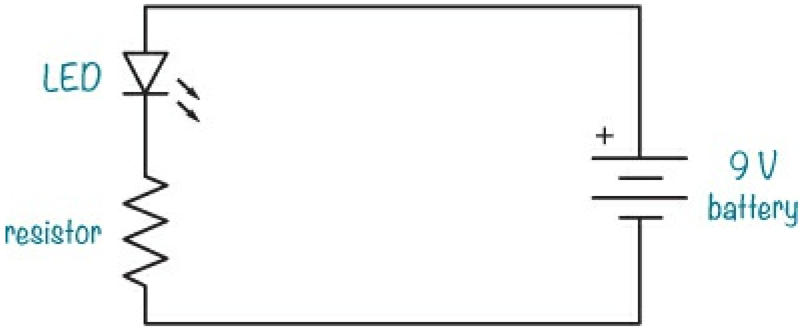
In Chapter 1, I explained that voltage pushes current through a circuit. For current to flow from the base to the emitter, there needs to be a voltage to push that current. When the current flows from the base to the emitter, this opens a path for the current to flow between the collector and the emitter. You can also control the amount of current that flows between the collector and the emitter by changing the current flowing from the base to the emitter.

The specific type of transistor we're talking about is an *NPN-type bipolar junction transistor*. This long name describes the materials inside the transistor. There's some advanced chemistry and physics behind how it works, but you don't need to know all of that to build cool circuits with a transistor—you just need to know what the transistor does.

The important thing to remember for now is that different transistor types exist. For each transistor project in this book, just use the type I describe in the Shopping List sections, and your circuits will work just fine. And of course, when you build circuits outside this book, be sure to use the type of transistor specified in the circuit diagram.

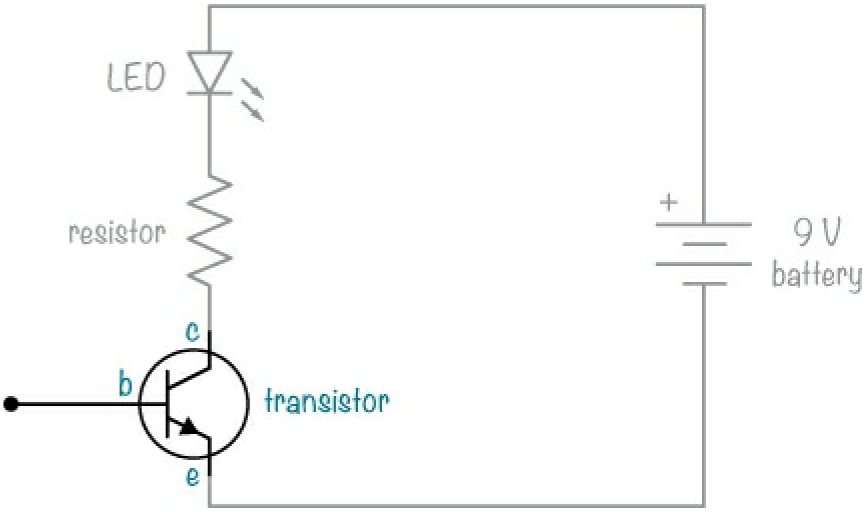
Controlling an LED with a Transistor

Other projects in this book have used this simple LED circuit, complete with a resistor and a battery:



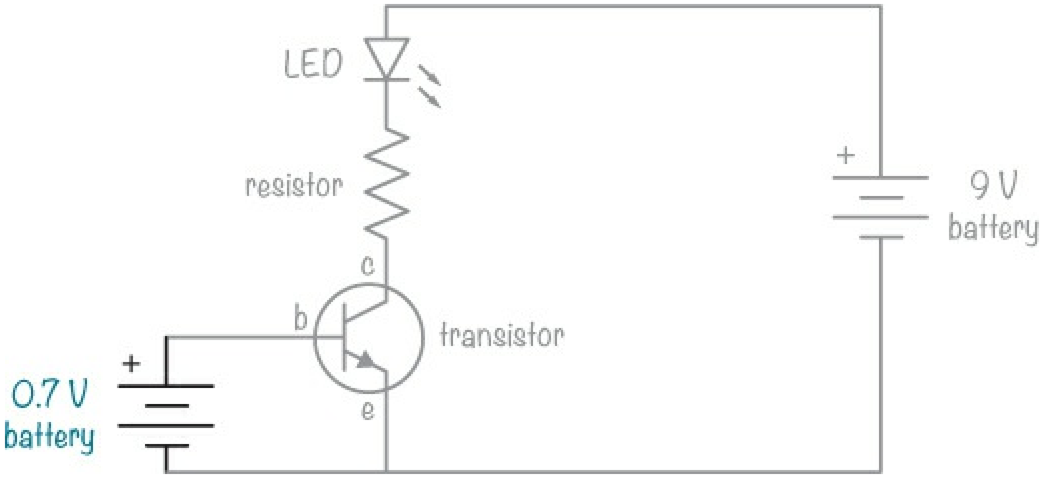
LED
resistor
+
9 V battery

Based on what you've learned so far, what do you think would happen if you put a transistor between the resistor and the battery's negative terminal?



With no voltage on the transistor's base, or the controlling pin, no current flows from the base to the emitter. That means no current can flow between the collector and the emitter either, and the LED would be off.

But if you were to apply a small voltage to the base—for example, by connecting a small battery to it—the transistor would let current flow from the collector to the emitter, and the LED would glow. A transistor that allows current to pass is considered *on*; a transistor that doesn't allow current to pass is considered *off*. The amount of voltage needed to turn an NPN transistor on is about 0.7 V, so a circuit like this one would allow current to pass through properly to light the LED:



Normally, you wouldn't connect a battery to the base. Instead, you'd connect another circuit that you want to control the transistor, like a light-sensing circuit that gives a small voltage when it detects light. A circuit like that would turn the transistor on and off according to the light.

You can build a circuit like this to control LEDs and other components. In the next project, I'll show you how to use a transistor to turn an LED on with the touch of your finger.

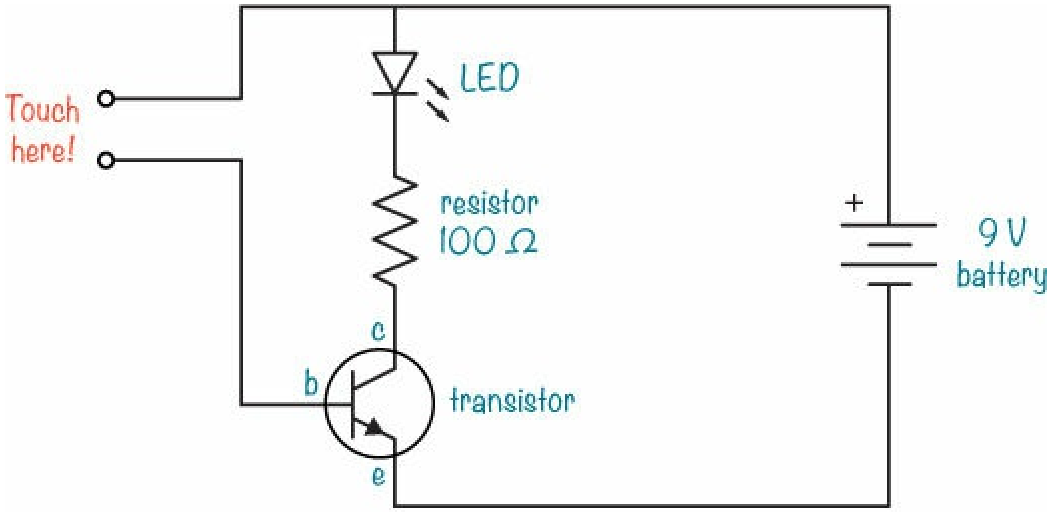
PROJECT #14: BUILD A CIRCUIT THAT SENSES TOUCH

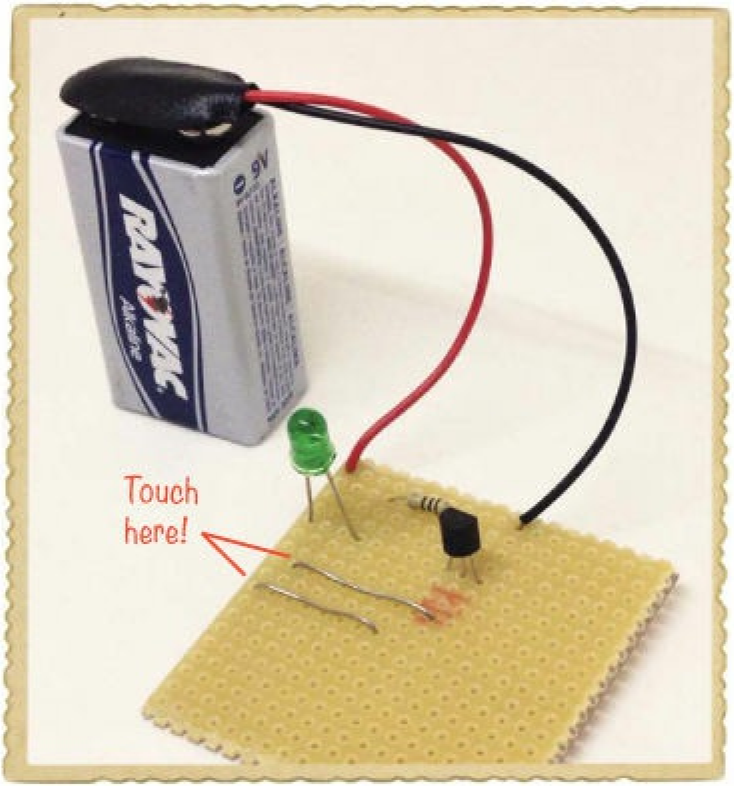
Did you know that your finger can act as a resistor? Your finger has a resistance of a few megohms (MΩ), and that's a lot! This resistance varies, though. If your finger is sweaty, for example, the resistance decreases.

In this project, you'll use your finger as a resistor to complete a circuit that turns on an LED, creating a touch sensor. A *sensor* is a component that can measure things in the world around you, like light or temperature. In many cases, a sensor is a resistor that changes its value based on light level, temperature, or some other physical quantity you might want to know about.

If you connect a resistor of a few megohms between the positive side of your battery and the base of the transistor in this circuit, a small current should flow through the base of the transistor to the emitter. This current should be large enough to turn the transistor on and let a little bit of current flow from collector to emitter.

This circuit has a transistor, a resistor, an LED, and a battery, just like the one in the previous section. This time, instead of a separate battery, you'll connect the 9 V battery to the transistor's base with your finger through a kind of touch pad. The touch pad will just be two exposed wires placed close enough together that you can touch both with your finger at the same time.





Notice that instead of a 330 Ω resistor with the LED that you used before, this circuit uses a 100 Ω resistor. Often the resistance in your finger is so high that the transistor won't turn on fully. With a smaller resistor, you should still get a bright LED, even if your finger's resistance is a bit high.

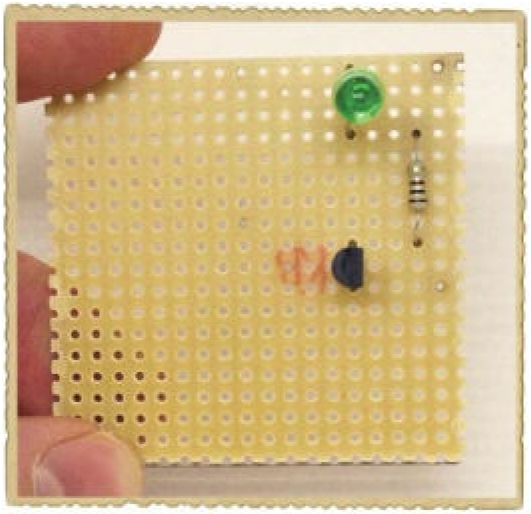
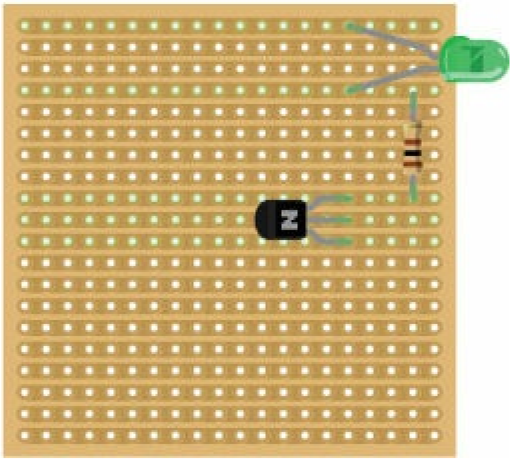
Step 1: Place Components on the Prototyping Board

Place the LED, the resistor, and the transistor into the prototyping board as shown. Make sure a copper strip connects the resistor to (1) the LED's cathode leg and (2) the transistor's collector leg. Bend the legs on the copper side of the board so that the components stay in place.



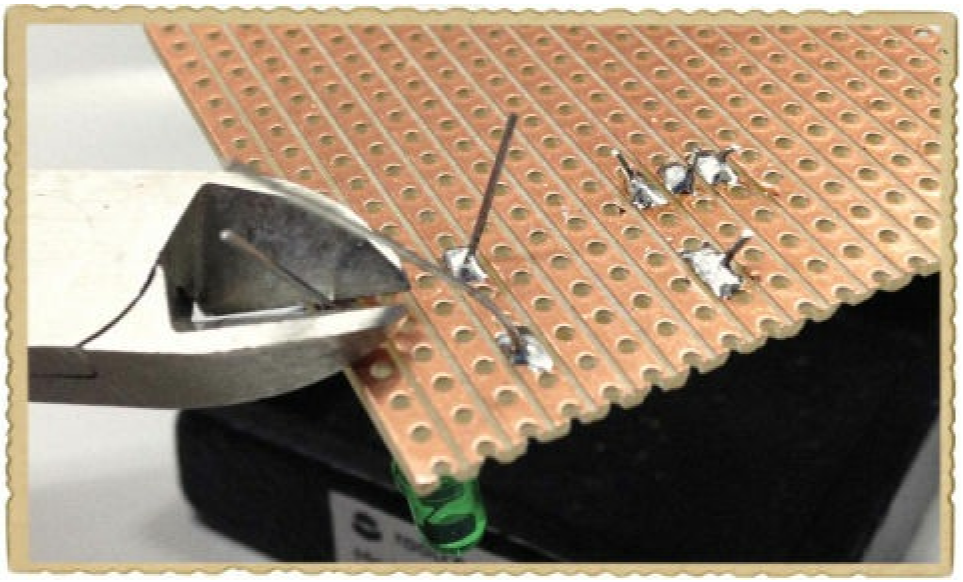


Step 2: Check Your Component Placement

Before soldering, look on the copper side of the board and double-check that your components are placed according to the directions in Step 1. Inspect the orientation of the LED and the transistor specifically, as these must be soldered the correct way for your circuit to work.

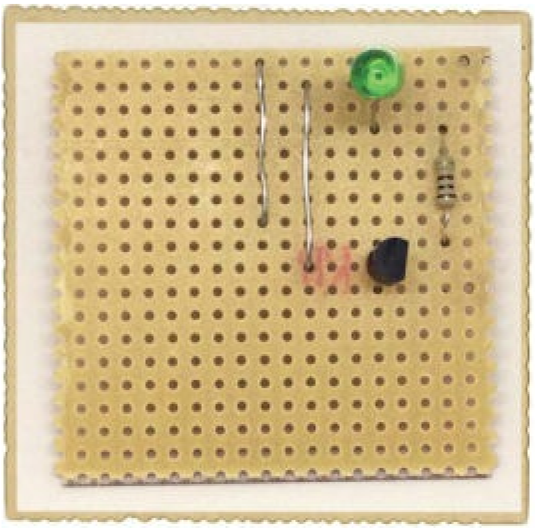
Step 3: Solder the Components and Trim Excess Legs

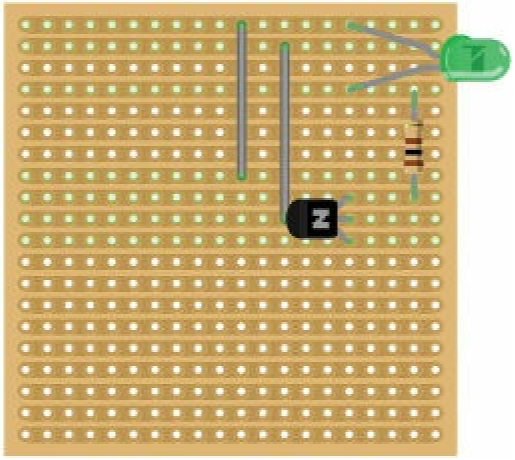
Solder the components to the board, just as you learned in “How to Solder” on page 112, and then use your wire cutters to cut off the excess legs. Wear your safety goggles and take care to turn the board away from yourself in case bits of wire fly off as you cut.



Step 4: Solder the Touch Pad

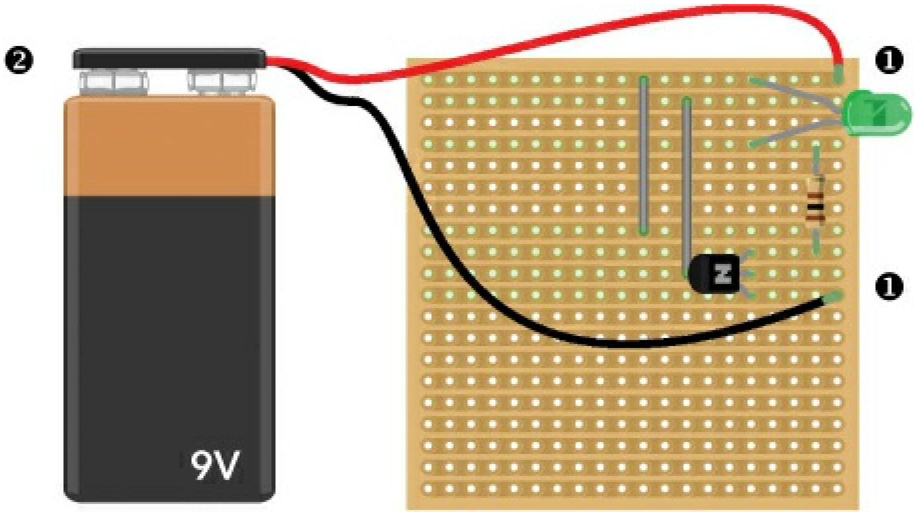
Next, solder the two pieces of exposed wire. Connect one wire to the LED’s anode leg, with the other end on an empty copper strip. Connect the other wire to the base of the transistor, also with the other end on an empty copper strip. Solder them in such a way that you can touch both with your finger.





Step 5: Power It Up!

Now you need power! To finish the job, first solder the battery clip to the board, placing the red and black wires as shown at ❶. After you've soldered the battery clip, plug the battery into it at ❷.



This touch-sensor circuit is ready to test!

Step 6: Test the Sensor

Touch both exposed wires at the same time with your finger. Your LED should light up. If you can't see the LED glow, try turning out the light in your room; the LED might just be dim. If you still can't see the LED glowing, dip your finger in water and try again, as wetting your finger reduces its resistance.

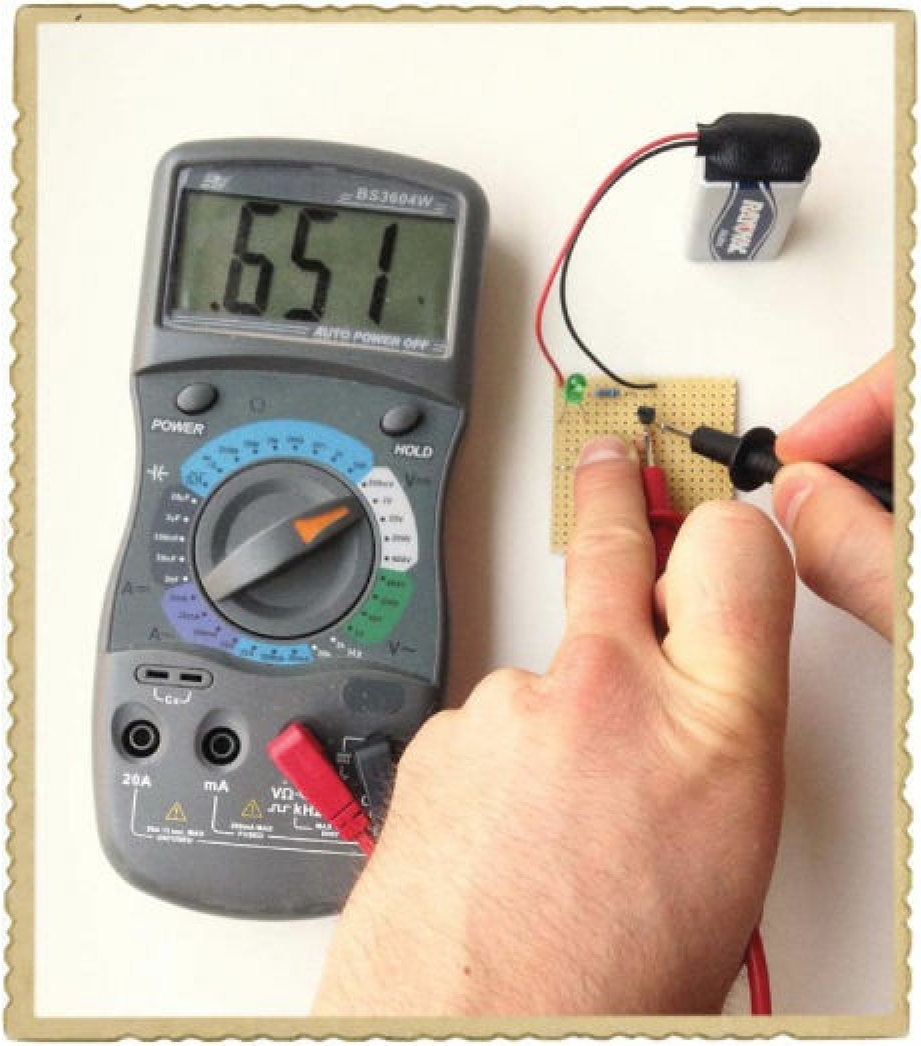
WARNING

Use only a finger to touch the exposed wires. If you use something with a very low resistance, like a piece of wire, you can destroy the transistor.

Step 7: What If the Touch Sensor Doesn't Work?

If nothing happens when you touch the wires, start by checking the direction of your LED and your transistor. It's very common to mix up the pins of these components, so go back to Step 1 and make sure they're connected on the prototyping board's copper strips, according to the images.

If the LED and the transistor are connected correctly, you can use your multimeter to measure the voltage between the base and the emitter of the transistor on the controller side, without touching the touch pad. Set your multimeter to a DC voltage range—20 V DC, for example—and then connect one multimeter cable to the base leg and one to the emitter leg, as shown. The multimeter should show a value around 0 V. Now, place your finger on the touch pad and measure the voltage again. The multimeter should show around 0.7 V.



If the controller side of the transistor is fine, check the switch side. Measure the voltage from one leg of the LED to the other, without touching the touch pad. You should see 0 V on the multimeter. Place your finger on the touch pad and measure again; now it should be around 1.7 to 2 V.

If either multimeter measurement gives you incorrect values, then check your connections against the circuit diagram one more time, paying extra attention to the two exposed wires. Finally, check your solder joints, look for stray pieces of wire or solder bridging the gap between copper strips, and fix any bad connections you find.

TRY IT OUT: CAN THE TOUCH SENSOR DETECT

DIFFERENT TOUCHES?

Try touching the two exposed wires lightly and note the brightness of the LED. Now, try pressing really hard. Can you see any difference? Have a friend repeat the experiment. Was the LED’s brightness when your friend touched the wires different from when you touched them? If so, that means your friend’s finger has a different resistance!

When you press harder, the connection between the wires and your finger improves, reducing the resistance so it’s easier for the current to flow.

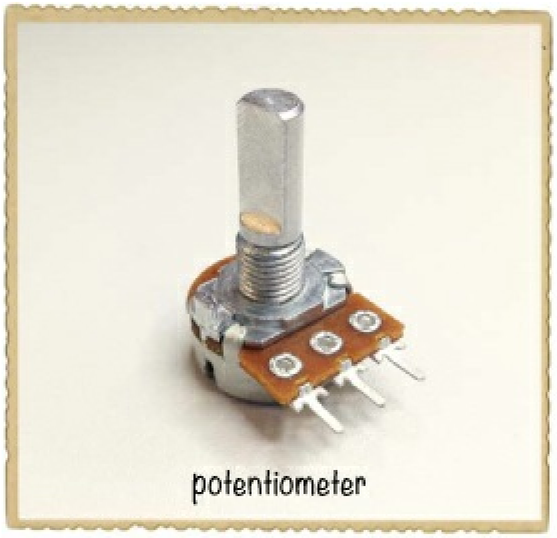
Here’s another fun thing to try with a friend: Touch one of the wires yourself and have your friend touch the other. Then, hold your friend’s free hand with your free hand. Can you see the LED light up? Now, the current goes from the battery through both of your bodies and into the transistor. But don’t worry—the current is so low that it’s not dangerous and you won’t feel anything.

RESISTORS THAT CAN CHANGE VALUE

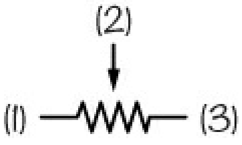
Up until now, you’ve used only resistors that have a fixed resistance, but you can also find resistors that have a *variable* resistance value, which means the resistance can change. For example, some resistors change value when you turn a knob, while others change their value based on the temperature or the amount of light. This section introduces two variable resistors: the potentiometer and the photoresistor.

Meet the Potentiometer

In Chapter 4, you learned about the standard resistor, a component that has a certain, unchangeable resistance. The *potentiometer* is also a resistor, but it has a variable resistance, and it’s often used to control things such as the volume of a speaker. (You know the volume control on the radio? That’s often a potentiometer.) A potentiometer usually has three pins and a shaft you can rotate to change the resistance.



potentiometer



potentiometer symbol

The potentiometer symbol represents how the potentiometer works and the functions of the three pins. The resistance between pins 1 and 3 is a fixed resistance of a certain value. This value is equal to the value listed when you buy the potentiometer. If you have a 10 kΩ potentiometer, for example, then the resistance between pins 1 and 3 will be 10 kΩ.

Pin 2 is called the *wiper*. It connects to the resistor somewhere between pins 1 and 3. You can change the position of the wiper by turning the shaft of the potentiometer. If you turn the shaft so that the wiper comes closer to pin 1, the resistance between pin 1 and the wiper gets smaller, but the resistance between pin 3 and the wiper becomes larger.

Meet the Photoresistor

A *photoresistor* is another variable resistor. *Photo* means *light*, and this component's resistance changes with the amount of light shining on the top of it. Sometimes this component is also called a *light-dependent resistor (LDR)* because its value depends on light.

Photoresistors are made of a material with some special properties. In the dark, this material has a high resistance, but when light shines on it, the light energizes electrons that would otherwise be bound in the material. Those energized electrons can flow freely through the material, reducing the resistance. The more light that shines on the photoresistor, the less resistance it has.

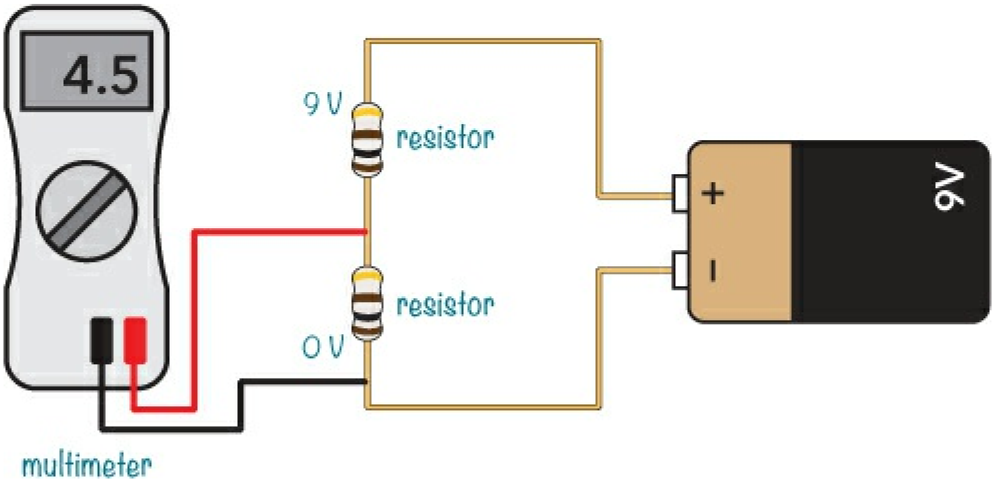
DIVIDING A VOLTAGE WITH RESISTORS

When the resistance of a photoresistor or potentiometer in a circuit changes, the voltage and/or the current must change, too, according to Ohm's law. (See "Introducing Ohm's Law" on page 73 if you want to walk through the math again.) If you make your variable resistor part of a circuit called a *voltage divider*, you'll get a voltage output that varies with the resistance. You can use that changing voltage to control another component in your circuit. Knowing how to identify voltage dividers can also help you understand how other circuits work.

What Does a Voltage Divider Look Like?

If you connect two resistors with the same resistance to each other and to the positive and negative sides of a battery, the voltage where your resistors meet will be half the battery voltage—for example, 4.5 V if you use a 9 V battery. This circuit is called a *voltage divider*.

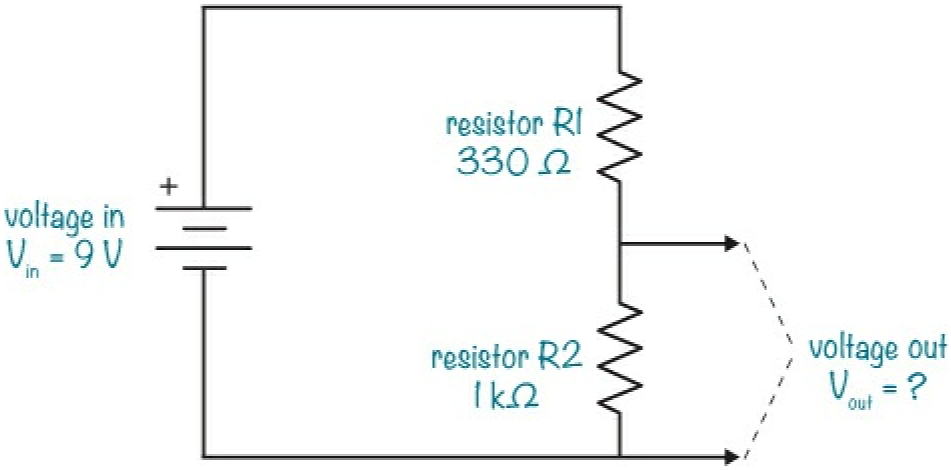


4.5
9 V
resistor
resistor
0 V
multimeter
+
-
9V

If you use unequal resistors instead of identical ones, you can use a voltage divider to get voltages anywhere from 0 V up to your battery voltage. You just need to do a little bit of math.

Calculating the Voltage from a Voltage Divider

Let's say you have the following circuit. What's the output voltage (V_{out}) from this circuit?



resistor R1
330 Ω
+
voltage in
V_{in} = 9 V
resistor R2
1 kΩ
voltage out
V_{out} = ?

To find V_{out}, enter the values from the circuit into the following formula:

$$V_{out} = V_{in} \times \frac{\mathrm{R2}}{\mathrm{R1} + \mathrm{R2}}$$

$$V_{out} = 9\ \mathrm{V} \times \frac{1000\ \Omega}{330\ \Omega + 1000\ \Omega}$$

$$V_{out} = 9\ \mathrm{V} \times 0.752$$

$$V_{out} = 6.77\ \mathrm{V}$$

In this example, the output voltage is 6.77 V—roughly two-thirds of the 9 V input from the battery.

How a Voltage Divider Can Help Measure Light

In the beginning of this section, I mentioned that the voltage divider can help you measure light, but how do you do that? Just replace one resistor in the voltage divider with a photoresistor, and you'll get a circuit that outputs a voltage based on the amount of light shining on it. And by adjusting the other resistor in the voltage divider, you can set the circuit to give a certain voltage at a certain light level. Connect the output of this circuit to a transistor that controls a buzzer, and you've got yourself a light-controlled alarm!

PROJECT #15: BUILD A SUNRISE WAKE-UP ALARM

It's time to combine all the concepts you've learned in this chapter into one fun project: a sunrise wake-up alarm!

This circuit starts an alarm when it detects light. After you build it, you can place it in your window (between any curtains and the glass) when you go to bed. When the sun rises, your circuit should detect the light and start the alarm, leaving you with no choice but to get up and turn it off.

This project uses a transistor, a photoresistor, a potentiometer, and a buzzer. The photoresistor and the potentiometer create the voltage divider, and the output of the voltage divider is connected to the base of the transistor. The amount of light the photoresistor detects will determine whether the transistor is on or off. If the transistor is on, current should flow through the buzzer, and the buzzer should make sound. The potentiometer is there to set how much light the circuit needs before the alarm triggers.

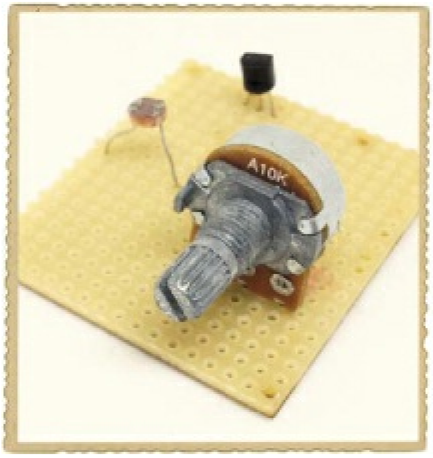
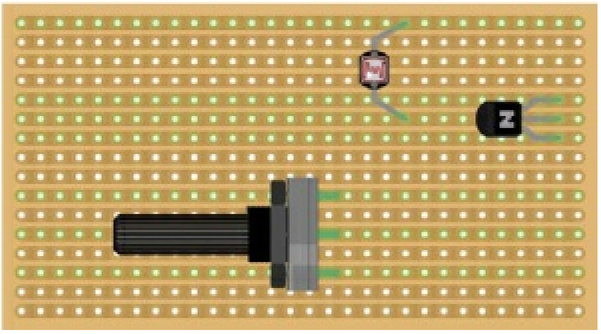
The top copper strip will be the positive battery connection, and the bottom copper strip will be the negative one.



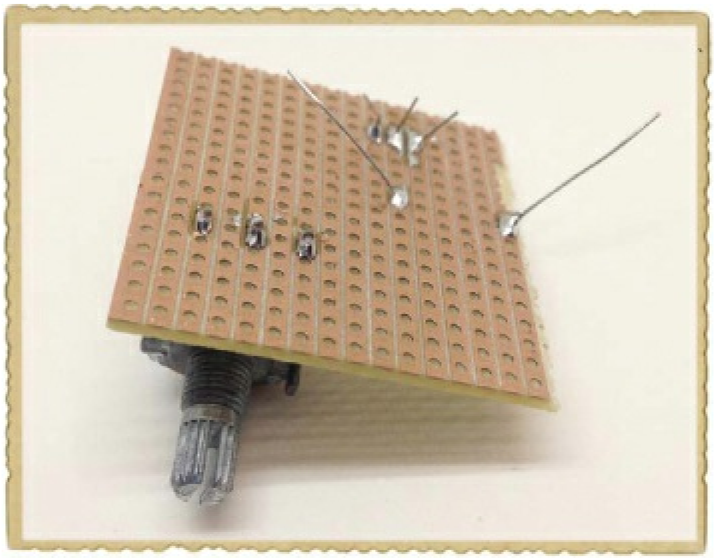


The diagram shows the components and the copper tracks underneath, while the photo shows what your board should look like in real life.

Step 2: Solder the Components and Trim the Legs

Check the placement of the components closely against the circuit diagram at the beginning of the project and the illustration in Step 1. Make sure the transistor is connected the right way and that the photoresistor has one leg on the same copper row as the center pin of the transistor. Each of the other pins, including each pin on the potentiometer, should be on a row of its own.

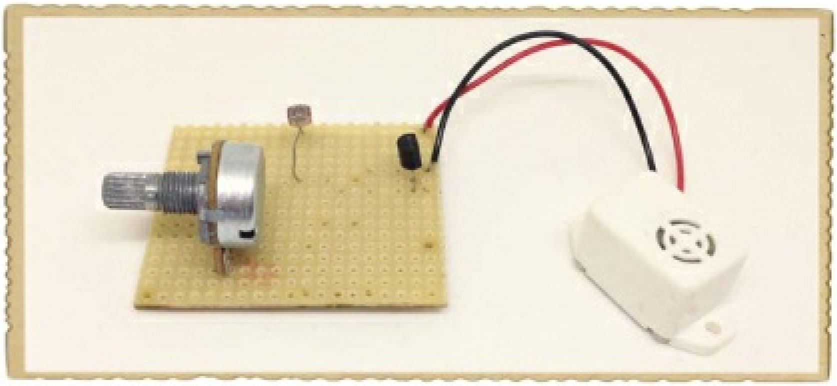
When you're sure your components are placed correctly, solder the pins to the board.

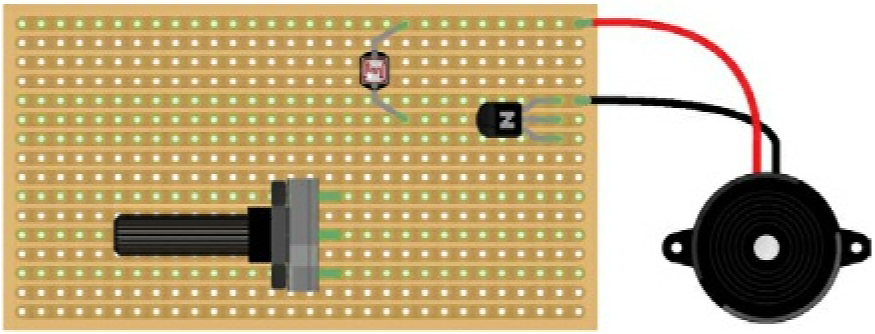


When you're finished soldering, cut off the excess legs.

Step 3: Add the Buzzer to the Board

Next, solder the buzzer to the board. Place the buzzer's positive (red) lead through a hole in the top copper row together with the photoresistor. Then place its negative (black) lead in the same row as the collector leg of the transistor. Solder both now.





Step 4: Make the Remaining Connections with Wires

If you compare your circuit to the circuit diagram, you'll see that you're still lacking a few connections to make the circuit complete. The circuit board is missing the battery clip, but to work when powered, the circuit also needs the following connections:

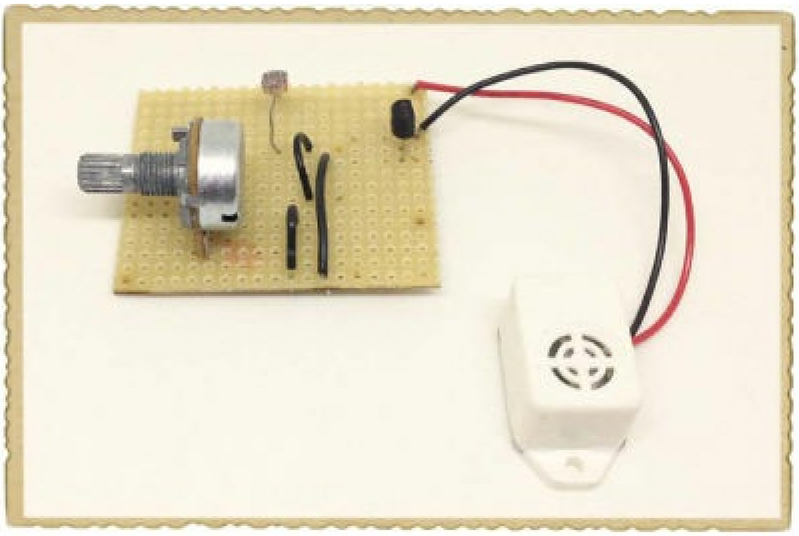
- The base of the transistor needs to connect to the upper potentiometer pin.
- The middle potentiometer pin needs to connect to the negative battery terminal.
- The emitter of the transistor needs to connect to the negative battery terminal.

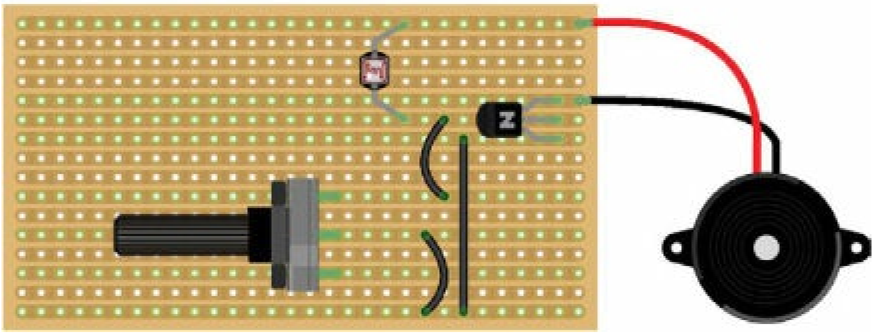
To create these remaining connections, you can solder three small wires like this one to the circuit board as jumper wires:

Cut a piece of wire about 2 inches long and strip about 0.3 inches of insulation from both ends. Removing insulation from shorter wires can be tricky, so if you're struggling with this step, use a longer wire instead. When you know what length of wire you can strip most easily, prepare two more wires. Then, solder the three wires to make the remaining connections.

Run one wire from the base of the transistor to the upper pin of the potentiometer. Next, connect the one wire from the middle pin of the potentiometer to an empty row at the bottom of the board.

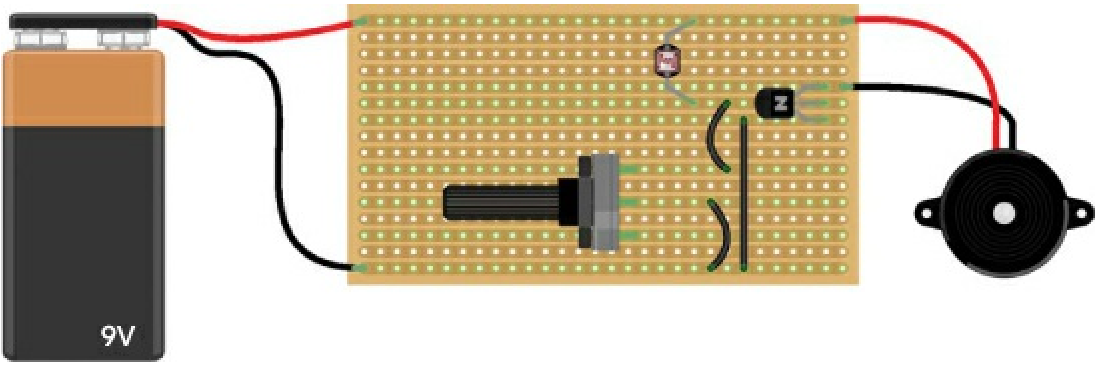
Finally, run one wire from the same row of the prototyping board, where you just connected the previous wire, to the row connected to the emitter of the transistor. Check that your wires match the illustration and then solder them to the board.





Step 5: Add the Battery Clip to the Board

All that's missing is the battery clip. Solder the battery clip's red wire to the top copper row of the board. The top row should also contain the photoresistor leg and the buzzer's red wire. Solder the battery clip's black wire to the bottom row.



Step 6: Set a Wake-Up Call

Plug in the battery and put the circuit in an area that has the amount of light that you want to activate your alarm. Turn the shaft of the potentiometer until you find a position where the sound turns on and off with just a little nudge back and forth on the shaft. Now, turn the shaft just enough to make the sound turn on all the way. Place your hand over the photoresistor to block the light, and the sound should stop. Remove your hand, and the sound should turn on again.

Remove the battery from the circuit and wait until you're about to go to bed. With the lights off, place the circuit in your window, connect the battery, and go to sleep. When the sun rises and the light outside is as bright as the light you used to set your potentiometer, you'll be awakened by your very own sunrise alarm!

Step 7: What If There's No Sound?

Go through the circuit component by component, preferably with a friend. Check that your prototyping board has every connection shown in the circuit diagram. Check that there are no *short circuits*, too. A short circuit is an unintentional connection between something in a circuit. For example, make sure solder joints that are close to each other aren't actually touching.

If all looks good, use your multimeter to measure the voltage between the base and the emitter of the transistor. First, turn the shaft of your potentiometer all the way to one side, measure the voltage, and write it down. Then, turn the potentiometer all the way to the other side and measure the voltage again. Your multimeter should show 0 V on one side and around 0.7 V on the other side. If it doesn't, check your connections again.

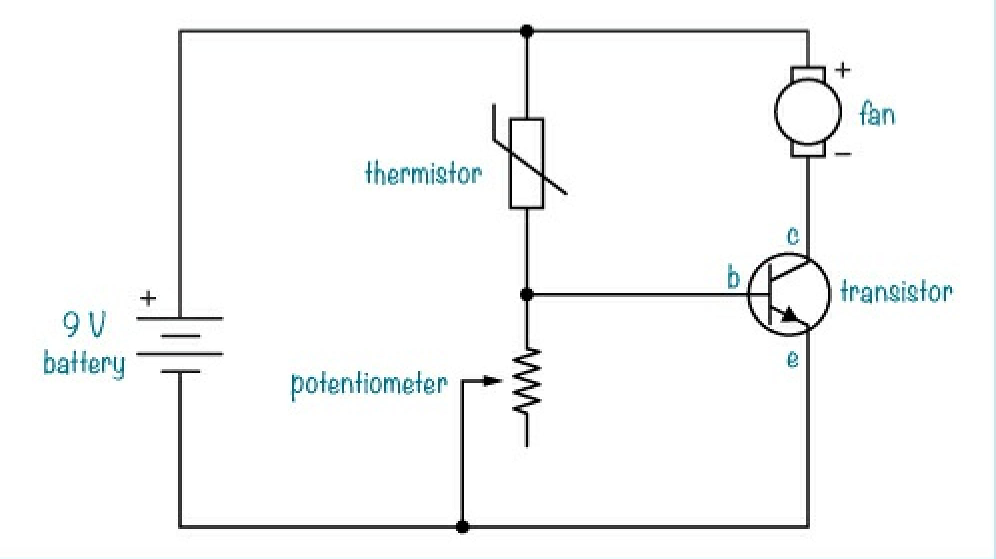
If you're still not sure what's wrong, turn the potentiometer all the way to one side and measure the voltage between the red and black buzzer wires. Then, turn the potentiometer all the way to the other side and measure again. You should get 0 V on one side and about 8 to 9 V on the other.

If all else fails, check your solder joints and redo any that look like the connections might not be complete. And if you've built your circuit flawlessly, you may just have some broken components. Try breadboarding the project with new components, and if that works, solder those components instead.

TRY IT OUT: TEMPERATURE-CONTROLLED FAN

You can use the circuit you built in Project #15 for other things as well. For example, if you exchange the photoresistor for a *thermistor*, a resistor that changes resistance value based on temperature, the circuit will respond to temperature instead of light.

You can also change what's being controlled. Instead of an LED and resistor, try putting in a fan. Now you have a temperature-controlled fan! The circuit diagram looks like this:



You'll need the following parts:

- **A standard 9 V battery** to power the circuit.
- **A 9 V battery clip** (Jameco #11280, Bitsbox #BAT033) to connect the battery to the circuit.
- **A circuit board** (Jameco #2191488, Bitsbox #HW005) with copper strips.
- **Insulated wire** (Jameco #36792, Bitsbox #W106BK), about 10 inches in length. Standard hookup wire works fine.
- **A 10 kΩ thermistor** (Jameco #207037, Bitsbox #ST021)
- **A 10 kΩ potentiometer** (Jameco #2118791, Bitsbox #VR004)
- **A transistor PN2222A** (Jameco #178511, Bitsbox #QD101)
- **A 12 V DC fan** (Jameco #1708465, Bitsbox #AF002)

For this circuit, I've specified a different transistor. Different transistors can handle different amounts of current. A fan often draws much more current than the LED, so I've listed a transistor that can handle more current than the one you used previously.

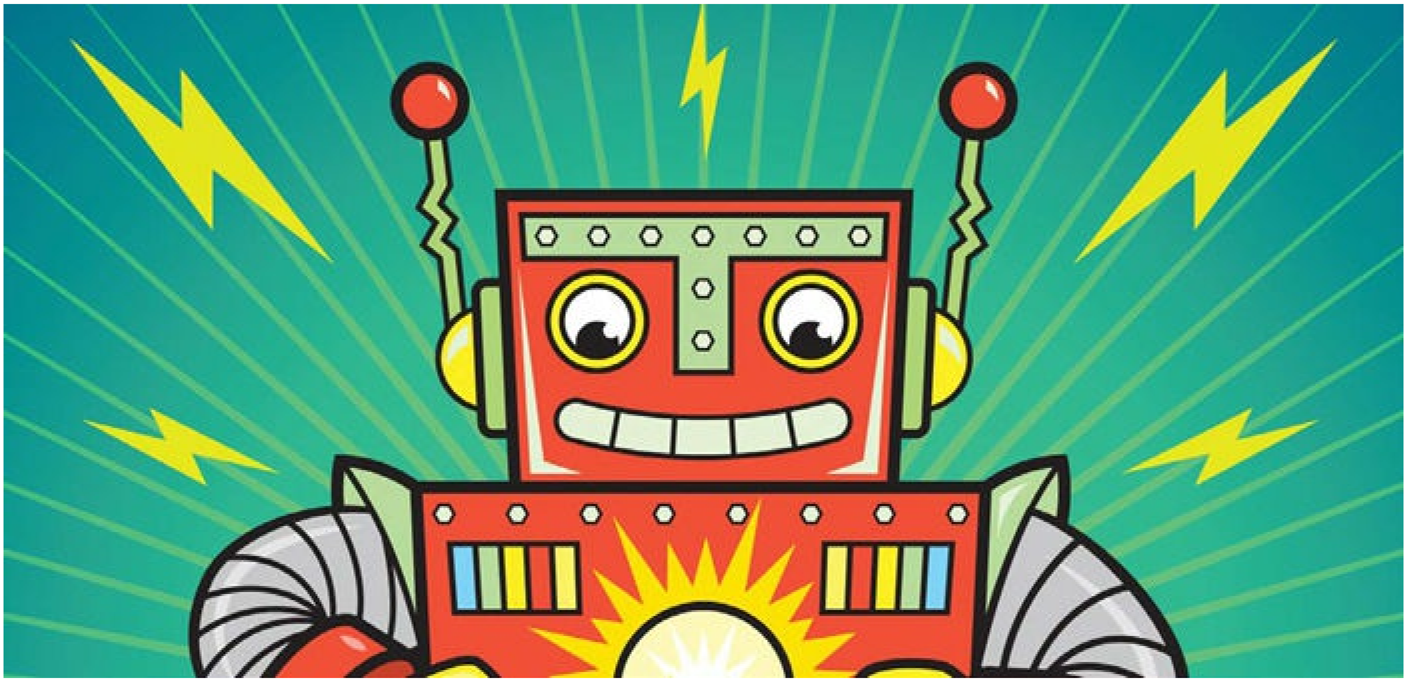
To test the circuit, first use an ice cube to cool down the thermistor and then warm it up with your fingers to see the fan come on.

WHAT'S NEXT?

In this chapter, you learned how the most important component in electronics—the transistor—works. You also learned about the potentiometer and the photoresistor, and you combined these to build a sunrise wake-up alarm.

Now you've met almost all of the most common components used in electronics! And you've gotten some practice with soldering. In the following chapters, you're going to build circuits on a breadboard again because it's much easier to fix mistakes and reuse your components. If you want to make a permanent version of any of the circuits, just refer back to Chapter 6 on how to solder.

In Chapter 8, you'll learn about *integrated circuits*. These are small components that contain circuits that have been shrunk down to fit on a tiny chip. These chips can be used to create the most amazing types of circuits. You'll see what I mean when you build your very own electronic instrument in Chapter 8!



8

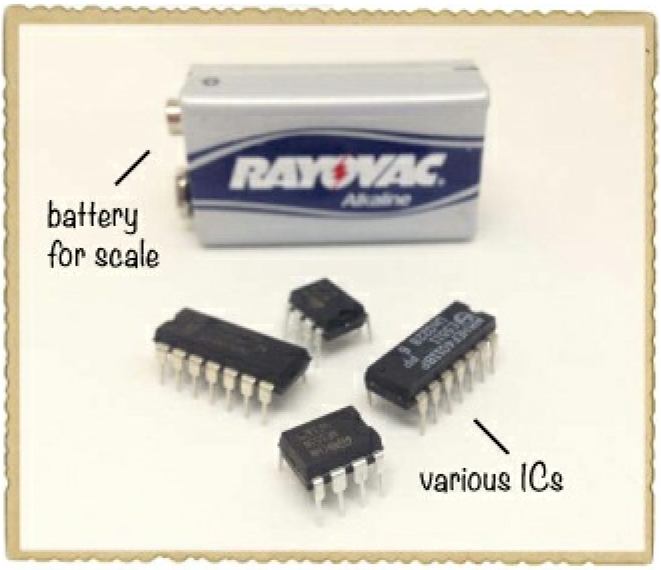
BUILDING A MUSICAL INSTRUMENT

This chapter will show you how to create sound with electronic components! Unlike other projects you've built so far, this chapter's projects use an *integrated circuit (IC)*, which is a whole circuit that's been shrunk down and packaged inside a tiny box. All sorts of circuits can be built as ICs, and most household devices are full of them. Peek inside a computer or an electronic toy, and you're sure to find a few.

To start, I'll explain what an IC is in more detail and describe how to figure out what a particular IC does. Then, you'll get some practice with ICs by building a simple circuit that makes some strange noises. At the end of the chapter, I'll show you how to build your very own electronic instrument that you can use to play music!

MEET THE INTEGRATED CIRCUIT

ICs are really small circuits that are conveniently packaged into little plastic boxes, which are often colored black. Any given IC has metal *pins* sticking out of it so you can connect other components to the circuit inside.



On the inside, an IC might contain a music player circuit, a radio circuit, a remote control circuit, or something else entirely. Because one little IC can contain a very complicated circuit, you can use ICs to make circuits with many different functions without building everything from scratch.

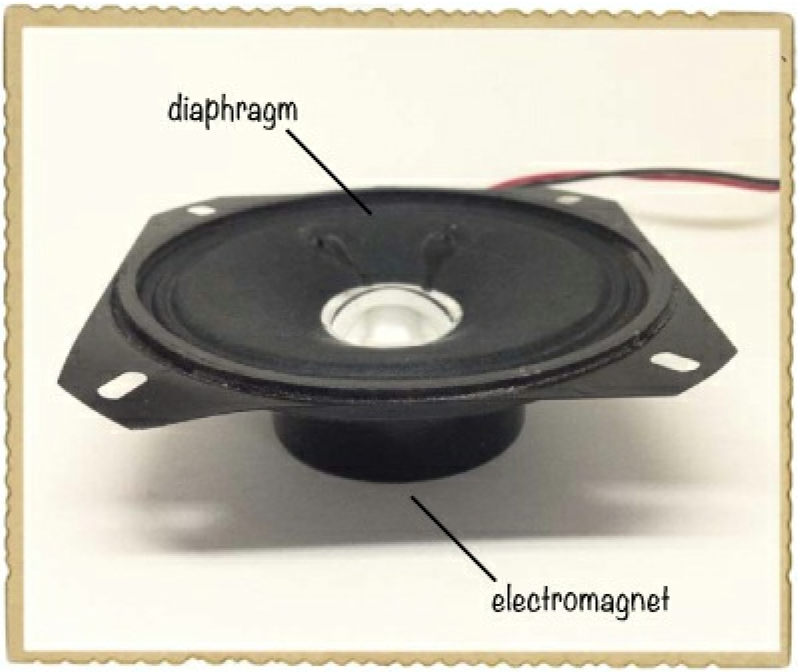
ICS AND DATASHEETS

Some ICs have only 8 pins, but other ICs have more than 100! To figure out what each pin on a specific IC does, you need to check that IC's datasheet, just as you did with the relay in "Project #11: Blink a Light!" on page 101. The datasheet tells you the function of each pin, and datasheets often show examples of how to use ICs in a circuit, too. To find a component's datasheet, try searching for the component name plus the term "datasheet" online, or check the website where you bought the component.

Datasheets often have tables with lots of numbers and technical terms, so the first time you see a datasheet for an IC, it might look very complex. But you usually don't need to read the whole datasheet. Instead, you can just look up the information you need and then go back to building your circuit.

HOW TO MAKE SOUND WITH ELECTRICITY

Sound is what you hear when air moves back and forth, or *vibrates*, really fast. Many devices that make noises, like the sound system in a car, do so with a *loudspeaker*, a component that vibrates air fast enough to make sound.



A loudspeaker has an electromagnet inside that moves a *diaphragm*, which is a surface that pushes the air in front of it. If a circuit turns the power to the loudspeaker's electromagnet on and off at, say, 1,000 times per second, then the diaphragm pushes the air back and forth 1,000 times per second. This is called the *frequency* of the sound, and frequency is measured in hertz (Hz). A frequency of 1,000 times per second, or 1,000 Hz, creates a steady beep.

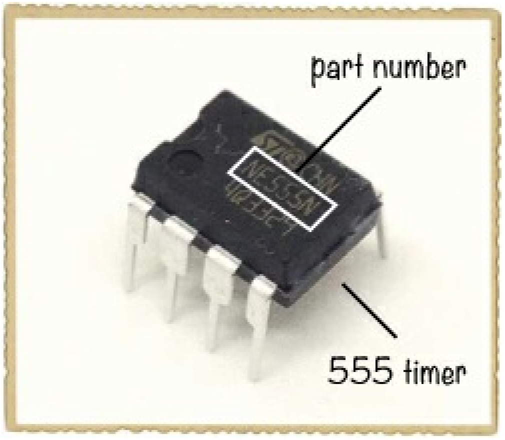
SOUNDS THAT HUMANS CAN HEAR

Humans can hear sound only from around 20 Hz up to around 20,000 Hz. In "Project #11: Blink a Light!" on page 101, you built a circuit that blinked a light about once per second. If you had connected the output of the circuit to a speaker instead, the sound from the speaker would have a frequency of 1 Hz, which would be too low to hear. Instead, you would hear clicks from the speaker as it was switched on and off.

This means that to create sound you can hear, you need to create a circuit that can turn the voltage to a speaker on and off hundreds or thousands of times per second! Fortunately, there's an IC that can help you do just that.

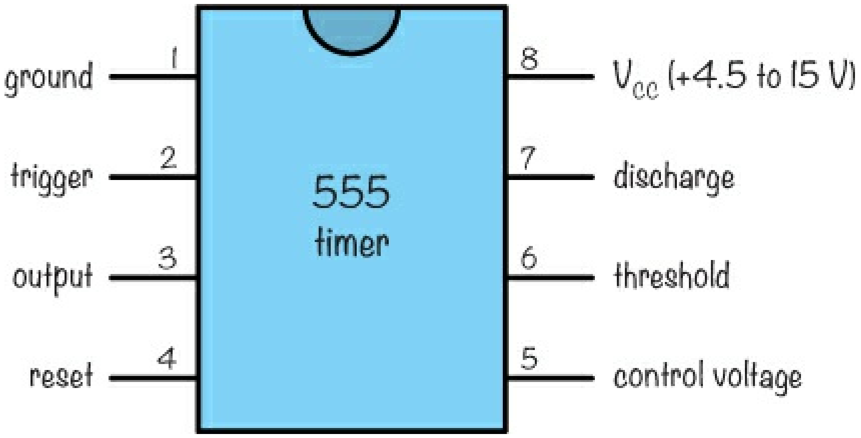
MEET THE 555 TIMER

One classic IC is the *555 timer*, which you can use to switch things rapidly on and off. For example, you could use a 555 timer to blink a light every second, or you could connect it to a loudspeaker to make sound. Along with the 555 timer, you'd need to add a few extra resistors and capacitors, and by carefully selecting the values of those components, you could control how fast the light blinks or the sound's frequency. The 555 timer is very popular with hobbyists because it's cheap and pretty easy to use once you learn the basics. You'll use a 555 timer IC like the one shown here for the projects in this chapter.



Powering an IC

The datasheet for the 555 timer should tell you what each pin does. Try searching online for "555 timer datasheet" now. When you find the datasheet and open it, you should see a *pinout* like this:



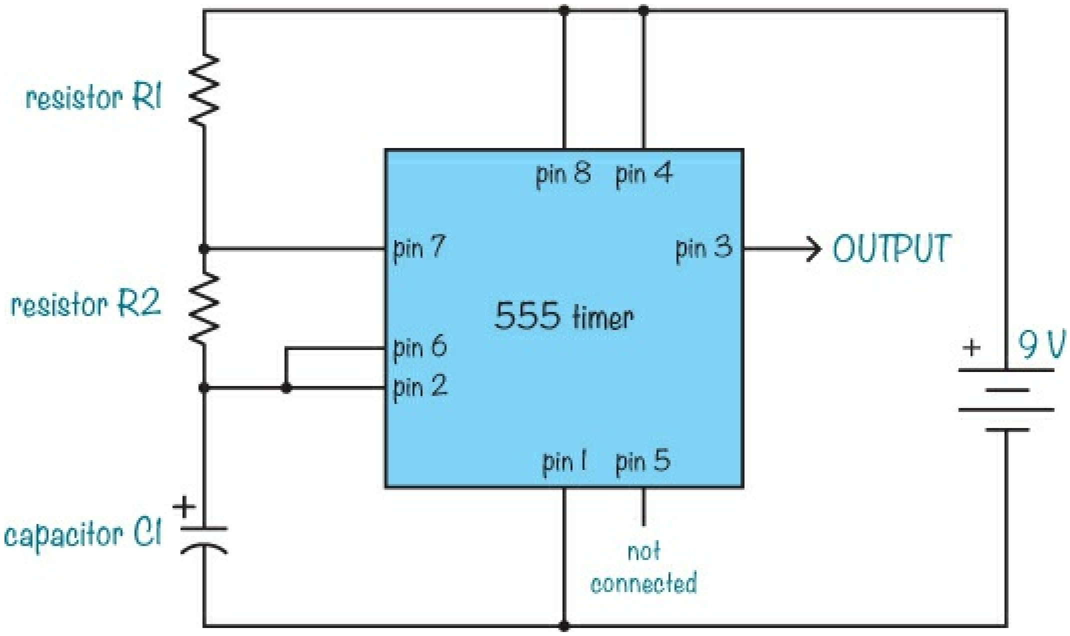
The 555 timer has eight pins. The pins of an IC are numbered counterclockwise, starting from the top left. (The top is indicated by a little notch or circle; some ICs have both.) The datasheet tells you the functions of each of the eight pins, but the following two pins are the most important to notice right now:

Pin 1, ground This pin must be connected to the negative terminal of your battery. Circuit diagrams that use ICs often label the negative battery terminal in a circuit schematic "ground," or GND for short.

Pin 8, V_{CC} This pin must be connected to the positive side of your battery, which must be at a voltage between 4.5 and 15 V. This means that a 9 V battery will work fine. On some ICs, this pin is called V_{DD} instead.

You'll find V_{CC} and ground pins on all ICs. They're the first pins to learn from any datasheet because you'll use them to power the circuit inside the IC.

The datasheet also shows how to connect the 555 timer in a circuit, and the circuit I find the most interesting connects the 555 timer in *astable mode*. *Astable* means that something is continually changing (not stable), and in astable mode, a 555 timer switches its output on and off constantly. That's perfect to blink a light or to create sound! Here's the circuit that tells the 555 timer to turn its output on and off:



NOTE

The positions of the 555 pins have been arranged to suit the diagram; they're not in the same order as on the IC.

How to Set the Output Speed of the 555 Timer

The values of R1, R2, and C1 in the circuit diagram determine how long the output pin stays *high*—meaning it outputs a voltage close to the battery voltage—and how long it stays *low*—meaning it outputs a voltage close to 0 V. The speed of the change in output, or the frequency, is the number of times the output goes from high to low in one second. When the 555 timer is connected in astable mode, as it is in the circuit diagram, the frequency of the output is controlled by resistors R1 and R2 and capacitor C1 according to the following formula:

$$\text{Frequency} = \frac{1.44}{(\text{R1} + \text{R2} + \text{R2}) \times \text{C1}}$$

Here, the resistor values are in ohms, and the capacitance is in farads. To find the frequency, first replace R1, R2, and C1 in the formula with the values of these parts and then punch the stuff on the right side of the equal sign into a calculator.

Let's try an example. Imagine a circuit with the following component values:

- R1 = 100 kΩ
- R2 = 10 kΩ
- C1 = 10 nF

What is the frequency of the output? Enter these values into the formula:

$$\text{Frequency} = \frac{1.44}{(100\ \text{k}\Omega + 10\ \text{k}\Omega + 10\ \text{k}\Omega) \times 10\ \text{nF}}$$

$$\text{Frequency} = \frac{1.44}{(120\ \text{k}\Omega) \times 10\ \text{nF}}$$

Now convert the units so the values are easier to multiply (120 kΩ = 120,000 Ω and 10 nF = 0.00000001 F):

$$\text{Frequency} = \frac{1.44}{120{,}000\ \Omega \times 0.00000001\ \text{F}}$$

$$\text{Frequency} = 1{,}200\ \text{Hz}$$

According to this calculation, the output should turn on and off 1,200 times per second with those values.

PROJECT #16: MAKE YOUR OWN SOUND WITH THE 555 TIMER

This project will show you how to play a sound with a frequency of about 1,200 Hz through a speaker. That's pretty cool! But a 1,200 Hz sound isn't very pleasant to listen to, and if you have any pets, they might appreciate the sound even less than you. In fact, when I turned on this circuit at my parents' home, their dog came running to me looking very confused and a bit scared. I turned it off quickly and moved my experiments to a place with no pets around, and I suggest not building this project around your pets, either.

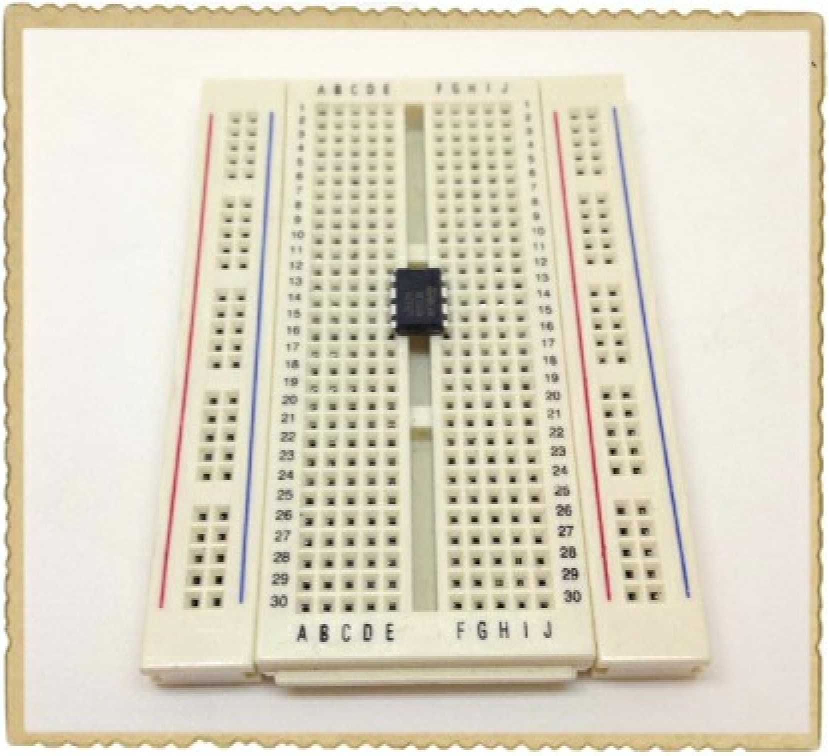
Step 1: Place the 555 Timer on the Breadboard

This circuit is built around the 555 timer IC, so first, place that IC in the middle of the breadboard, making it easy to connect all the components around it.

NOTE

When connecting an IC to a breadboard, always place it over the middle notch, with one set of pins on the left side and the other on the right side. Otherwise, any pins that share a row on the breadboard will be connected to each other.

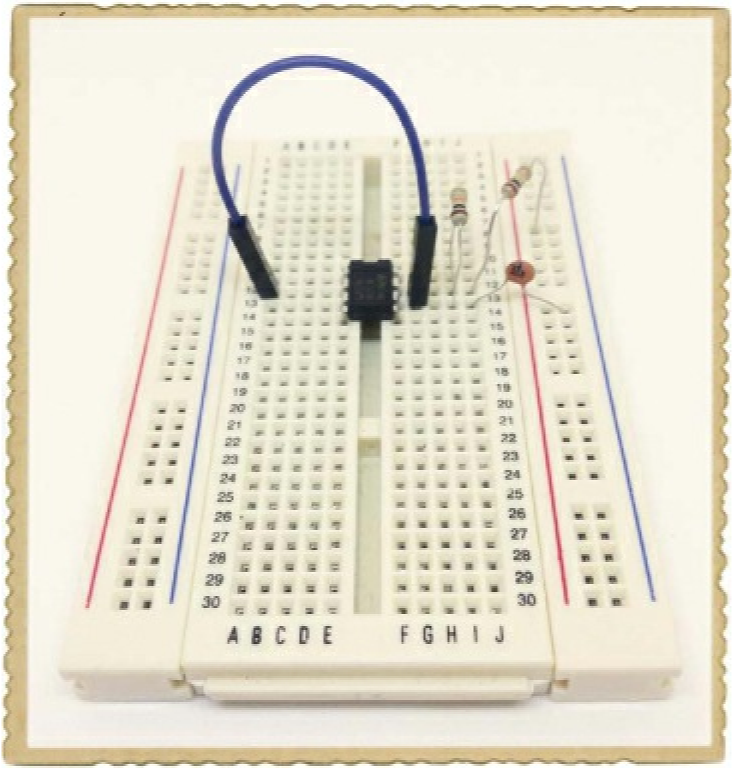
Place the IC's notch marker toward the top of the board so that pin 1 is at the upper-left corner and pin 8 is at the upper-right corner, as shown. Triple-check that you've oriented the chip as I describe; otherwise, the rest of the instructions in this project won't work.



Step 2: Set the Frequency

Next, connect the resistors and capacitor that set the frequency: R1, R2, and C1. The C1 capacitor isn't polarized, so it doesn't matter which way you connect it. Use the two vertical columns on the right for positive and negative: the red column for positive and the other for negative.

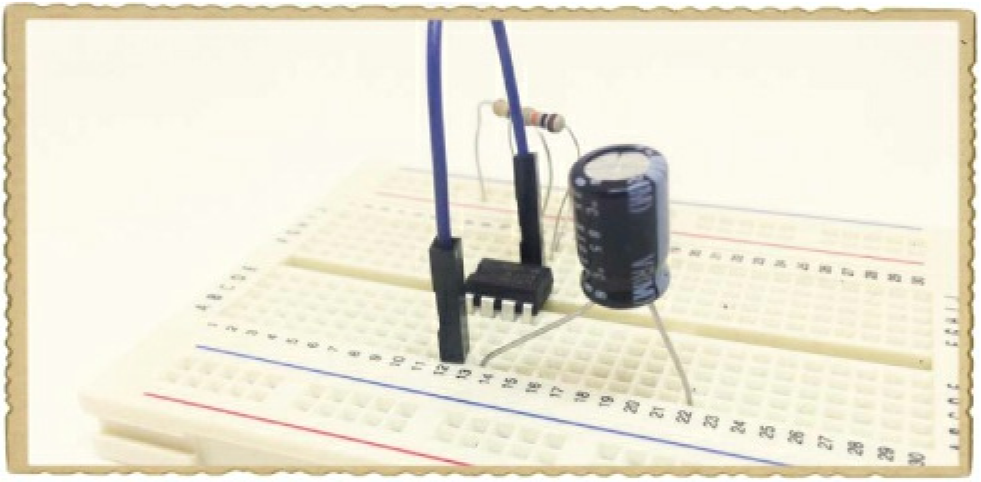
Connect R1, the 100 kΩ resistor, from pin 7 of the 555 timer to the positive column. Connect R2, the 10 kΩ resistor, from pin 6 to pin 7. And connect C1, the 10 nF capacitor, from pin 6 to the negative column. Then, connect a jumper wire from pin 2 to pin 6 to complete the rest of the connections that are needed to set the frequency.



Step 3: Connect the Speaker and Coupling Capacitor

All the components to make the 555 timer output pin 3 turn on and off around 1,000 times per second should be in place on your breadboard now. If you were to connect the speaker directly to the output, a large current would flow through the speaker, possibly damaging both the speaker and the 555 IC. You could connect the speaker through a resistor to reduce the current, but using a capacitor is even better. When a capacitor is connected to an AC voltage, the capacitor acts a bit like a resistor, but if you connect it to a constant DC voltage, the current will be blocked. This means that there won't be any current running through the speaker unless there's actually a frequency to be played. When a capacitor is used like this, it's called a *coupling capacitor*.

The coupling capacitor for this project is a 10 µF polarized capacitor, so first identify which leg is negative. Connect the positive capacitor leg to the 555 timer's output pin 3. Then connect the capacitor's negative leg to an empty row on your breadboard.



Next, if your speaker comes without wires, solder a wire about 6 inches long to each of the two contacts on the back of the speaker (ignore any + or – labels by the speaker contacts). Then, connect one of the speaker wires to the same row as the negative capacitor leg and the other wire to the negative supply column.

Step 4: Connect the Power and Reset Pins

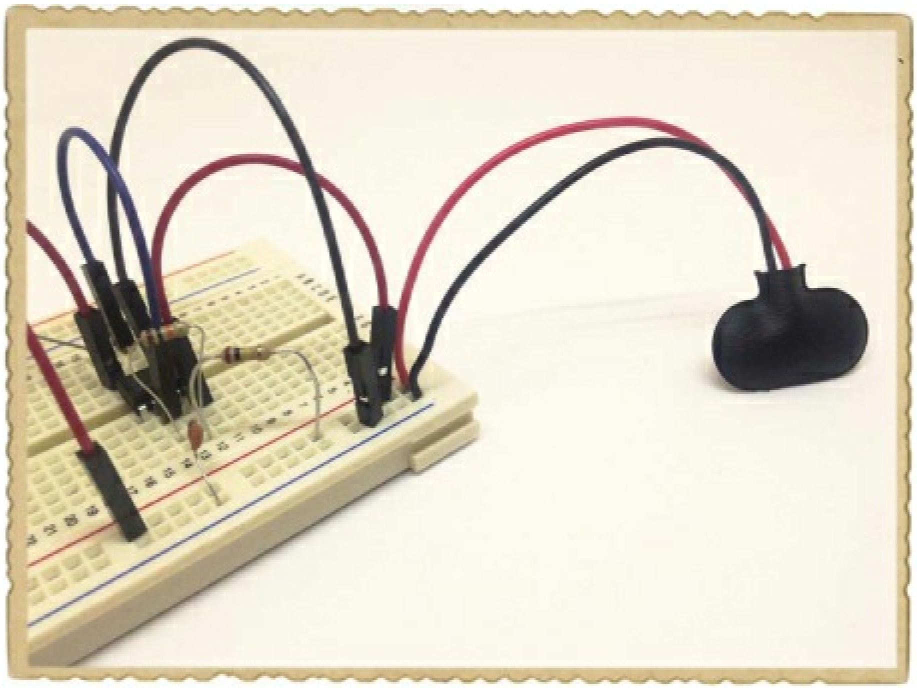
Compare your breadboard to the circuit diagram at the beginning of the project, and you'll see that there are a few connections missing. Once you have all of your components in place on the breadboard, you can make those final connections with jumper wires. Add a jumper wire for each of the following connections:

- From pin 1 on the 555 timer to the negative supply column
- From pin 8 on the 555 timer to the positive supply column
- From pin 4 on the 555 timer to the positive supply column

Note that there's no connection to pin 5 of the 555 timer in this circuit.

Step 5: Make Some Sound!

Connect the battery clip to your supply columns on the right side of the breadboard. The red wire goes to the positive supply column, and the black wire goes to the negative supply column.



When you're ready, connect the battery, and you should hear a loud beep. Congratulations: You just made your first electronic sound!

Step 6: What If There's No Sound?

There are a lot of connections in this circuit, so if your circuit doesn't work on your first attempt, don't worry: that happens to everyone who plays with electronics at some point. First, disconnect the battery, and then check the resistor and capacitor legs. These legs are long, and they can easily end up in contact with each other by accident, creating a short circuit. (For example, if you accidentally connect the positive terminal of the battery directly to the negative terminal, that short-circuits the battery.)

Next, check the component connections to the 555 timer. The 555 timer's pins must connect to the rest of the circuit according to the circuit diagram, or the IC won't work. When there are a lot of connections, it's easy to plug a wire into the wrong row of the breadboard.

CHECKING CONNECTIONS AS A TEAM

Finding circuit problems is called *debugging*, and it's easier to do with some help. When you get stuck, ask someone else to look at the circuit diagram and say the connections out loud one by one while you check the real connections. For example, if your friend is reading the schematic and you're looking at the breadboard, you might have a conversation like this:

> Friend: "The positive side of the battery is connected to one side of R1."
>
> You: "Got it!"
>
> Friend: "The positive side of the battery is also connected to pins 4 and 8 of the IC."
>
> You: "Got it!"
>
> Friend: "The other side of R1 is connected to pin 7 of the chip and to one side of the resistor R2."

You: “Oh, wait! I don’t have the connection to pin 7!”

And just like that, you’ll discover the problem.

If all your components appear to be oriented correctly and you see no short circuits, then check all your breadboard connections to make sure components that should be connected share a row. Start with the connection from the positive terminal of the battery on your circuit diagram. Is it connected on the board just as the circuit diagram shows? If yes, then move on to the next connection; keep going like this until you’ve checked all the connections.

TURNING AN ANNOYING BEEP INTO MUSIC

The sound you created in the previous project isn’t very pleasant. So how can you turn it into music? Musical notes are just sound waves that vibrate at specific frequencies, and that means it’s possible to make an electronic instrument with the 555 timer. If you change the frequency of the signal that goes into the speaker, then the tone of the sound will change. You just have to find a way to change the 555 timer’s output frequency at will, without rebuilding the circuit every time.

Chapter 7 introduced two components that can change their resistance value: the potentiometer and the photoresistor. If you use one of those components to control the frequency of the 555 timer’s output signal, then when that component’s resistance changes, the sound will change, too. That’s how you’ll make the instrument in the next project.

PROJECT #17: AN INSTRUMENT THAT BEEPS AND BOOPS

This project shows you how to combine what you’ve learned so far to build your very own electronic instrument. Specifically, you’re going to build an instrument with a button to play sound and a potentiometer shaft to change the tone.

This instrument is like a very simple *synthesizer* that uses electricity to make sounds. Synthesizers have been used to add all kinds of bleeps, bloops, and glitchy sounds to songs since the beginning of the electronic music genre. This one is pretty basic, but it still makes plenty of fun noises. In fact, the circuit for this project looks very similar to the circuit from “Project #16: Make Your Own Sound with the 555 Timer” on page 167, but it has a few twists.

This circuit replaces the separate R1 and R2, which the circuits in Project #16 used, with a potentiometer (and a protective 1 kΩ resistor). The potentiometer acts like two resistors, meaning that you can effectively change the values of R1 and R2 whenever you want to change the tone you hear.

Notice that this circuit also has a switch connected to the positive battery terminal. This switch is a push button, and with a switch between power and your circuit, the instrument should make a sound only when you push the button.

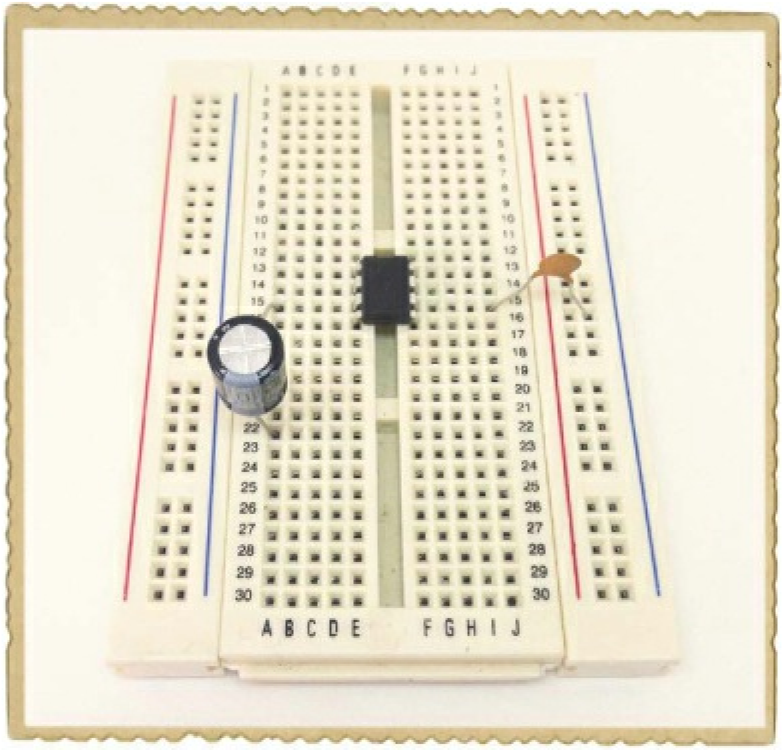
- **A 555 timer IC** (Jameco #904085, Bitsbox #QU001) to create the timing.
- **A 8 Ω speaker** (Jameco #1954818, Bitsbox #ST063) to play the sound.
- **A 10 µF capacitor** (Jameco #29891, Bitsbox #EC10U25) to connect to the speaker.
- **A 10 nF capacitor** (Jameco #15229, Bitsbox #CC10N) to help set the frequency of the sound.
- **A 100 kΩ potentiometer** (Jameco #2161406, Bitsbox #VR006) to control the tone.
- **A 1 kΩ resistor** (Jameco #690865, Bitsbox #CR251K) to protect pin 7 from being connected directly to V_{CC}.
- **A push button** (Jameco #119011, Bitsbox #SW087) to play tones with.

Step 1: Connect the 555 Timer and the Capacitors

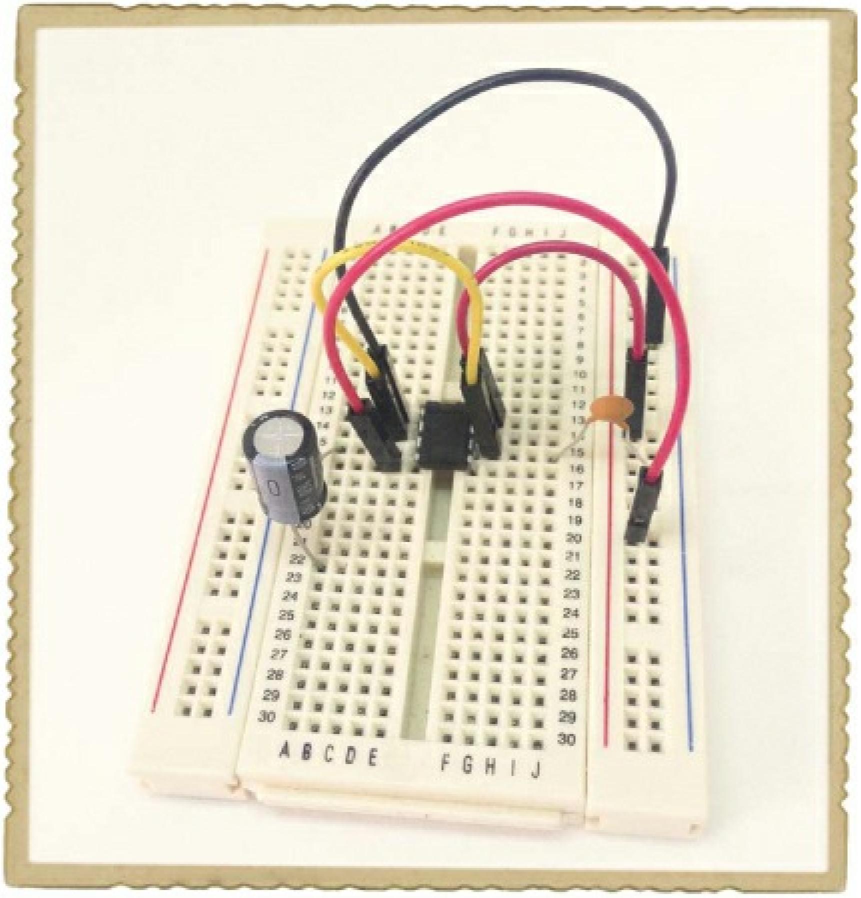
Start by connecting the 555 timer in the middle of the board. Then, connect both capacitors. Connect C1, the 10 nF capacitor, from pin 6 to the negative power column. And connect C2, the 10µF capacitor, with its positive leg at pin 3 of the chip and the negative leg on an empty row farther down. When you're done, your board should look something like this:



Step 2: Connect Jumper Wires

Use jumper wires to create the following connections:

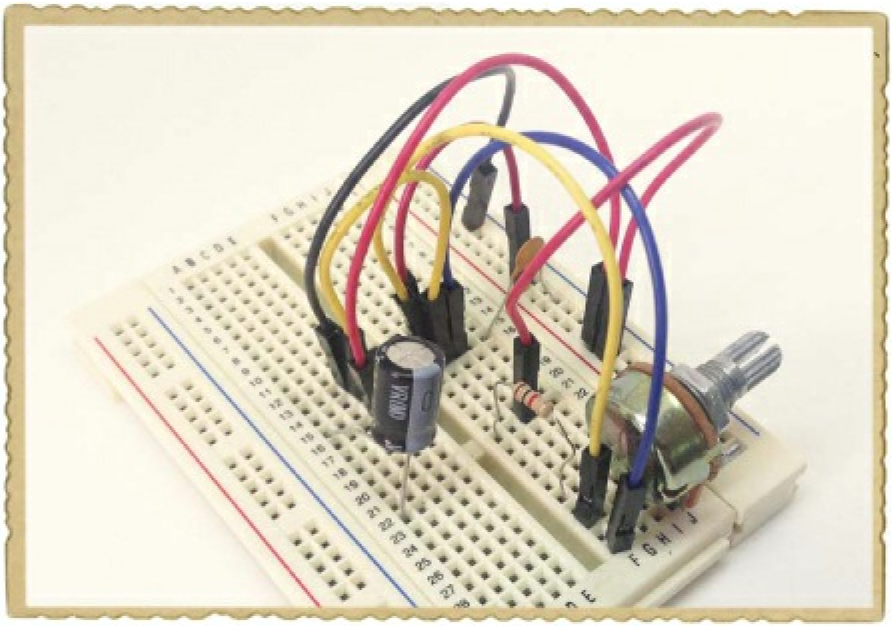
- Pin 8 to the breadboard's positive supply column
- Pin 4 to the breadboard's positive supply column
- Pin 1 to the breadboard's negative supply column
- Pin 2 to pin 6



Step 3: Connect the Note Controller and Resistor

Next up is the potentiometer, which controls the note that plays. Because it takes up more space, plug this in at the bottom of the breadboard, as shown, and be sure each leg is in its own row.

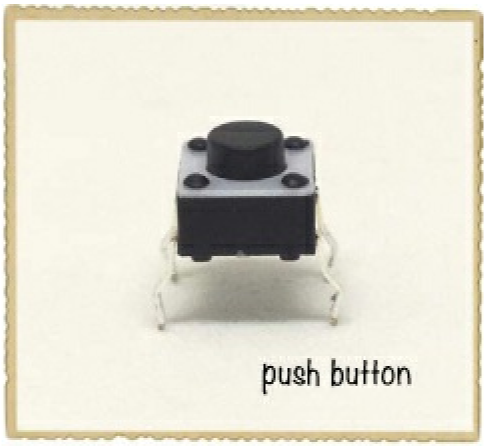
Connect the 1 kΩ resistor from the uppermost leg of the potentiometer to an unused row away from the 555 IC and connect a jumper wire from this row to the positive supply. Then, connect one jumper wire to each of the two remaining potentiometer legs. Connect the wire on the middle potentiometer leg to pin 7 on the 555 timer, and connect the wire on the lower leg to pin 6 on the 555 timer.



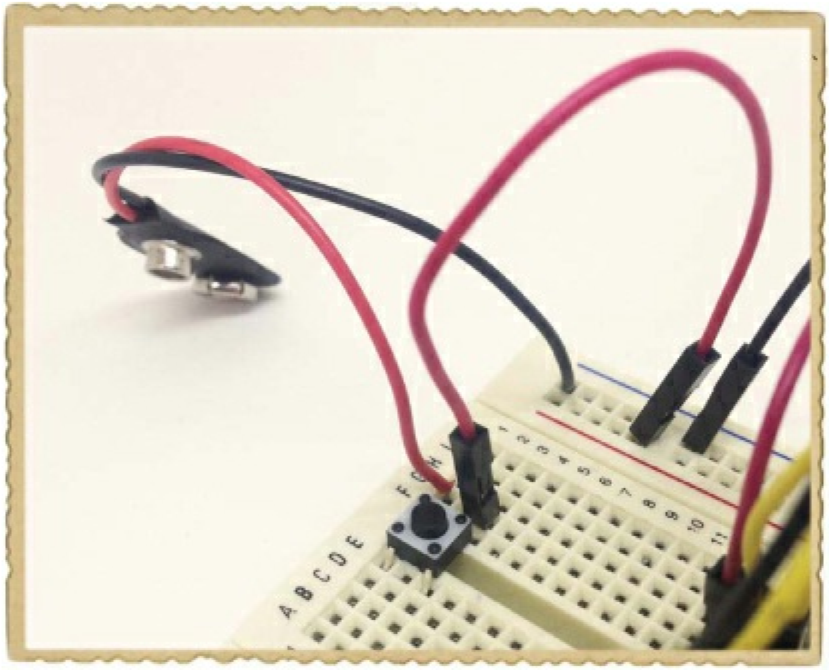
Step 4: Add the “On” Button

You’re almost done! Instead of wiring the battery clip directly to the positive supply column on the breadboard, you’re going to connect it through a push button, which will act as an “on” button for your instrument. This way, the circuit will get power from the battery only when the button is pushed and, therefore, make sound only when you push the button.

The push button in the Shopping List (page 177) has four pins, but the two legs in the front are connected and the two pins in the back are connected. That means this button works exactly like a two-pin switch. When you push the button, you connect the front pair of pins with the back pair. Your circuit will get power and you’ll hear the sound. When you release the button, the circuit loses power again and the sound will stop.

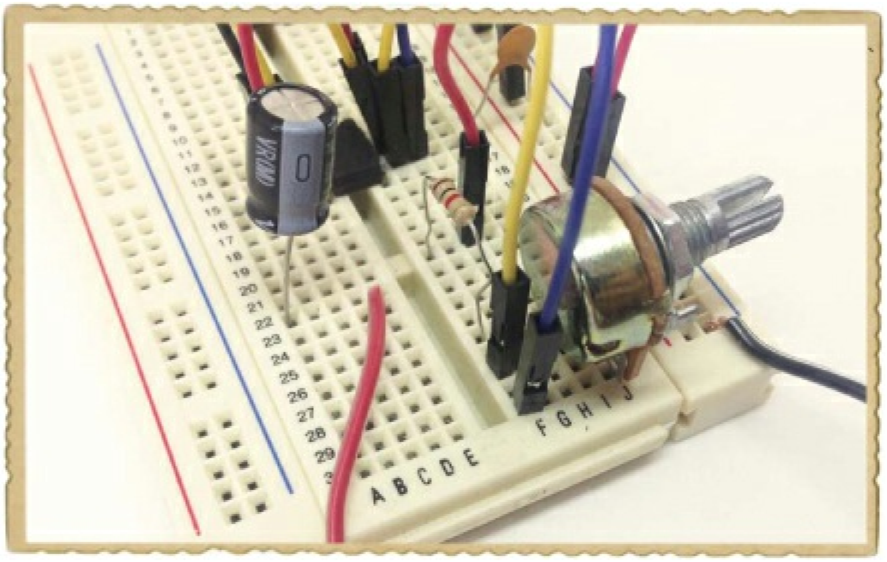


Plug the push button into your breadboard over the notch in the middle. Then, use a jumper wire to connect one side of the push button to the breadboard’s positive supply column. Next, connect the positive wire from your battery clip to the other side of the push button. Finally, connect the negative battery clip wire to the negative supply column.



Step 5: Add the Loudspeaker

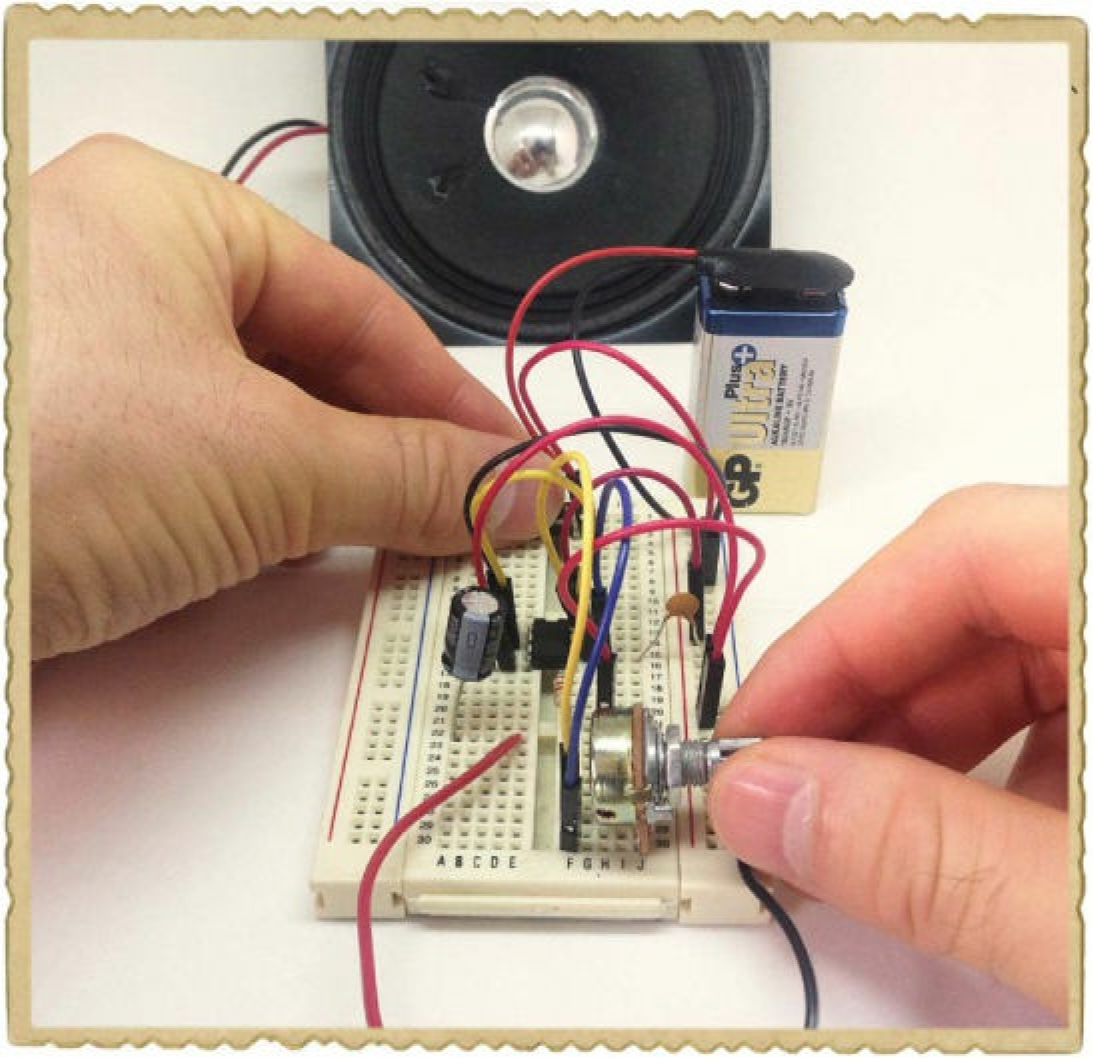
Connect one of the speaker wires to the same row as the negative capacitor leg and the other wire to the negative supply column.



Step 6: Play Some Music!

Connect your battery to the battery clip and push the button. Did you hear a sound? Try turning the potentiometer spindle back and forth until you hear something.

You can make a beat by pushing the button in any rhythm you like, and you can control the tone by turning the shaft of the potentiometer in between. Beep, baap, booop!



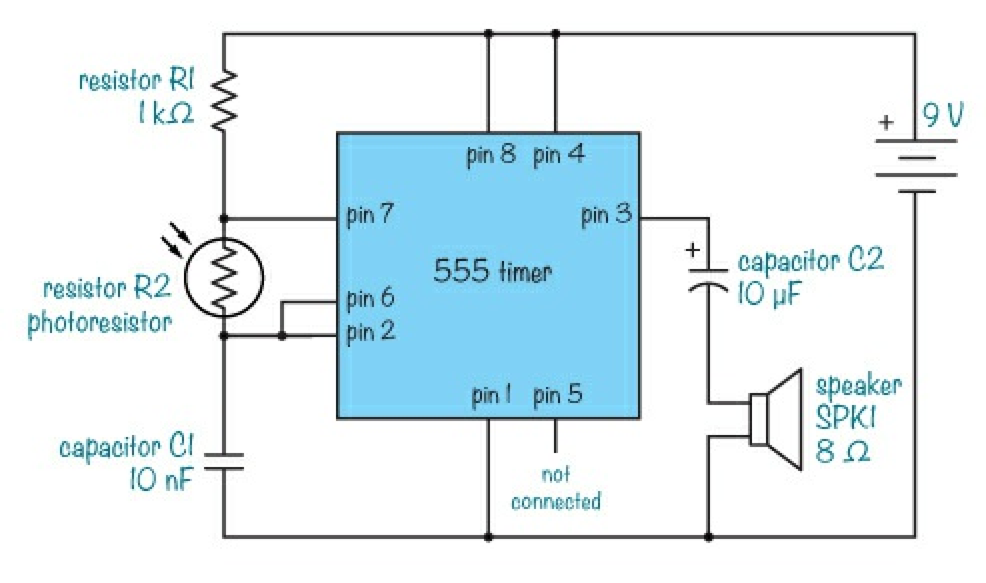
Step 7: What If the Instrument Doesn’t Work?

Some potentiometers aren't perfectly fitted for breadboards, so start by checking whether your potentiometer is properly connected to the breadboard. Next, check that the two capacitors and the push button are connected according to the circuit diagram at the beginning of the project.

There are a lot of wires on this board, so it's easy to mix up connections. If you still aren't able to hear any sound, then go through all the connections on your board and check that they're correct. I suggest using the process I described in "Checking Connections as a Team" on page 174.

TRY IT OUT: MAKE A MOTION-CONTROLLED INSTRUMENT

Instead of replacing both R1 and R2 with a potentiometer, try using a 1 kΩ resistor for R1 and a photoresistor for R2, as shown in this circuit diagram. As you move your hand over the photoresistor, the amount of light hitting it should change, and the instrument should play different notes!



WHAT'S NEXT?

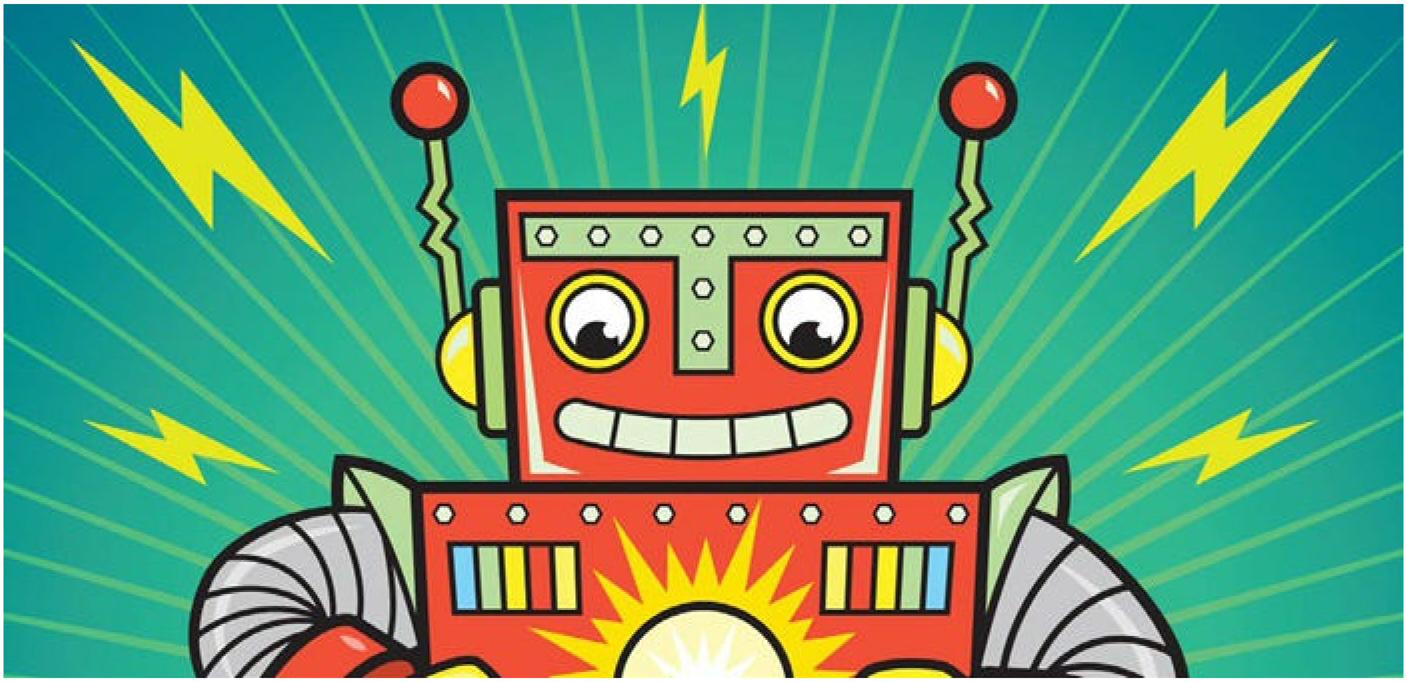
There are millions of integrated circuits in the world, and they do all kinds of awesome things. Remember, whenever you want to use an IC in your projects, you can use its datasheet to find out both what the IC does and what kind of circuit you need to make it work.

In this chapter, you learned how to use a 555 timer IC to make music. These circuits had lots of connections, so if you didn't get them right the first time, then you're in good company. Most people mix up wires the first time they connect a circuit, and fixing the connections is great practice! And speaking of practice, now would be a good time to do some more soldering. Why not solder your instrument on to a prototyping board—and maybe even put it in a box?

Integrated circuits are very commonly used in *digital circuits*. Digital circuits can do many things simply by switching the right parts on and off, often very rapidly, just as in the musical instrument you made in this chapter. Modern gadgets like your computer use digital circuits, and you’ll learn more about digital electronics in the last few chapters of this book.

PART 3

THE DIGITAL WORLD



9

HOW CIRCUITS UNDERSTAND ONES AND ZEROS

Mobile phones, computers, TVs, video game consoles, and almost all the other technology you see around you is built with digital electronics. If you've ever looked inside a computer, the circuits might seem complex, but when you break that hardware down into small pieces, it's actually quite simple: every action a computer takes is based on whether some circuit sees a high or low voltage.

You've used transistors to make circuits that control things, and in this chapter, you'll learn the basics of using digital electronics to make even smarter circuits. You're going to learn a new number system, what bits and bytes are, and how you can use bits and bytes to create messages with electricity.

ONES AND ZEROS AS VOLTAGES

When I was in school, my teacher told me that computers used ones and zeros to communicate, but he didn't explain it any further. I wanted to know more, so I decided to ask my dad. Because computers are complex machines, I assumed the way they use ones and zeros was going to be complex, too, but my dad told me, "In a computer, a one is just a wire with voltage, and a zero is a wire without voltage." (By "without voltage," my dad meant the voltage was zero.)

In "How to Set the Output Speed of the 555 Timer" on page 166, I mentioned briefly that the pins of the 555 timer could be either high or low. The pins on the ICs in a computer work the same way: high is one, and low is zero. Digital circuits work by flipping the voltages on different wires between high and low.

MEET THE BINARY NUMBER SYSTEM

Normally, when you talk about numbers, you use *decimal numbers*, which are in the *base-10* number system. In base-10 numbers, a digit can have one of 10 possible values, from 0 to 9. But digital circuits can work with only two voltages (high and low), so they can understand only *binary numbers*. Binary is also called the *base-2* number system, and a binary number's digits have only two possible values: 0 and 1.

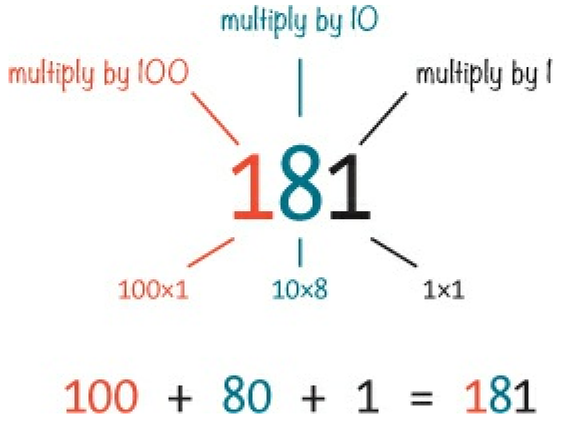
Here's how you'd count to 10 in both decimal and binary:

Decimal number	Binary number
0	0
1	1

2	10
3	11
4	100
5	101
6	110
7	111
8	1000
9	1001
10	1010

What's going on here? The number 2 in decimal is 10 in binary, and 4 in decimal is 100 in binary!

You can figure out the value of any number in any system using the digits and their position. The rightmost digit always gets multiplied by 1. Going left from there, each position's value equals the base times the value of the previous position. In decimal, the base is 10, so the second position's value is 10, or 10 × 1; the third position's value is 100, or 10 × 10; the fourth position's value is 1000, or 10 × 100; and so on. Here's an example:



In the number 181, the first digit is 1, the second digit is 8, and the third digit is 1. Once you multiply those digits by their position values, you can add the resulting values to get 181. You don't need to use this method to figure out decimal numbers, though. It's pretty clear that 181 equals 181! But this method is very useful for finding the value of binary numbers. Binary follows the same rules, but it uses a base of 2 instead.

PROJECT #18: CONVERT FROM BINARY TO DECIMAL

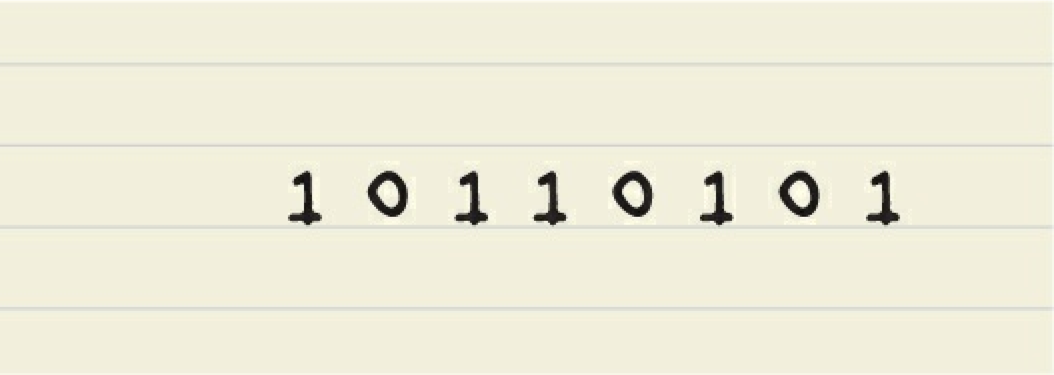
In this project, you're going to *convert* a binary number into its decimal form. Converting a number to a different base just means calculating that number's value and writing it using digits in the new base.

Tools

- **A pen or pencil** to write with.
- **Paper** to write on.
- **A calculator** to add numbers. If you're good at doing math in your head, try this project without one.

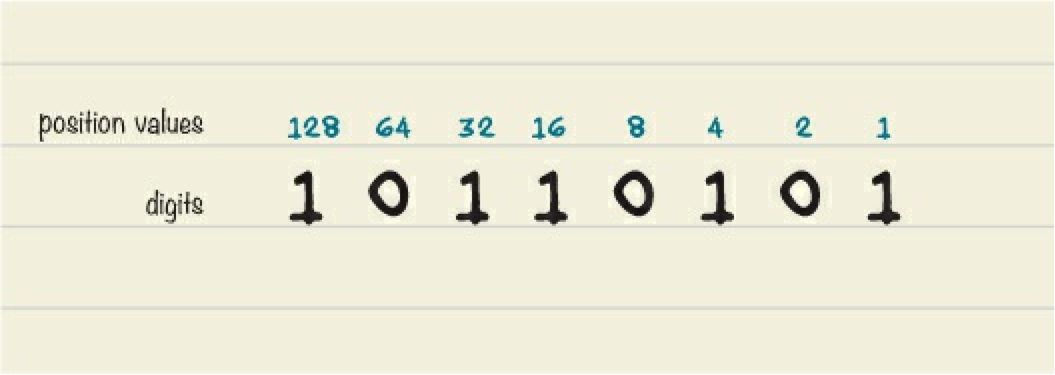
Step 1: Write It Down on Paper

First, write an eight-digit binary number on paper, leaving space between the digits, both above and below the number. I'm going to convert the binary number 1011 0101, and I wrote it out like this:



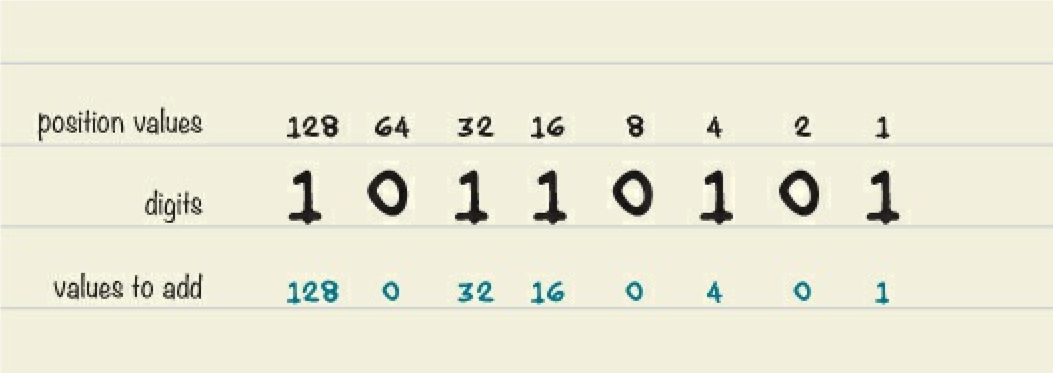
Step 2: Write the Position Values

Next, write the value of each position above each digit. Binary works the same way as the decimal example, but the base is 2. That means the value for the rightmost position is 1, and to find the next position to the left, you'd multiply the previous position's value by 2. For example, the second position's value is 2 × 1 = 2; the third position's value is 2 × 2 = 4; the fourth value is 4 × 2 = 8; and so on. Use a calculator if you don't want to calculate it all in your head. When you write those values down, you should have something like this:



Step 3: Find the Value of Each Digit

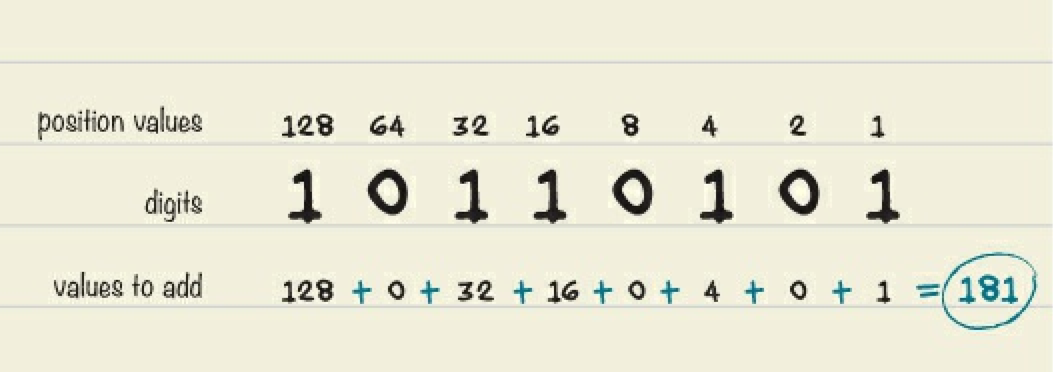
Look at each digit of the binary number you wrote down. If a digit is 0, write 0 below it. If the digit is 1, write the value of that position below it. Those are the values you'll add together to get your final decimal number.



position values
128 64 32 16 8 4 2 1
digits
1 0 1 1 0 1 0 1
values to add
128 0 32 16 0 4 0 1

Step 4: Add the Numbers

You should now have three rows of numbers. Add the numbers in the bottom row (you might find it helpful to write a + sign between each pair of numbers) to get the sum, which is the decimal value of your binary number.



position values
128 64 32 16 8 4 2 1
digits
1 0 1 1 0 1 0 1
values to add
128 + 0 + 32 + 16 + 0 + 4 + 0 + 1 = 181

The binary number 1011 0101 is 181 in decimal. If you've been following along with that number and your answer is different, go through the steps again and check your results against mine to find out where the error is.

TRY IT OUT: TRANSFORM MORE BINARY NUMBERS

To get more practice with ones and zeros, let's bring some more binary numbers into the decimal world. Here are a few to try:*

1010
0011 1111
1000 0000
0011 1011 0101

* In decimal, these binary numbers are 10, 63, 128, and 949.

BITS AND BYTES

Each digit in a binary number is called a *bit* (that's short for *binary digit*), and computers handle numbers in blocks of eight bits called a *byte*. The binary number 1011 0101 has eight bits, so it's a byte. You can interact with a computer in many ways, but all your mouse clicks, key presses, webcam videos, and so on need to be translated into bits and bytes before the computer can understand them.

In fact, when working with computers and other digital gadgets, you usually see much, much larger numbers than just 1 byte. All the files on a computer are collections of bytes, but if you tried to describe their size in bytes alone, those numbers would be huge! That's why files are usually described in larger units, like kilobytes* (kB), megabytes (MB), gigabytes (GB), terabytes (TB), and so on. Here's what those units mean:

1 kB = 1,000 bytes

1 MB = 1,000 kB = 1,000,000 bytes

1 GB = 1,000 MB = 1,000,000 kB = 1,000,000,000 bytes

1 TB = 1,000 GB = 1,000,000 MB = 1,000,000,000 kB = 1,000,000,000,000 bytes

If a computer's hard disk can hold 1 TB of data, then it can hold one trillion bytes, which is eight trillion ones and zeros!

NUMBERS CAN BE ANYTHING

Now you might be thinking, "Why on Earth would I ever need eight trillion ones and zeros in my computer?" The fact is, whether you use a computer to write stories, draw pictures, talk to your friends, play video games, or anything else, you're actually using those ones and zeros.

For example, how does a computer show an image on a screen? A computer screen is made of a lot of small points called *pixels*, and each pixel can be set to a color that is a mix of red, green, and blue light. If you want a pixel to be the brightest yellow possible, you'd use numbers to tell the computer to turn that pixel's red and green settings to full intensity and its blue setting to zero (because mixed red and green light looks like yellow). This way you can translate numbers into an image on the screen.

PROJECT #19: COLOR GUESSING GAME

In this project, you'll build a pixel-color guessing game using binary values. It's a two-player game where you and a friend take turns being "the computer" and "the user."

The person who is the computer sets the color of the pixel by pushing a combination of three buttons. When the computer is ready, the user must try to guess which color the pixel is. When the user is ready to make the guess, they should say the chosen color out loud and then push the color revealer button to show the actual color. If the user guesses correctly, they get one point and get to guess again. If the guess is wrong, you switch roles. The first one to reach three points wins the round.

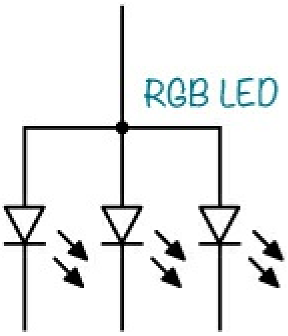
Meet the RGB LED

To create the pixel for this project, you're going to use a *red-green-blue (RGB) LED*, which combines a red LED, a green LED, and a blue LED into one component. By turning on and off each of these LEDs, you can create different colors. For example, turning on only the red and green LEDs would give you yellow.

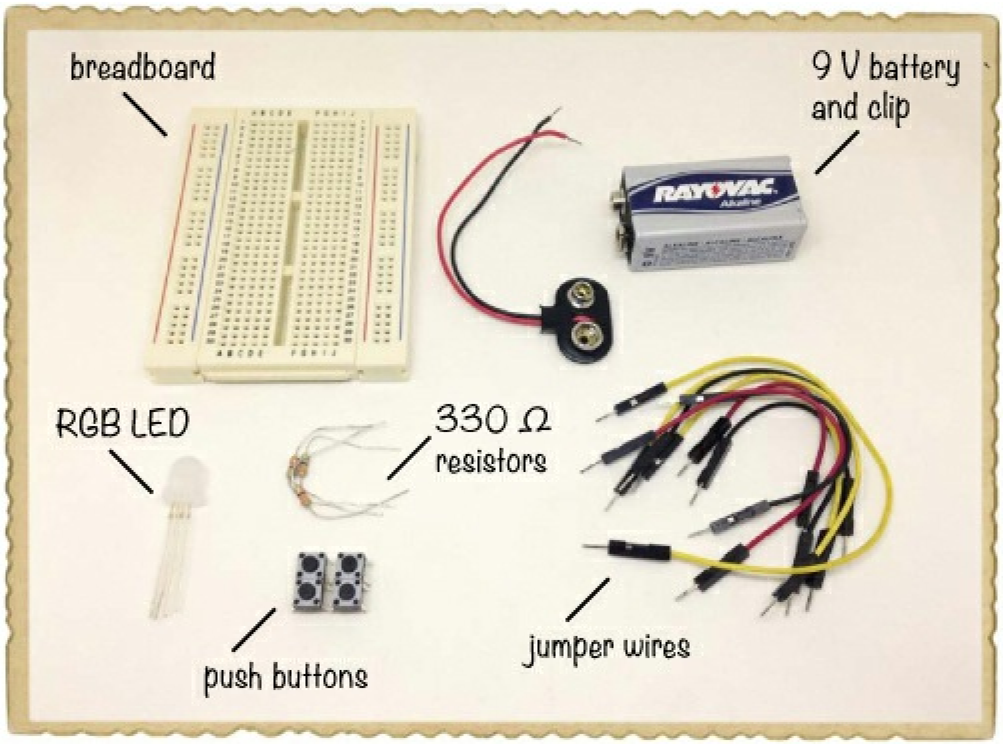
There are two types of RGB LEDs: *common anode* and *common cathode*. This is what a common anode RGB LED looks like, along with its symbol:



RGB LEDs have four legs. You’ll use three legs to set the color, and the fourth leg is the *common* leg. In common anode RGB LEDs, the positive (anode) sides of the three LEDs are combined into one pin; common cathode RGBs combine the negative (cathode) sides into one pin.

In this project, you’re going to build the following circuit, which uses a common anode RGB LED and some buttons.

Shopping List

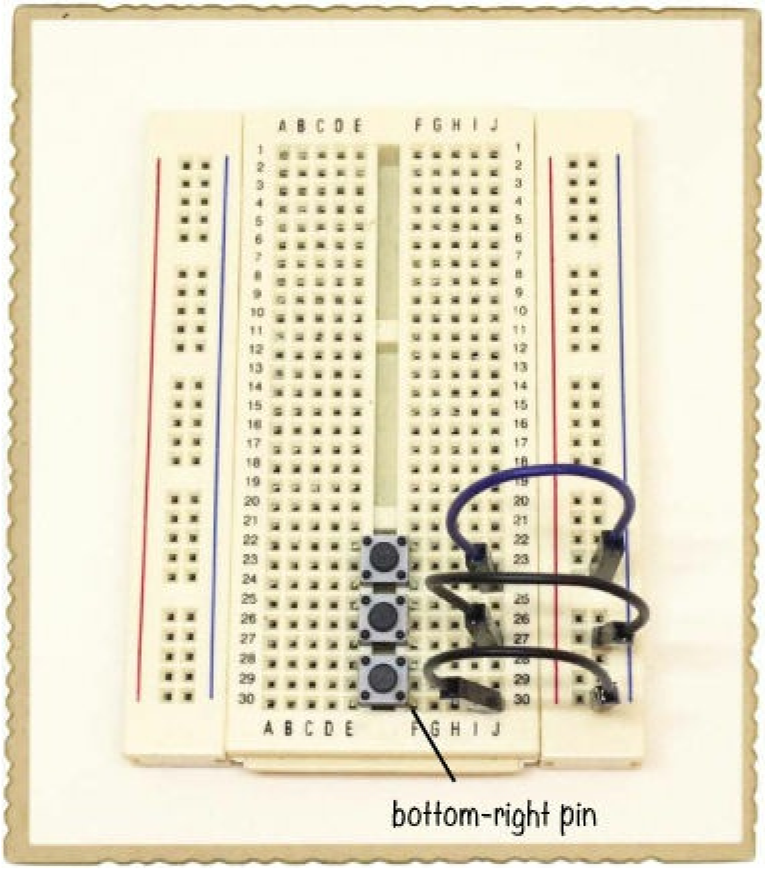


- **A standard 9 V battery** to power the circuit.
- **A 9 V battery clip** (Jameco #11280, Bitsbox #BAT033) to connect the battery to the circuit.
- **A breadboard** (Jameco #20601, Bitsbox #CN329) with at least 30 rows.
- **Breadboard jumper wires** (Jameco #2237044, Bitsbox #CN236) to easily connect parts. (Standard hookup wire works, too.)
- **Three 330 Ω resistors** (Jameco #661386, Bitsbox #CR25330R) for limiting the current to the LED.
- **RGB LED with common anode** (Jameco #2219567, Bitsbox #OP100) to create colors.

- **Four push buttons** (Jameco #119011, Bitsbox #SW087) to set and reveal colors.

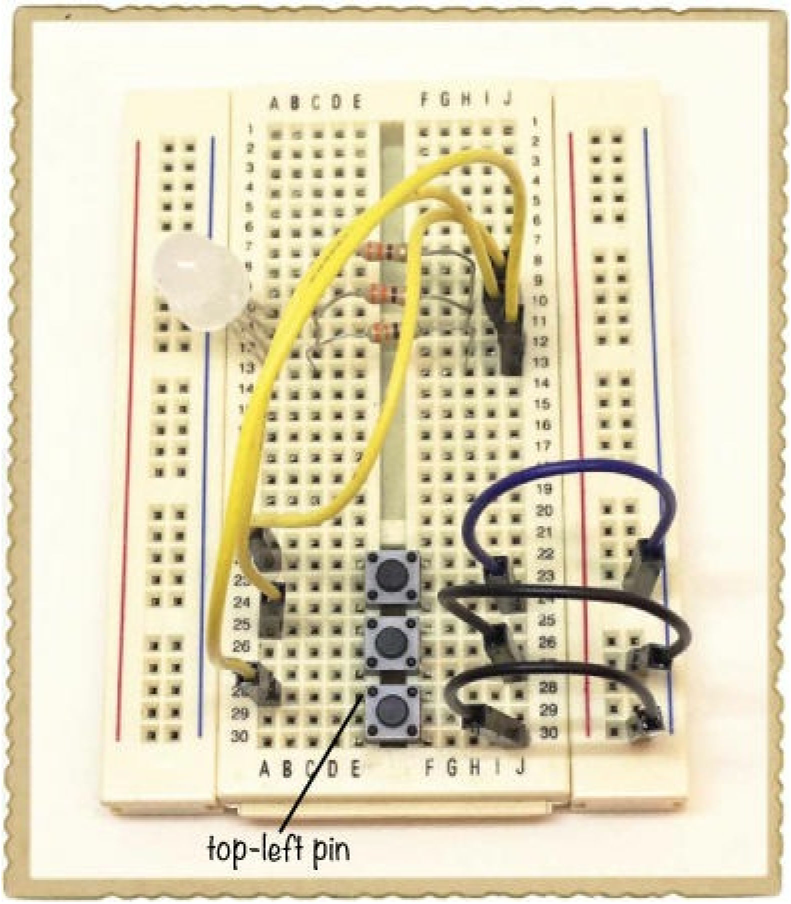
Step 1: Place the Color Chooser’s Push Buttons

Orient your breadboard so that the notch down the middle runs from top to bottom. Then, place three push buttons at the bottom of your breadboard; each should have one pair of legs on the left side of the notch and one pair on the right. This should leave you plenty of room to connect components on both sides of the buttons, and you’ll be able to separate the computer’s buttons from the user’s button more easily. With your buttons in position, connect three jumper wires from the bottom-right pin of each push button to the negative supply column.



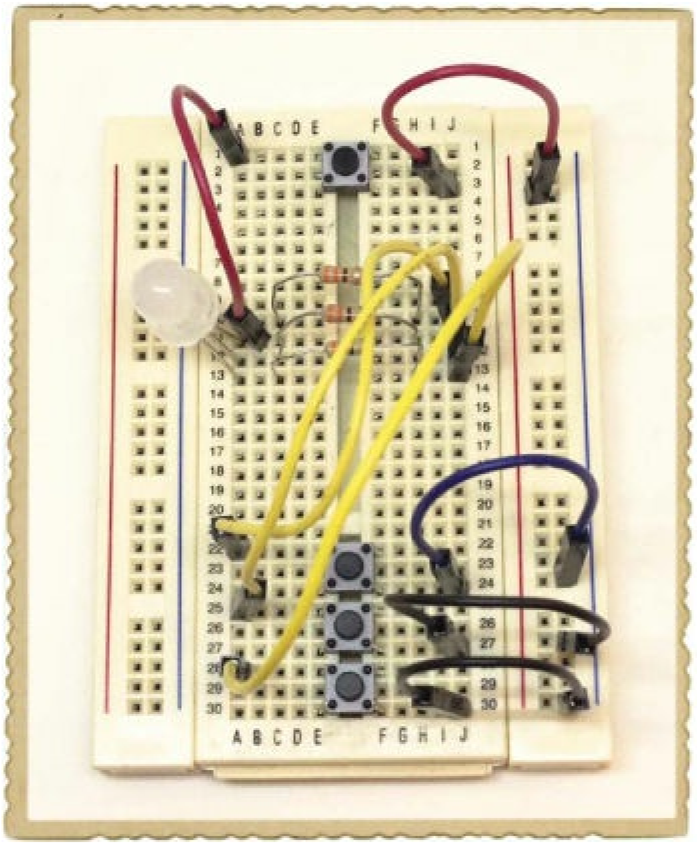
Step 2: Connect the RGB LED

In the middle of the board on the left, connect your RGB LED. The longest leg of the RGB LED is the common anode leg. Leave this unconnected for now. Connect a 330 Ω resistor from each of the remaining LED legs to an empty row on the right side of the breadboard. From each of these three rows, connect a jumper wire to the top-left pin of each push button.



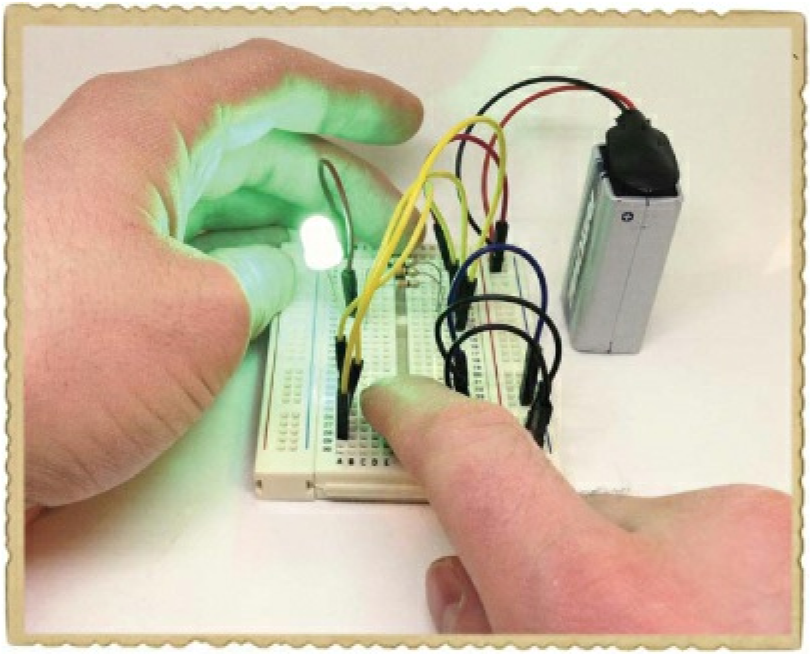
Step 3: Connect the Color Revealer Button

Next, add the button that reveals the computer's chosen color to the user. Place a fourth push button all the way at the top of the breadboard, across the middle notch. Connect a jumper wire from the common anode leg of the RGB LED to the top-left pin of the fourth push button. Then, connect one jumper wire from the bottom-right pin of this push button to the positive supply column on the right.



Step 4: Test the Colors

Connect the battery clip to the supply columns on the right, connect a battery, and try it out! Push some of the buttons on the bottom and then push the color revealer button to see the color. In this photo, I set my RGB LED to green.



You should be able to see the following seven colors, depending on which buttons you push:

Color	Top button	Middle button	Lower button
Red	Pushed (1)	Not pushed (0)	Not pushed (0)

Green	Not pushed (0)	Pushed (1)	Not pushed (0)
Blue	Not pushed (0)	Not pushed (0)	Pushed (1)
Yellow	Pushed (1)	Pushed (1)	Not pushed (0)
Cyan	Not pushed (0)	Pushed (1)	Pushed (1)
Magenta	Pushed (1)	Not pushed (0)	Pushed (1)
White	Pushed (1)	Pushed (1)	Pushed (1)

If your buttons do not match these colors, switch the wires between the three resistors to the buttons so that they match.

Step 5: What If the Game Doesn't Work?

If you see no colors at all, check that your connections match the circuit diagram. If the connections are correct and you still can't see any colors when pushing the color revealer button, you may have a common cathode LED instead of a common anode. To check for this, simply switch the positive and negative connections from the battery.

When you've verified that all the colors work, invite a friend to play!

TRY IT OUT: SOLDER THE COLOR GUESSING GAME

This is a perfect circuit to practice your soldering skills on. Get a prototyping board and solder the circuit onto it so that you have a permanent Color Guessing Game to bring with you on a long car ride.

HOW BINARY NUMBERS CAN CREATE WORDS

Images aren't the only things that can be stored as binary numbers; you can represent letters as numbers, too. One way to do this is to use the *ASCII code*, which is a standard set of bytes that computers understand as upper- and lowercase letters, numbers, punctuation marks, and so on. The numbers in this table represent the lowercase letters in the English alphabet.

Decimal ASCII code	Binary value	Lowercase letter
97	0110 0001	a
98	0110 0010	b
99	0110 0011	c
100	0110 0100	d
101	0110 0101	e

102	0110 0110	f
103	0110 0111	g
104	0110 1000	h
105	0110 1001	i
106	0110 1010	j
107	0110 1011	k
108	0110 1100	l
109	0110 1101	m
110	0110 1110	n
111	0110 1111	o
112	0111 0000	p
113	0111 0001	q
114	0111 0010	r
115	0111 0011	s
116	0111 0100	t
117	0111 0101	u
118	0111 0110	v
119	0111 0111	w
120	0111 1000	x
121	0111 1001	y
122	0111 1010	z

For example, the letter *a* can be represented by the decimal number 97, which is the binary number 0110 0001. You can use this table to encode and decode secret messages written with only ones and zeros.

PROJECT #20: THE SECRET MESSAGE MACHINE

This project is a circuit that shows eight-bit binary numbers with LEDs. An LED that is lit is a 1, and an LED that is off is a 0. You'll use switches to set the binary number and a push button to show the binary number on the LEDs.

Eight bits are enough to represent an ASCII character, so you can use this project to generate secret messages that can only be decoded by someone who knows binary! This finished Secret Message Machine shows the letter *w*, or 0111 0111.

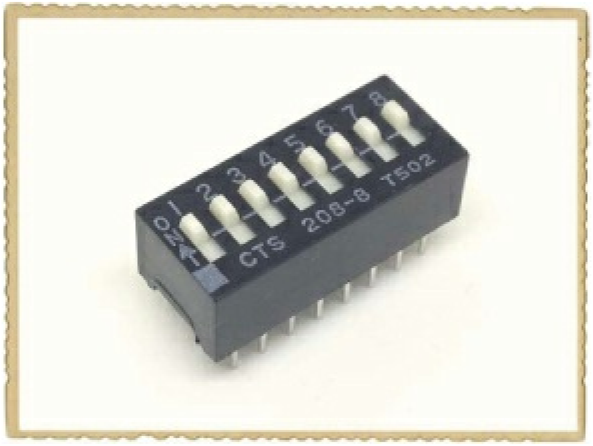
Meet the DIP Switch

This circuit uses eight switches to set the binary value, but it would be a pain to plug that many individual buttons into your breadboard. Fortunately, you can just use a *DIP switch*, which is a component with a row of one or more mini switches.



NOTE

DIP stands for dual in-line package, *which is how the pins are arranged. A component with "DIP" in its name has two rows of pins that you can plug into a breadboard. The DIP switch in this project has eight individual switches. This is perfect for creating a binary value input to a row of LEDs.*

- **A standard 9 V battery** to power the circuit.
- **A 9 V battery clip** (Jameco #11280, Bitsbox #BAT033) to connect the battery to the circuit.
- **A breadboard** (Jameco #20601, Bitsbox #CN329) with at least 30 rows.

- **Eight 330 Ω resistors** (Jameco #661386, Bitsbox #CR25330R) for limiting the current to the LEDs. Any value between 270 Ω and 470 Ω works well.
- **Eight blue LEDs** (Jameco #2193889, Bitsbox #OP033) to show the binary number.
- **One 8-position DIP switch** (Jameco #696984, Bitsbox #SW098) to set the binary number.
- **A push button** (Jameco #119011, Bitsbox #SW087) to turn on the LEDs.

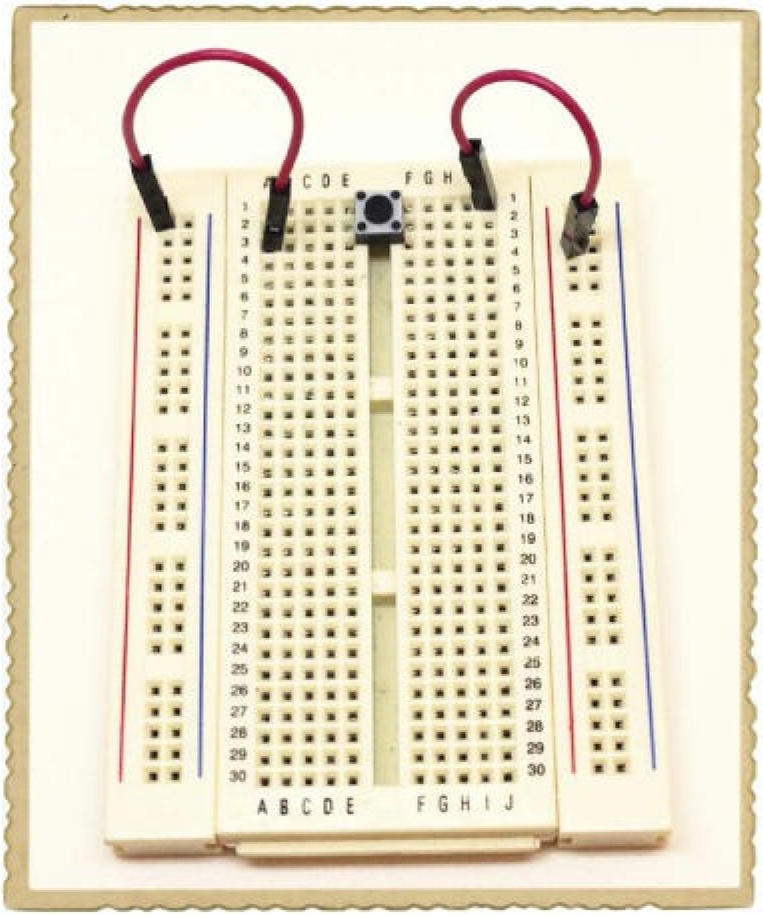
Step 1: Connect the Push Button

Plug the push button into the top of your breadboard. This project will take up a lot of space on your breadboard, so from here on, try to keep your components as close together as possible.

Connect a jumper wire from the top-right breadboard row, which should be connected to the upper pin of the push button, to the positive supply rail on the right side. Then, connect a jumper wire from the lower pin to the positive supply column on the left.

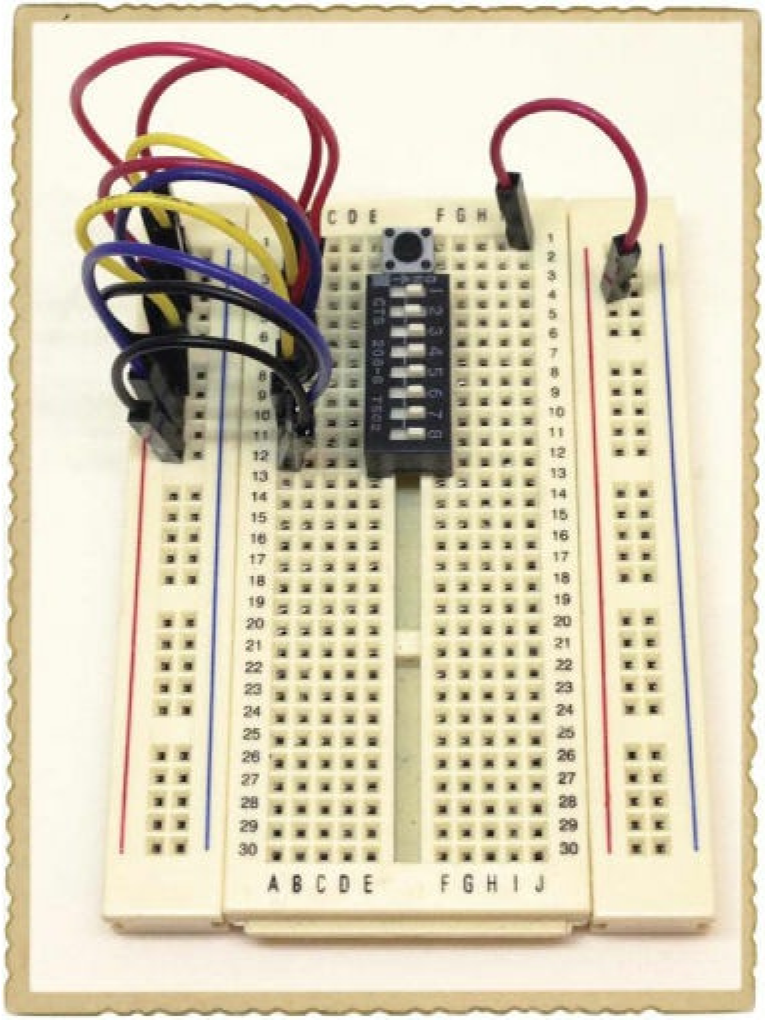
Your breadboard should look something like this:



This push button controls the connection from the battery's positive terminal to the rest of the circuit. When the button is not pushed, there's no closed loop for the current to flow through, and the circuit doesn't have power.

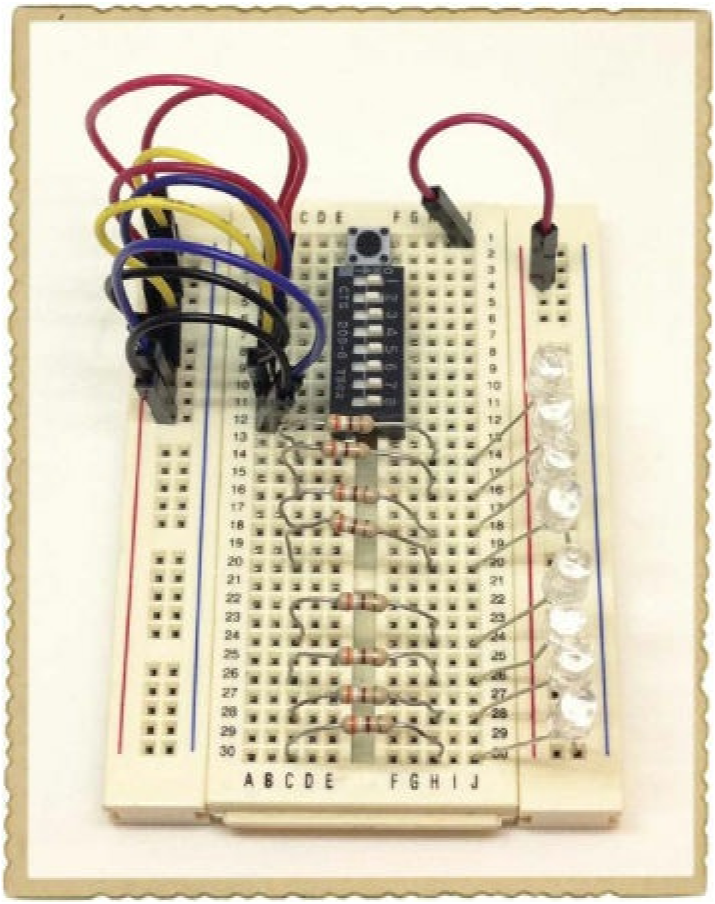
Step 2: Connect the DIP Switch

Next, connect the DIP switch to your breadboard just below the push button, with the numbers on the right side of the middle notch. Run one jumper wire from each of the eight rows to the positive supply column on the left, for a total of eight wires. You'll need to be able to set the switches on and off, so connect the wires as far away from the switch as possible to leave room for your fingers.

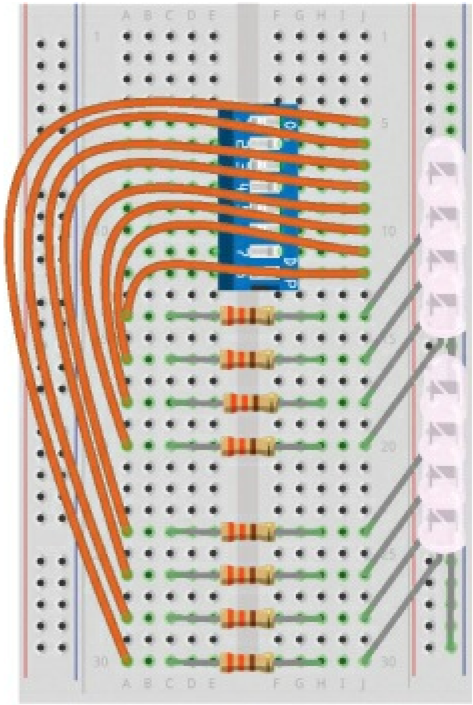


Step 3: Connect the LEDs

Now, connect one LED’s short leg to the negative supply column on the right, and connect its long leg to the last row at the bottom of your breadboard. Follow the same pattern upward to plug the rest of the LEDs into the breadboard on rows of their own, leaving one empty row between LEDs. (If you want to make it easier to read the LEDs, put your LEDs in two groups of four by leaving a couple of extra rows after the fourth LED.) Then, connect a resistor from each row with an LED to the same row on the left side of the notch in the middle of the breadboard.

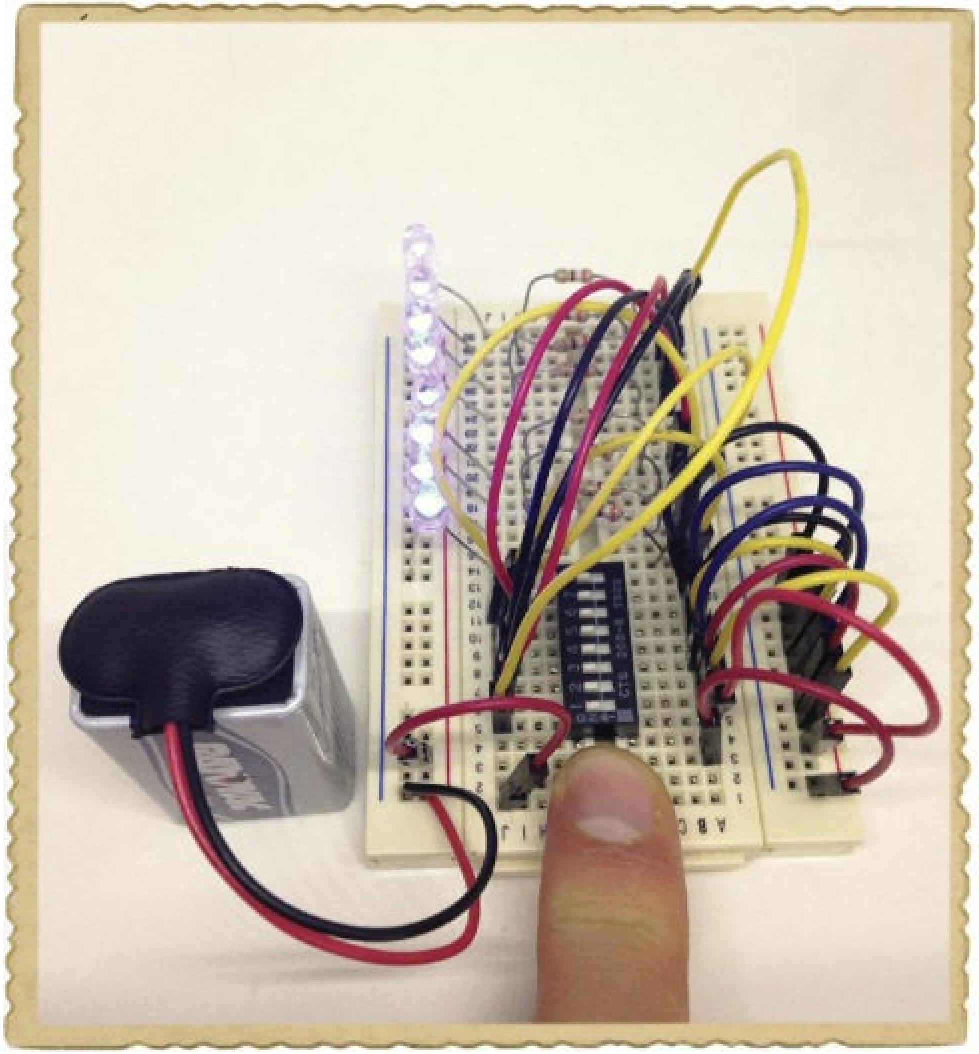


It will be best to connect the LEDs and switches so that you and your friend can sit on opposite sides of the board and see the bits in the same order, so pay careful attention to these connections. With your resistors in place, connect a jumper wire from each resistor row on the left side of the breadboard notch to a DIP-switch pin on the right side of the notch. Connect the resistor closest to the bottom of the breadboard to Switch 1, the next LED to Switch 2, and so on; you should end by connecting the top resistor to Switch 8.



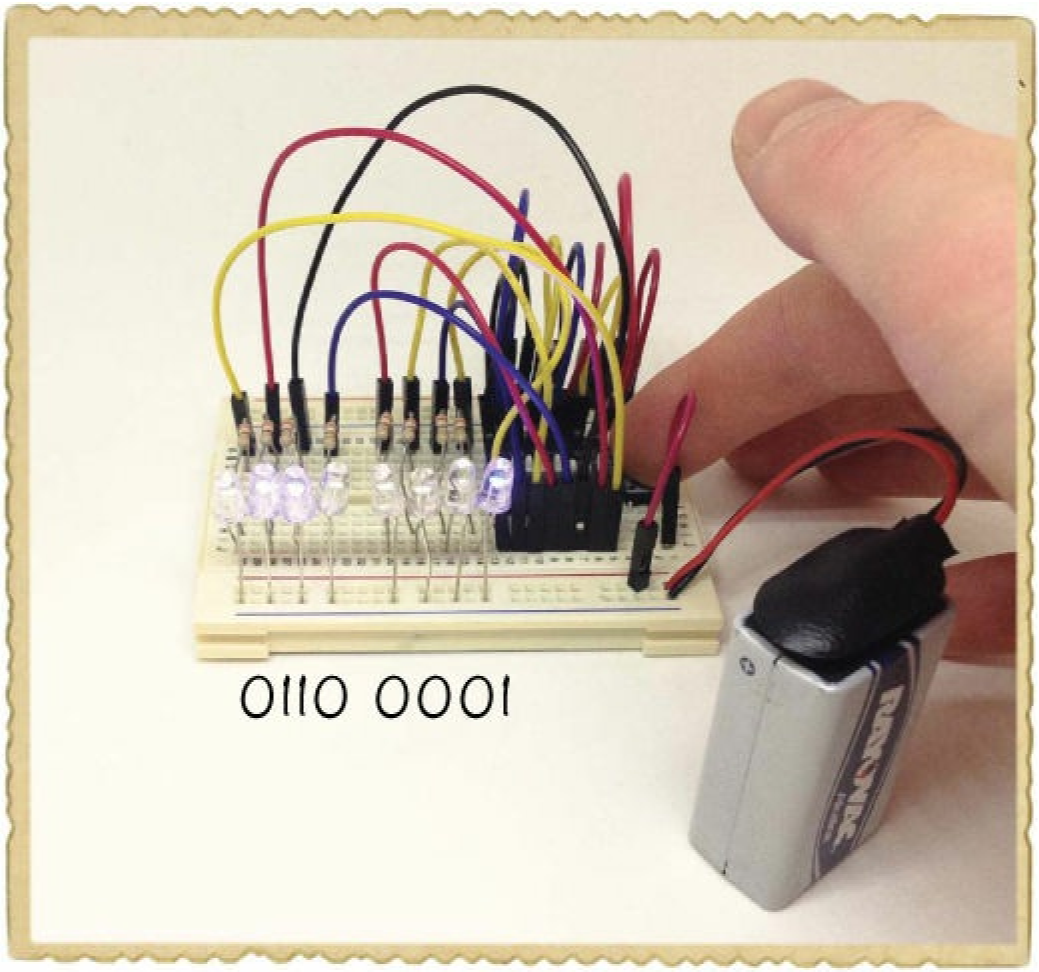
Step 4: Send a Secret Message!

Connect the negative side of the battery clip to the negative supply column, and then connect the positive side to the positive supply column, as shown.



Then, push all the switches in the “on” direction, press and hold the button to see whether all the lights light up, and turn off each LED one by one.

If all the LEDs work, it’s time to play! Invite a friend over and use this circuit to “talk” to them without speaking. Sit on opposite sides of a table, write down a word on a piece of paper for your own reference, and keep it hidden from your friend. Look at the ASCII code table and set the switches to the binary values for the first letter in your word. For example, the switch in the next photo is set to display a lowercase letter *a*.



When your switch bank is ready to show a letter, push the button so that the LEDs light up. Hold the push button while your friend writes down the binary value. Then, release the push button and set the binary value for the next character. Keep doing this until you've shown all the characters in your word. When you're done, show the ASCII code table to your friend so they can try to figure out your word.

Step 5: What If the Secret Message Machine Doesn't Work?

If you've been following along for the whole book, you've connected a lot of LED circuits, but this one does have a lot of components. It's easy to make a wrong connection somewhere, so if your circuit doesn't work right away, check each connection carefully against this project's circuit diagram.

If none of the lights work, first check that the battery's positive and negative terminals are connected correctly. Next, check that the LEDs are oriented the right way and that the resistors are the right values. If some lights work while others don't, then some of the LED or resistor legs may be touching when they shouldn't. Inspect them closely to find the error.

WHY COMPUTERS USE ONES AND ZEROS

Computers use ones and zeros instead of the decimal numbers from 0 to 9 because when you have only two values, it makes constructing electronic circuits to do calculations and store the values much easier.

For example, because each digit has only two possible values, one or zero, it's easy to create a simple memory block to store binary numbers using switches, as you did with the DIP switch in Project #20.

It's possible to save ones and zeros in many different ways, thereby creating *memory*. In the early days of computing, it was common to save sets of ones and zeros as physical cards with holes in them. Today, many hard disks save ones and zeros on magnetic disks, or even via electrons stored inside an integrated circuit.

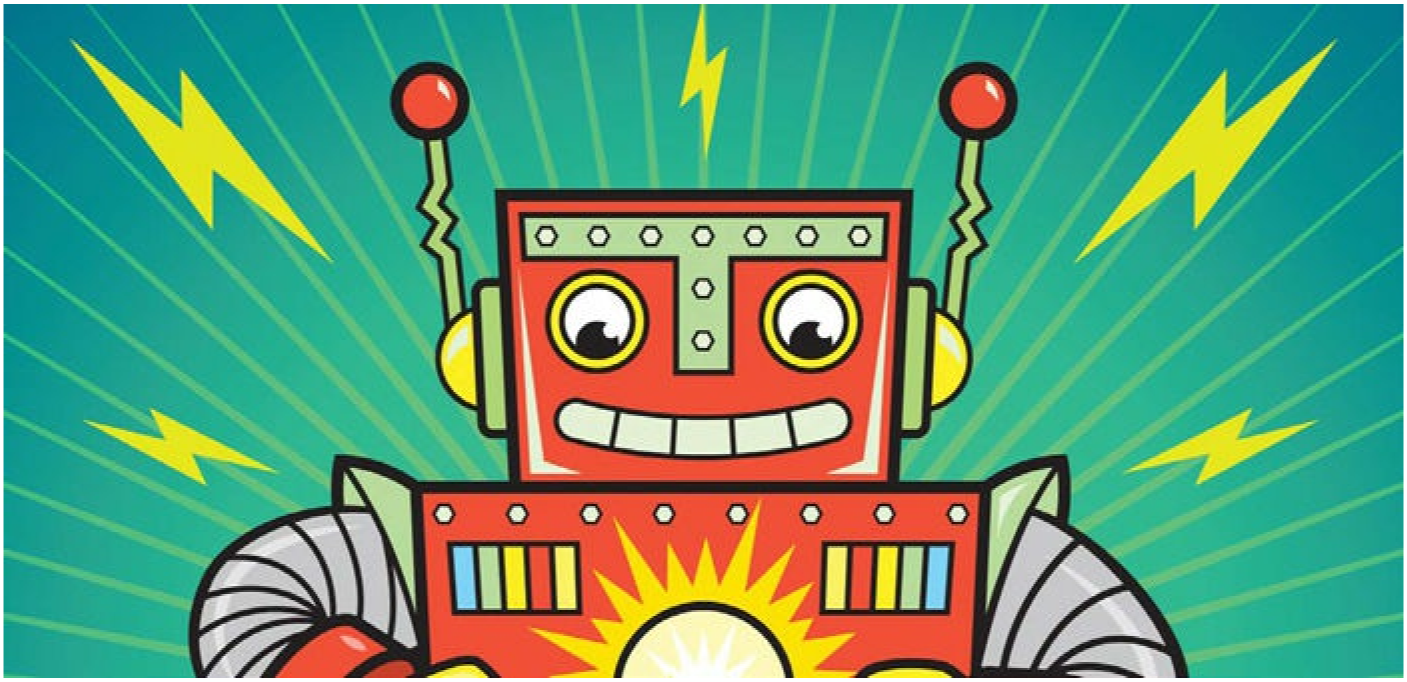
WHAT'S NEXT?

In this chapter, you learned how binary numbers work. You've seen how ones and zeros can be used to show images on your computer screen and how to decode a bunch of seemingly random ones and zeros into readable text. To explore binary numbers a bit more, come up with your own binary codes for the letters in the alphabet. There are 26 letters from *a* to *z*. How many digits do you need to represent all 26 letters? To figure this out, you can start by saying that the binary number 1 means *a*. The next binary number, 10, is *b*. Next, 11, is *c*. Write this down and keep increasing until you reach *z*. Then, count the number of digits you needed for the *z*. This is the minimum number of digits you need.

Here's another thing to try. Normally, if you count with your fingers, you can count to 10, right? If you don't use your thumbs, you can only count to 8. But what if you count in binary instead? A straight finger is 1, and a bent finger is 0. How high can you count with eight fingers now?

Digital values have another very important use: they allow you to create *logic circuits*, which make decisions based on whether certain wires see a high voltage or a low voltage. High is typically considered "true," and low is typically "false." If those wires are associated with simple true-or-false questions and the voltages are the answers, then you can think of the output from a logic circuit as a conclusion reached after asking a series of questions.

With logic, you can make circuits that do math, like adding two numbers, or circuits that do something only under a certain condition, like a door lock that opens only if you input the right combination of numbers. In Chapter 10, I'll show you some of the building blocks of digital logic and how you can make smart circuits with them.



10

CIRCUITS THAT MAKE CHOICES

Chapter 9 was all about ones and zeros, and you played with bits and bytes in a couple of projects. Now in this chapter, you'll make circuits that actually use ones and zeros to make decisions. *Logic gates* are components that check for the voltages that represent those ones and zeros and output a voltage accordingly. I'll show you a few types of logic gates and how you can use them to create a secret code detector.

IT'S ONLY LOGICAL

Logic is a way of reaching a conclusion based on pieces of information that you know to be true or false. For example, imagine you know the following statement is true, beyond a doubt:

> **Statement 1: If there are oranges in your fridge AND you have an orange squeezer, THEN you're able to make orange juice.**

If you trust the preceding statement, then there are two conditions to check before you can make orange juice:

> **Condition 1: There are oranges in your fridge.**
>
> **Condition 2: You have an orange squeezer.**

If you check your kitchen and find that these conditions are true, then you can logically conclude that you can make orange juice.

Computers use *Boolean logic*, which is a system of logic that works only with the values *true* and *false* to convert ones and zeros into actions. For a computer to know whether you can make orange juice or not, it would have to reach that conclusion through Boolean logic. Let's try thinking like a computer!

First, look for the conditions in Statement 1 that affect whether you can make orange juice or not. In this case, the conditions are the two phrases between "if" and "then," joined by "and." Assign them letters as follows:

> **There are oranges in your fridge. = A**
>
> **You have an orange squeezer. = B**

The conclusion is the statement after "then." Give it a letter, too:

> **You're able to make orange juice. = Q**

With these letters, you could rewrite Statement 1 as "If A and B, then Q." In Boolean logic shorthand, that looks like this:

A AND B = Q

This is a *logic equation*, where *AND* is an operator like addition or subtraction. When both statements on either side of AND are true, the conclusion Q is true.

Given Condition 1 and Condition 2, A and B are both true. Substitute both into the equation to get:

True AND True = Q

Q = True

Because both A and B are true, then Q must be true. Time to make orange juice!

How a Computer Decides When It Can Make Orange Juice

Condition A (There are oranges in your fridge.)	Condition B (You have an orange squeezer.)	Result Q (You're able to make orange juice.)
False	False	False
False	True	False
True	False	False
True	True	**TRUE!**

MEET THE LOGIC GATES

Many of the circuits inside your computer are physical versions of logic equations, complete with smaller circuits called *logic gates*, which are physical logical operators. A logic gate takes ones and zeros—representing true and false, respectively—as inputs and then outputs a 1 or 0 based on the results of the equation inside.

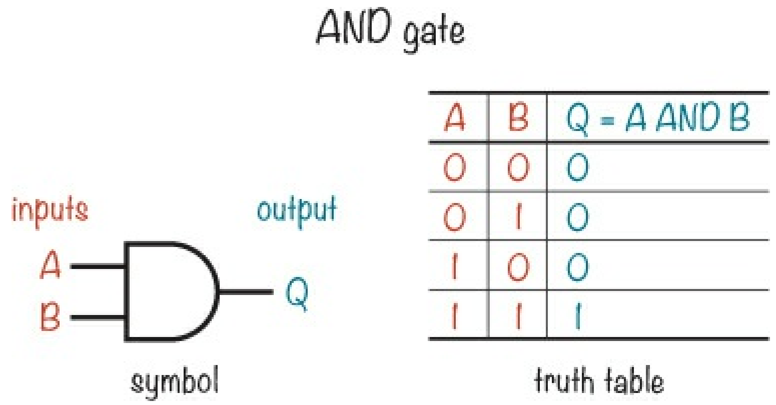
You can make really awesome projects with logic gates yourself, too!

I remember the first time my dad told me about logic gates: I went straight to my room and spent hours trying to combine them on paper in different ways to add binary numbers. I hope you have as much fun with them as I did! Now, let's look at how a few different logic gates work.

AND Gates Check for Two True Inputs

The *AND gate* is the physical form of the AND operator you used to decide whether you were able to make orange juice. An AND gate has two or more inputs—A and B, for example—and one output—Q, for example. It checks whether A and B are both 1, and if they are, then Q is 1; otherwise, the output is 0. Q is 1 only if both A *and* B are 1; if one or both inputs are 0, the output is 0.

I find it helpful to write out the values of Q that result from different input combinations in a *truth table*. This truth table shows all possible input combinations for the AND gate and what the output will be for each. In a truth table, 0 stands for *false*, and 1 stands for *true*.



AND gate

OR Gates Check for One True Input

The *OR gate* checks whether input A *or* input B is 1. If either is 1 or both are 1, then the output Q is also 1. But if both inputs are 0, then the output is 0.

NOT Gates Flip Inputs

The *NOT gate*, also called an *inverter*, has only one input and one output, and its function is very simple: the output is the opposite of the input. If the input is 1, then the output is 0. If the input is 0, the output is 1.

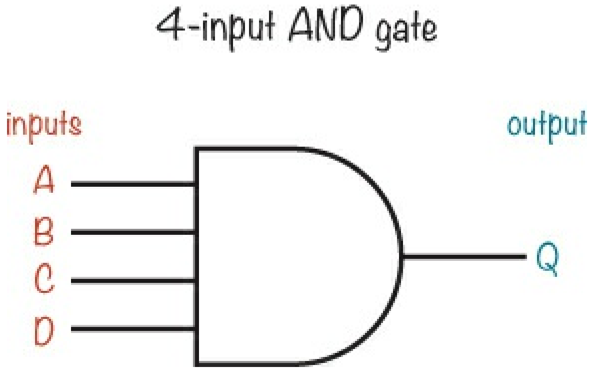
A Bigger AND Gate

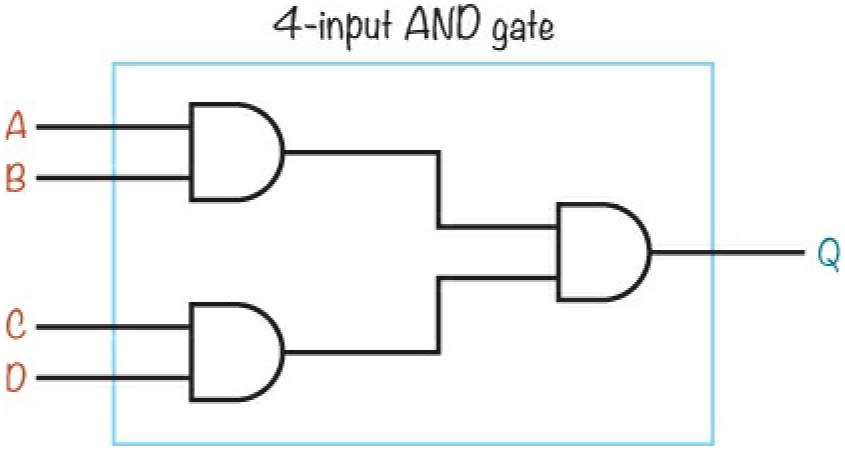
AND gates and OR gates can have more than two inputs. For example, here’s a 4-input AND gate symbol:



Because it’s an AND gate, the result will be 1 only if all four inputs are 1; otherwise, it will be 0. That is, the output Q is true (1) if all four inputs—A, B, C, and D—are true (1):

Q = A AND B AND C AND D

We can also make a 4-input AND gate from three 2-input AND gates, like this:



HOW TO DRAW LOGIC CIRCUIT DIAGRAMS

You can use logic gates to build a circuit that checks for conditions and decides what to do based on them. For example, imagine you could deactivate your alarm system from Chapter 1 by entering a secret code. Then, you could leave the alarm system on while you’re gone, and if someone opened the door, they’d have to know the right code to turn the alarm off. With logic gates, a circuit can check easily whether the right code was entered.

A Logic Equation for a Secret Code

Let’s say the secret code is 1001, and when the secret code is detected, an LED should turn on to indicate success. When building logic circuits, it’s helpful to write the logic equation for your circuit before building, so let’s practice.

First, think about what each 1 and each 0 in the secret code represents in terms of logic gates. In this case, you want the LED to turn on only when four conditions are true, and you can connect those conditions with AND operators as follows.

Let’s represent the four bits in the secret code with the letters *W*, *X*, *Y*, and *Z*. Then, you can check each bit to see whether it’s the correct value, testing for W = 1, X = 0, Y = 0, and Z = 1.

You’ll need to AND the four secret code bits together using a 4-input AND gate. But simply connecting W, X, Y, and Z straight to the AND gate would give this logic equation:

Q = W AND X AND Y AND Z

This would test whether all the bits are 1 because Q = 1 only if W, X, Y, and Z are all 1. Instead, you need to test for the secret code where W and Z are 1, but X and Y are 0.

Fortunately, in Boolean logic, you have only two options: 1 or 0 (true or false). If something is 0, then it is NOT 1; in words, if something is false, then it is NOT true. This means that if X = 0 (false), then NOT X = 1 (true). Knowing that, you can rewrite the equation as follows:

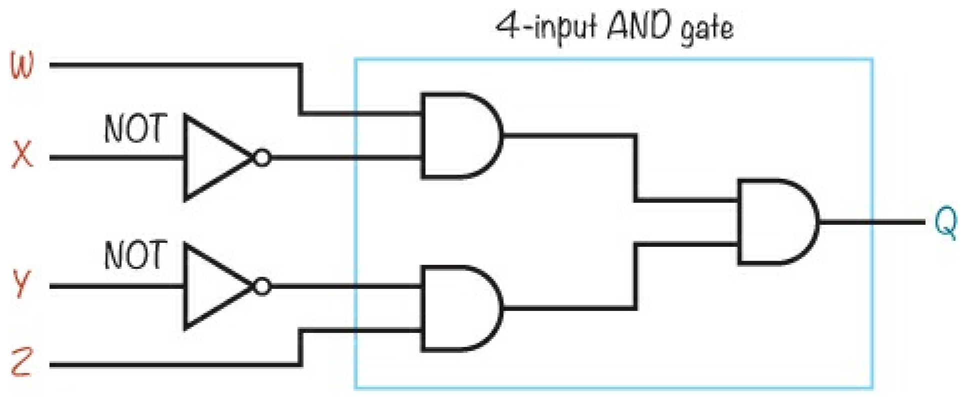
Q = W AND (NOT X) AND (NOT Y) AND Z

This equation uses NOT on bits X and Y, which should be 0 for the secret code. The NOT will invert their values, changing 0 to 1 and 1 to 0.

Converting a Logic Equation into a Circuit Diagram

Now we'll draw the secret code equation as a circuit. The final output will be a single 1 or 0. You need a 4-input AND gate to test all four code bits at once, and you're going to make this using three 2-input AND gates as explained earlier. Because you need to test whether the X and Y bits are 0, you'll need to use a NOT gate for each to invert the 0 to 1.

Here's the final circuit:



A logic circuit that checks for a secret code (1001)

The first bit (W) should be a 1 and the second (X) should be a 0, so the second bit gets a NOT gate. The third bit (Y) has a NOT gate as well, and it goes into an AND gate with the fourth bit (Z).

The first AND gate should output 1 if it sees W = 1 and X = 0, and the second AND gate should output 1 if it sees Y = 0 and Z = 1. If both of those AND gates output 1, then so will the third AND gate, which ultimately confirms that 1001 was entered.

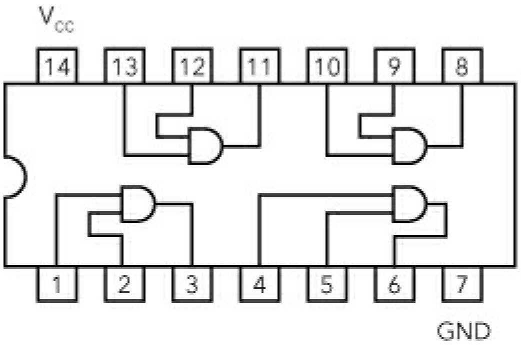
TRY IT OUT: DRAW MORE LOGICAL STATEMENTS AS CIRCUITS

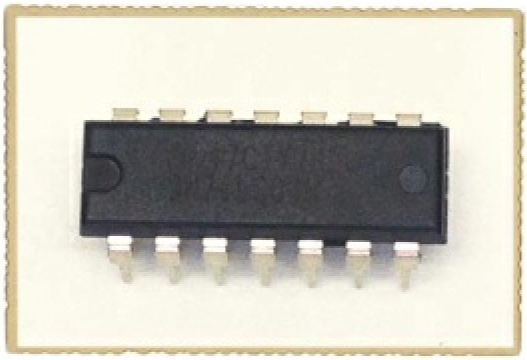
Now that you've seen the basics, transform a few logical statements of your own into logic circuits on paper. For example, how might you draw up plans for a "Can I Make Orange Juice?"

decision maker? Create one based on the statements under “It’s Only Logical” on page 214.

USING LOGIC GATES IN REAL LIFE

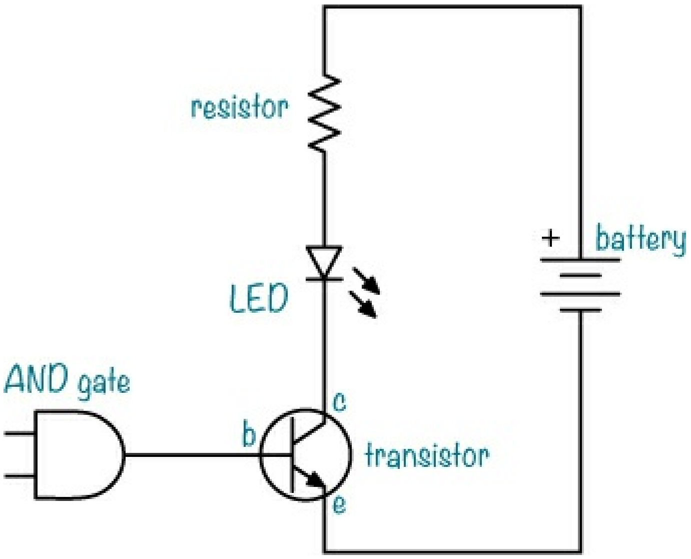
When I learned about logic gates, I thought they’d be small two- and three-legged components. But logic gates come boxed inside integrated circuits (ICs). Each IC contains several gates, so even if you want to use just one, you’ll have to use an IC anyway.





It’s also important to know that logic gate outputs don’t supply much current. Even if a logic gate outputs 5 V, that doesn’t mean that you can connect your 5 V motor to it. The logic gate simply can’t give enough current for the motor to run.

Recall from Chapter 7 that a transistor needs only a little current flowing into its base to turn on and let a lot more current flow from its collector to emitter. When you want to use a logic gate to turn on a circuit or component that requires more current, you can connect the logic gate to a transistor. Do you remember the circuit from “Project #14: Build a Circuit that Senses Touch” on page 136? You can modify this circuit to turn on an LED from a logic gate, like this:



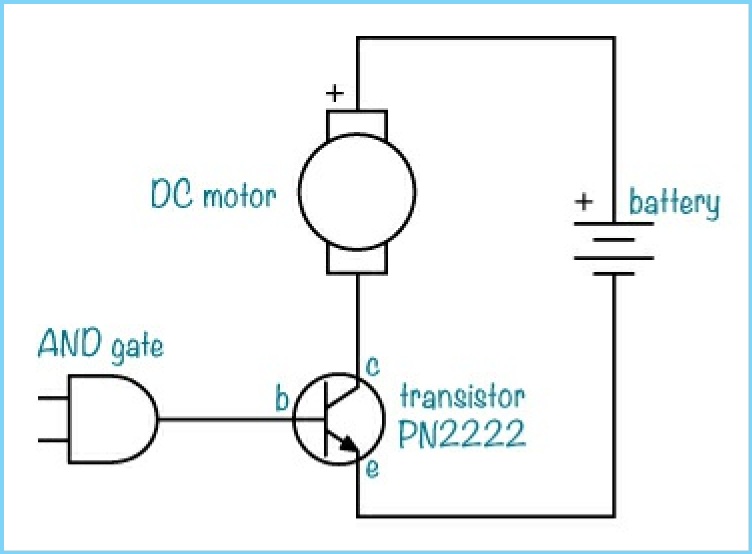
I’ll show you how to incorporate this into a project in the next section.

MORE ABOUT CURRENT, COMPONENTS, AND TRANSISTORS

You can easily replace the LED and resistor with something else that you want to control, like a motor, a fan, or a relay. But when doing this, be mindful of the current. How much current does your motor need, and how much current can the transistor handle?

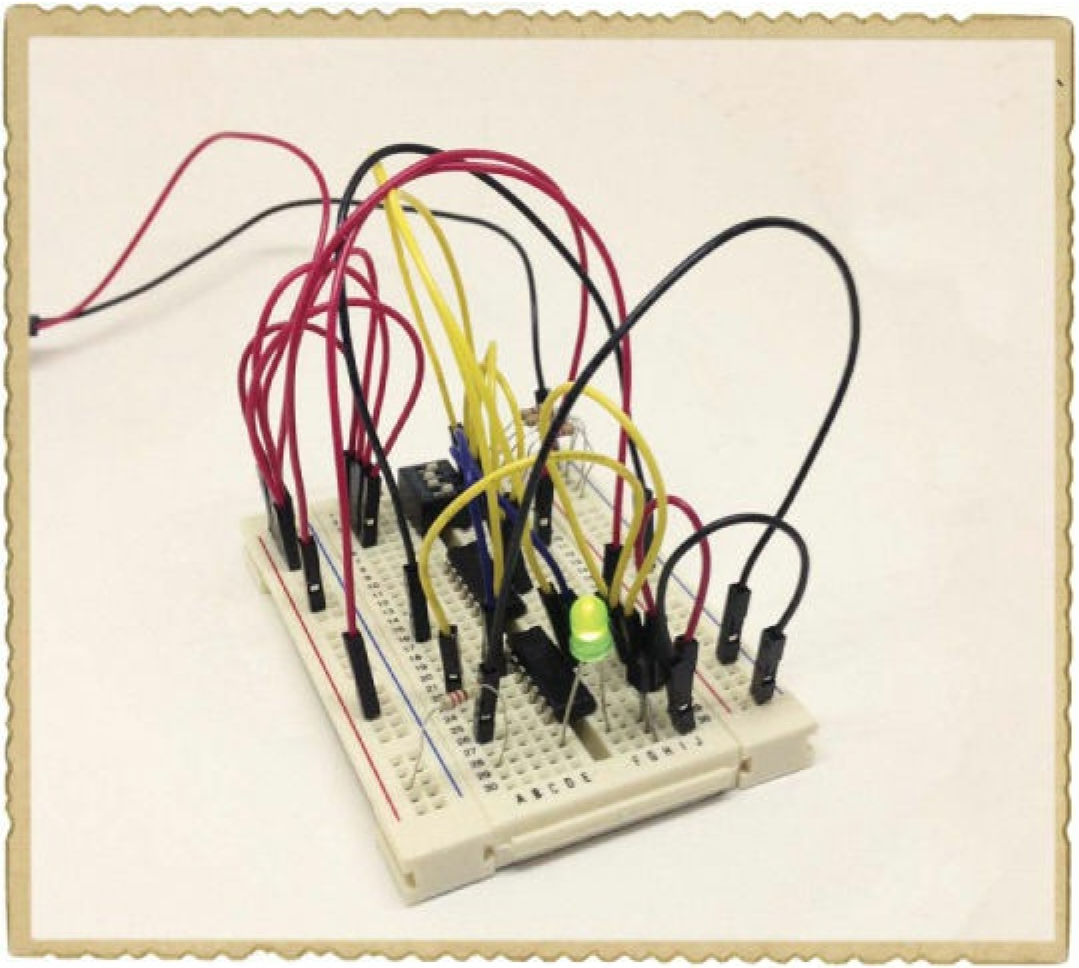
Both values can be found in the components' datasheets. For transistors, the value you are looking for is called I_C, or *collector current*. According to the datasheet of a BC547 transistor, its maximum collector current is 100 mA. That's more than enough to power an LED, which usually uses about 15 to 20 mA at the most.

But what if you want to connect a motor? First, you'd need to find out how much current the motor needs, and you'll find that in the motor's datasheet. If a motor needs 500 mA, you'll need to connect it to a transistor that can handle more than 500 mA of current. For example, a PN2222 transistor can handle up to 600 mA, so it should be able to switch the motor on and off.



PROJECT #21: A SECRET CODE CHECKER

In this project, you'll build a logic circuit that checks whether a set of four input bits matches a secret code. You'll use four switches, inside one DIP switch, to set the code. If the input bits match the code, then the logic circuit should output a voltage, representing a 1; otherwise, it should output zero voltage, to indicate 0. This final output will go to a transistor so you can use it to control something—like an alarm!



The basic Secret Code Checker circuit turns on an LED when you input the right code. At the end of the project, I'll show you how to use the Secret Code Checker to disarm your intruder alarm from Chapter 1.

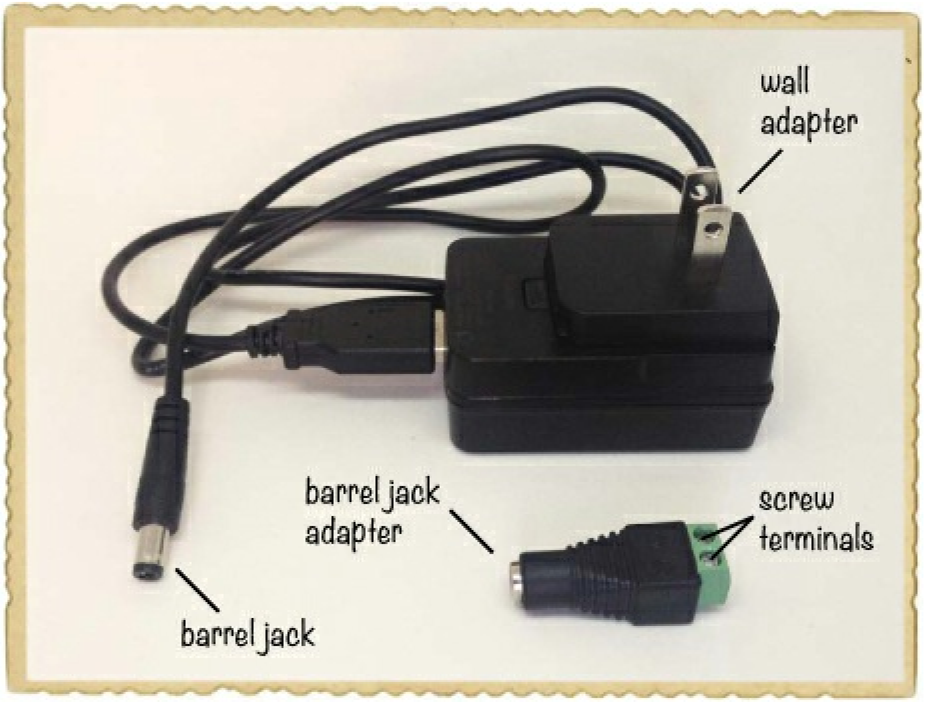
How to Use Other Voltages with a Breadboard

You've used 9 V batteries for each circuit in this book so far, but most digital circuits need to use lower voltages. For example, a lot of ICs with logic gates inside use 5 V instead. But 5 V is not a standard battery value; there are 4.5 V and 6 V batteries, but not 5 V.

What can you do when your circuit requires 5 V? Say hello to the *wall adapter* and the *barrel jack adapter*.



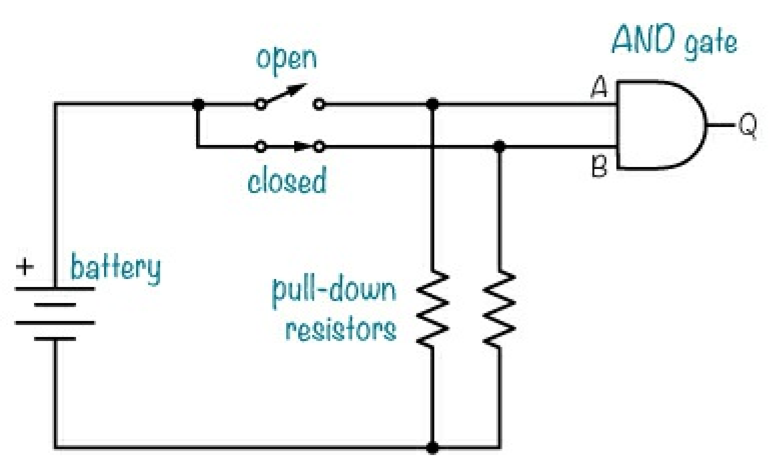
Many electronic devices use wall adapters to recharge batteries or just to stay powered. The pronged side of a wall adapter plugs into a wall socket, and the other side plugs into something you want to power. Wall adapters come in many values, and this project uses a 5 V DC regulated adapter.

To supply power to a circuit, the wall adapter in this project needs to plug into a barrel jack adapter. The barrel jack adapter listed in this project's Shopping List (page 224) has two *screw terminals*, where you can plug in jumper wires that connect to the breadboard. You can connect any wall adapter with the standard round plug into this barrel jack adapter.

MAKING CIRCUITS MORE RELIABLE

If a circuit needs an input voltage and you don't connect the input to anything, then that input is *floating*. A floating input is unreliable because the circuit may see it as a 1 or a 0, and you can't control which.

The individual switches on a DIP switch are either open or closed. When the switch is open, the input it controls will be floating if it's not connected to anything else. To fix this, you can attach a *pull-down resistor* to each input on the logic gates, like this:

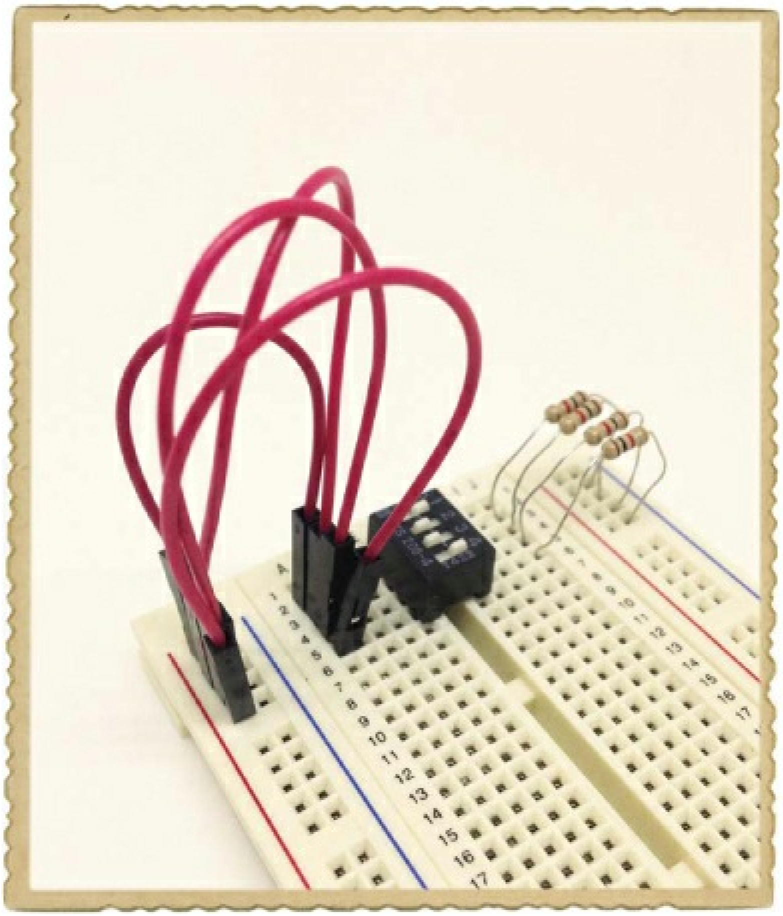


Each pull-down resistor in this circuit diagram connects to a switch and a gate input on one side and to the negative battery terminal on the other. When a switch is open, the resistor "pulls" the gate input down to 0 V, which is a 0. When a switch is closed, the gate input connects to the positive terminal and gets the positive supply voltage, which is a 1.

In this project's circuit diagram on page 224, there are four switches with 1 kΩ pull-down resistors. All of them are shown as open, and all of the AND gate inputs would be 0 in that state.

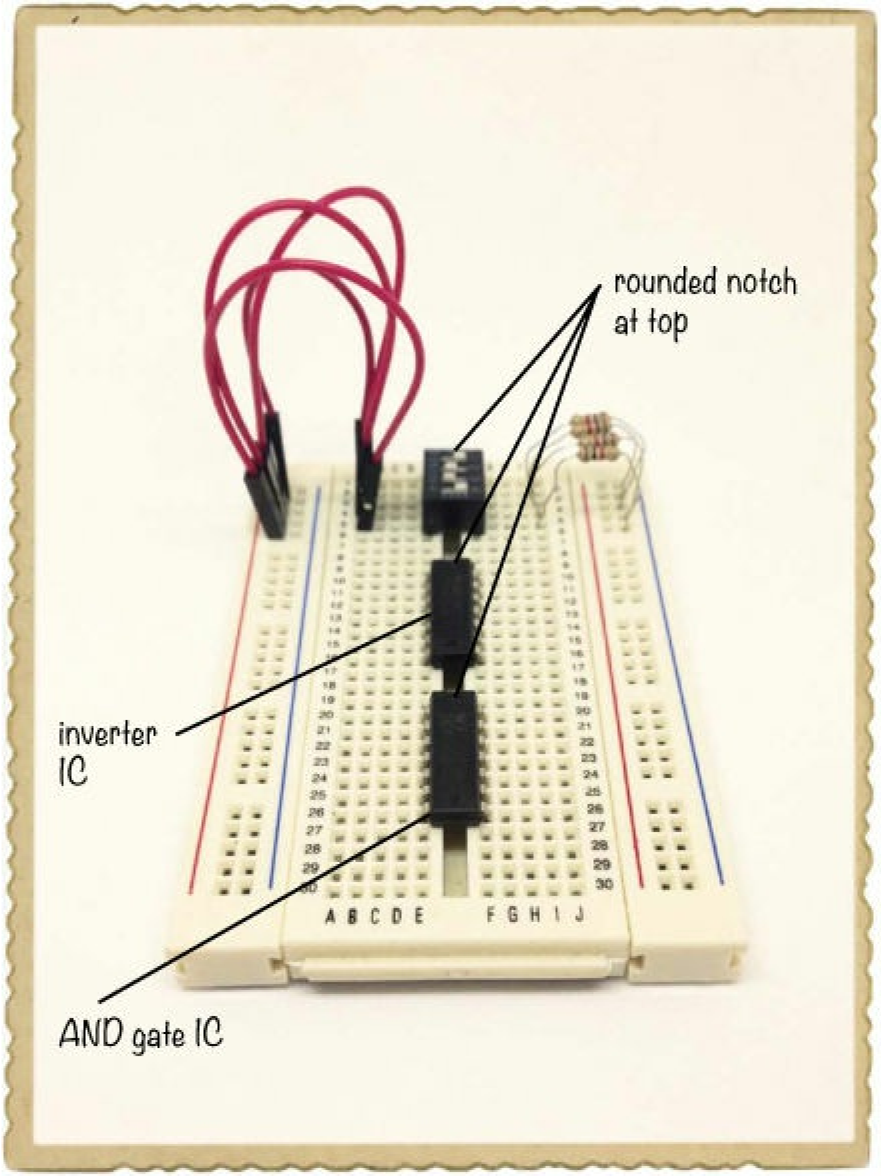
Step 1: Place the Switches and Resistors

Plug your DIP switch in at the top of the breadboard, with one side of the switch on each side of the notch in the middle. Use jumper wires to connect the left side of each DIP switch to the positive supply rail on the left, and connect a 1 kΩ resistor from the right side of each DIP switch to the negative supply rail on the right.



Step 2: Place the ICs

Place the IC with NOT gates, marked *74LS04*, in the middle of the breadboard and place the IC with AND gates, marked *74LS08*, farther down. For both ICs, point the rounded notch toward the DIP switch. Leave at least three rows at the bottom of the breadboard for the transistor.



Step 3: Place the Transistor and LED

Plug your transistor into three rows at the bottom of the breadboard. If you used the BC547 transistor from this project’s Shopping List (page 224), face the flat side left so that the collector is the upper pin, the base is the middle pin, and the emitter is the bottom pin. If you used a different NPN transistor, check its datasheet to see which pin is which.

Connect the LED’s short leg, the cathode, to the same row as the collector. Connect the LED’s long leg, the anode, to an empty row on the left side of the breadboard. Finally, connect the 220 Ω resistor from the LED’s anode to the positive supply rail.

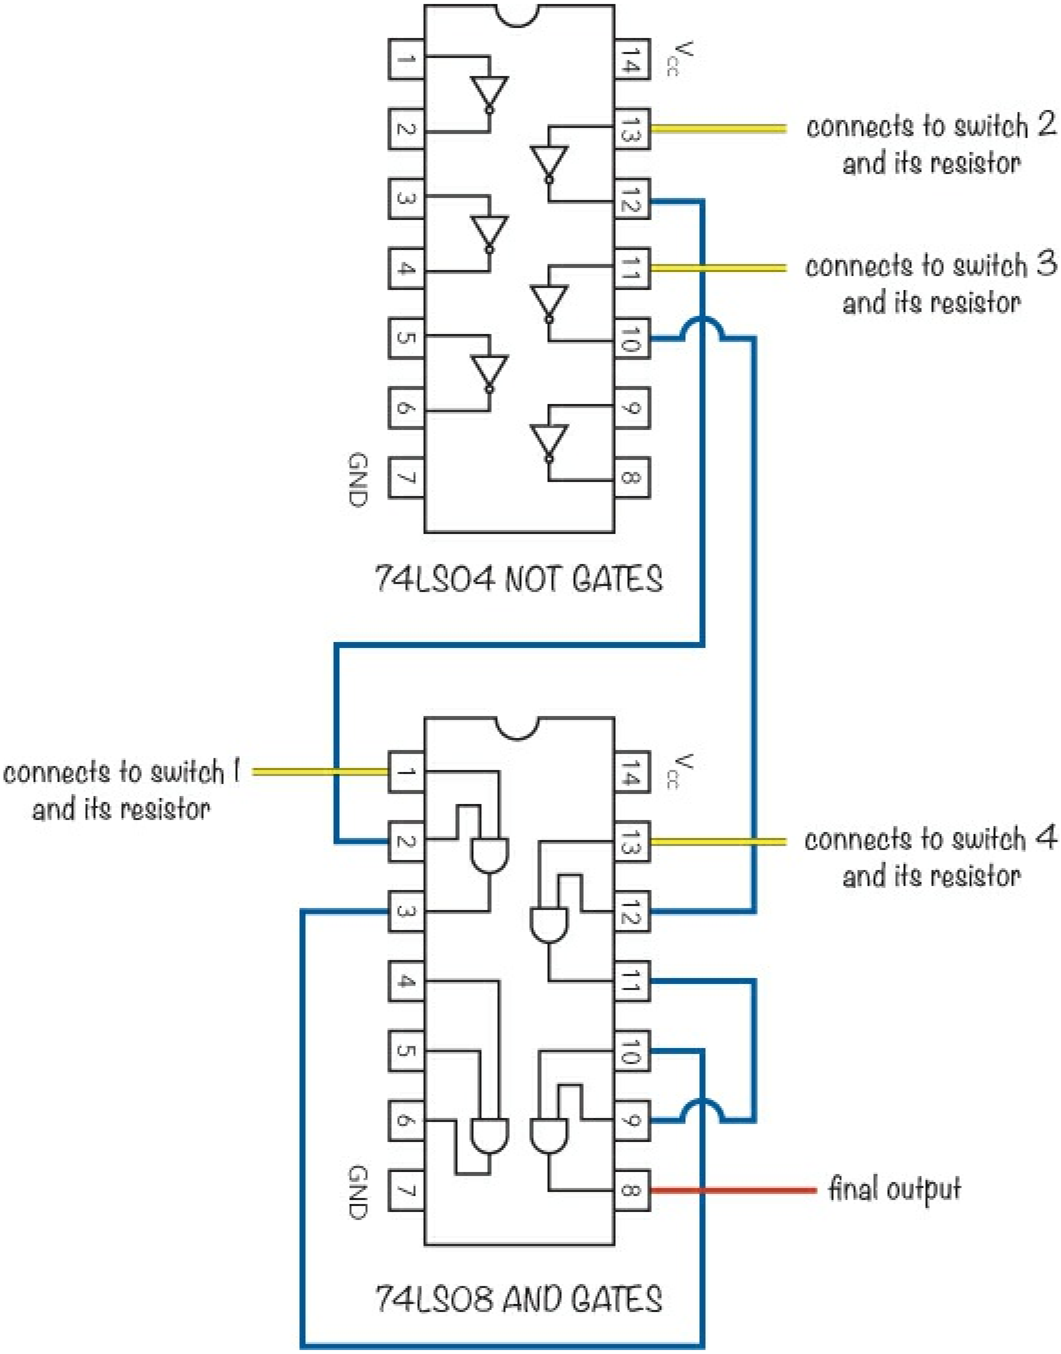
Step 4: Build the Logic Circuit

First, look at the following diagram to see where the AND and NOT gates are inside your ICs and to see the connections you need to make.



V_{cc}
connects to switch 2 and its resistor
connects to switch 3 and its resistor
GND
74LS04 NOT GATES

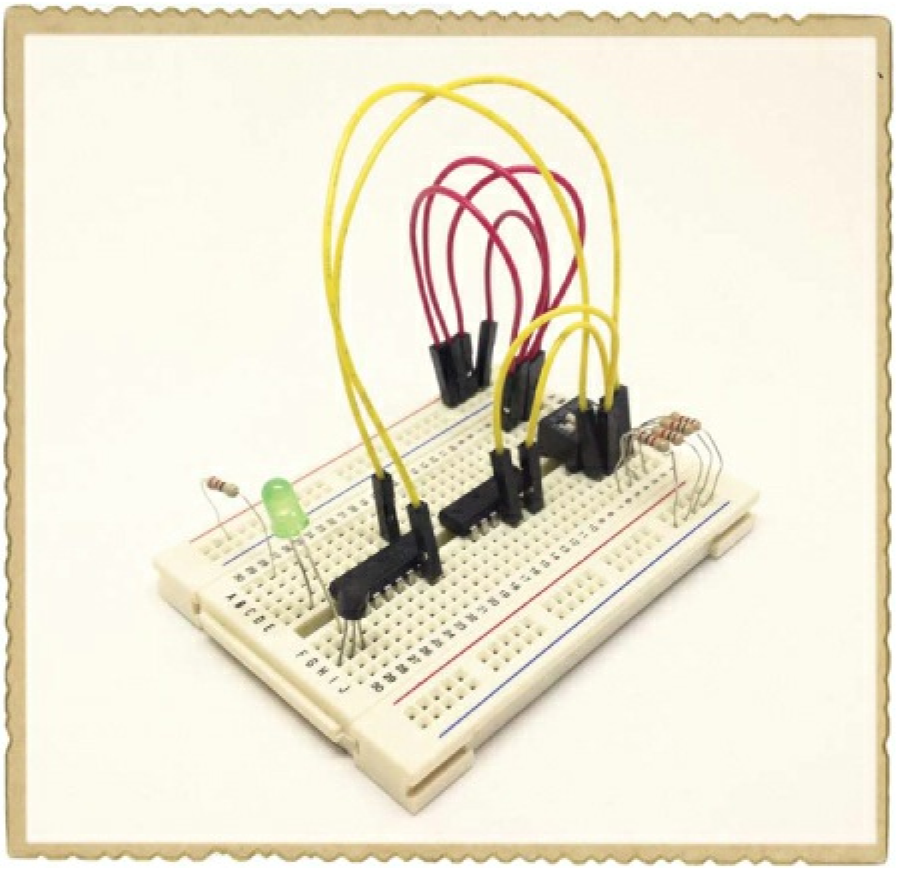
connects to switch 4 and its resistor
final output
74LS08 AND GATES
1 2 3 4 5 6 7 8 9 10 11 12 13 14

Take four jumper wires and connect them from the switch outputs to the gate inputs as follows:

- The output from switch 1, the uppermost switch, goes to the AND gate input on pin 1 of the lower IC (74LS08).
- The switch 2 output goes to the NOT gate input on pin 13 on the upper IC (74LS04).
- The switch 3 output goes to the NOT gate input on pin 11 on the upper IC.
- The switch 4 output goes to the AND gate input on pin 13 of the lower IC.



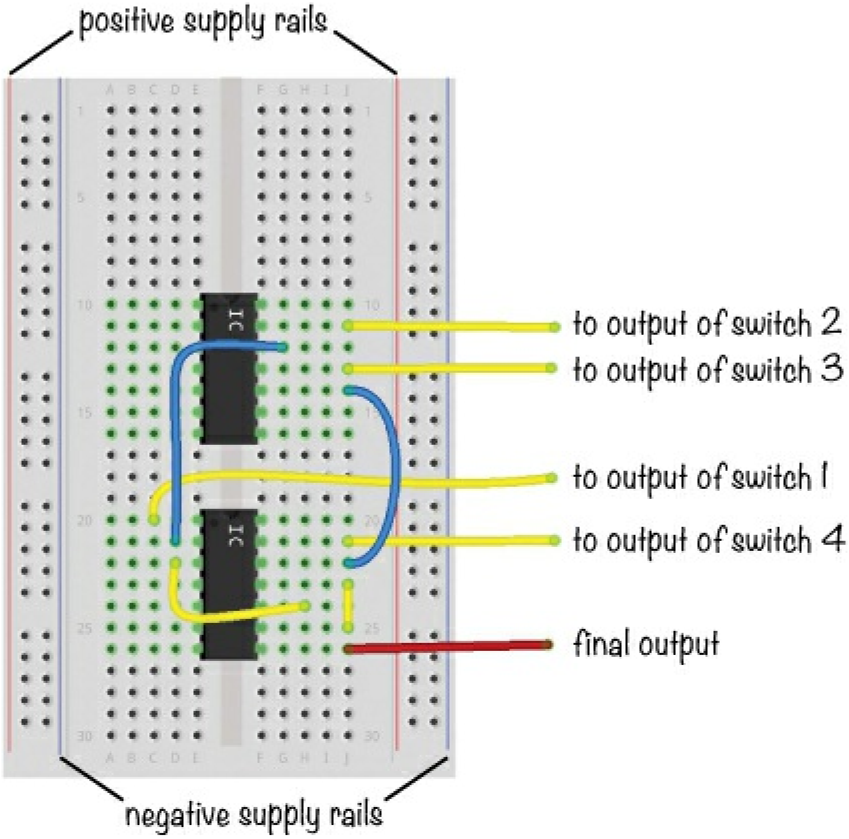
Next, get two jumper wires to connect the outputs of the NOT gates to the AND gate inputs like this:

- One jumper wire goes from pin 12 on the upper IC to pin 2 on the lower IC.
- The other jumper wire goes from pin 10 on the upper IC to pin 12 on the lower IC.

Now, each output from the AND gates needs to go into the third AND gate, as follows:

- Connect one jumper wire from pin 3 to pin 10 of the lower IC.
- Connect another jumper wire from pin 11 to pin 9 on the lower IC.
- Finally, connect a jumper wire from the final output of the AND gate with the other side hanging loose for now.

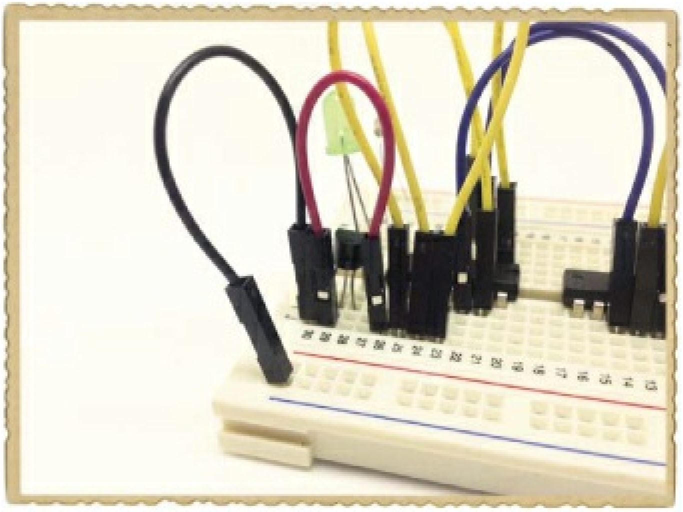
Your IC connections should look like this:



positive supply rails
IC
IC
to output of switch 2
to output of switch 3
to output of switch 1
to output of switch 4
final output
negative supply rails

Step 5: Finish Wiring the Transistor

Now, connect the output from the final AND gate—pin 8 of the lower IC—to the base of the transistor. This output will control whether the transistor allows current to pass through to the LED or not. Connect a jumper wire from the emitter of the transistor to the negative supply rail.



PROTECTING YOUR COMPONENTS

The circuit for this project relies on the fact that gates supply only a tiny amount of current to the transistor base. Your transistor will be perfectly fine while you use your secret code checker, but to protect the transistor base from damage by larger currents in other circuits, you should place a resistor around 1 to 10 kΩ between the transistor base and its current source—in this case, the AND gate output.

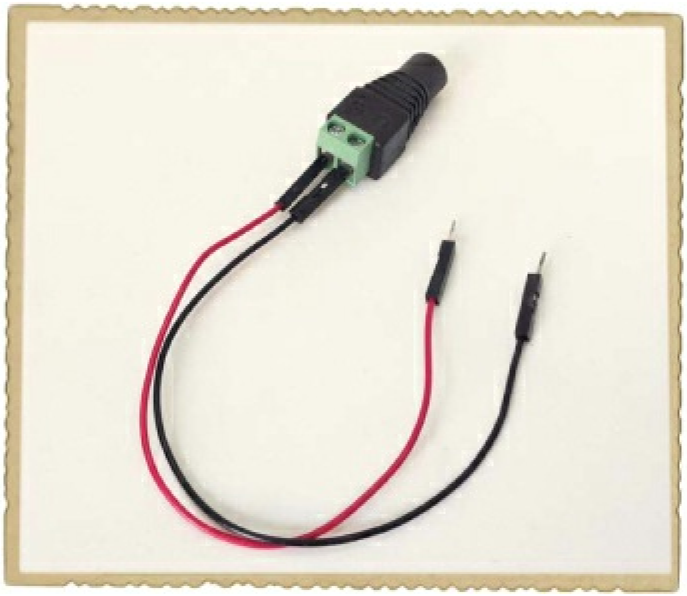
Transistors also should usually be protected in motor circuits, like the one in “More About Current, Components, and Transistors” on page 222. That circuit should work as is, but to be really careful, it’s good to connect a diode across the motor, with the cathode on the positive side. That should protect the transistor from any high-voltage spikes that might happen when the motor is switched off.

Step 6: Power and Test the Secret Code Checker

Connect jumper wires from pin 14 on both ICs to the positive supply rail and from pin 7 of both chips to the negative supply rail. Then, turn off all the switches on the DIP switch and connect your 5 V source, with plus to the positive supply on the left and minus to the negative supply on the right.

Use your barrel jack adapter with a couple of jumper wires to make this connection. The barrel jack adapter should have + and – markings to tell you which supply is which. Just loosen the screws on the adapter, insert a wire into each, and tighten the screws again. Follow the conventional color code by using a red wire for positive and a black wire for negative so you will be sure to connect them the correct way on your breadboard.

The LED should stay dark when the switches are off, but when you set the code to 1001 by switching on the top and bottom switches, it should light up.



Step 7: What If the LED Doesn’t Light Up?

First, check that the two ICs have power. Do both ICs have pin 14 connected to the positive supply column and pin 7 connected to the negative supply column? If you find the ICs become too hot to touch, disconnect the 5 V power supply from the wall immediately and wait for the ICs to cool down. Then, make certain you have the supply connections the correct way before trying again. The wire plugged into the barrel jack adapter’s positive (+) terminal should be plugged into the positive supply column on the breadboard, and the wire in the barrel jack adapter’s negative (–) terminal should be plugged into the negative supply column.

If the ICs are powered and the circuit still doesn’t work, then check the input values on the switches. Use a multimeter to measure the voltage from the negative supply rail to the pins on the

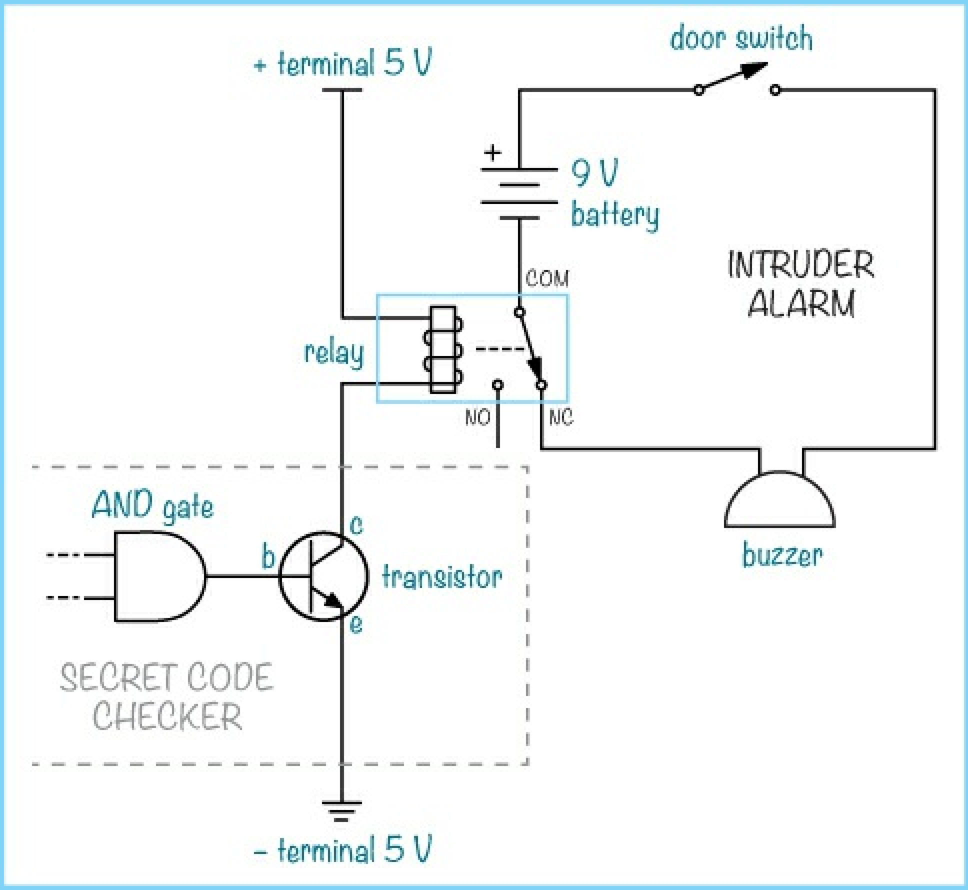
AND and NOT gates that take inputs from the switches. You should get 5 V on pins 1 and 13 of the AND IC and 0 V on pins 11 and 13 of the NOT IC. Check that the output from each AND gate you're using is 5 V, too; you should see 5 V on pins 3, 8, and 11. If any AND gate in the IC doesn't output 5 V, then one of its inputs is 0 V. Figure out why it's 0 V, and you should find the problem.

TRY IT OUT: DISARM YOUR INTRUDER ALARM

Instead of an LED and a resistor, you can connect a relay to the Secret Code Checker and combine this project with the intruder alarm you built in Chapter 1. Connect the 9 V battery to the intruder alarm through the relay so that when you input the right code, the power to the alarm is cut and the noise stops. Refer back to "Meet the Relay" on page 97 to see how to connect a relay.

Notice that the secret code checker, with its 5 V supply, is being used to control the completely separate intruder alarm circuit with a 9 V supply. Connecting two circuits with separate power supplies this way is okay because there's no electrical connection between the two circuits. Relays are useful when you need to control a circuit with a different type of power supply!

Here's the circuit:



And these are the components you'll need:

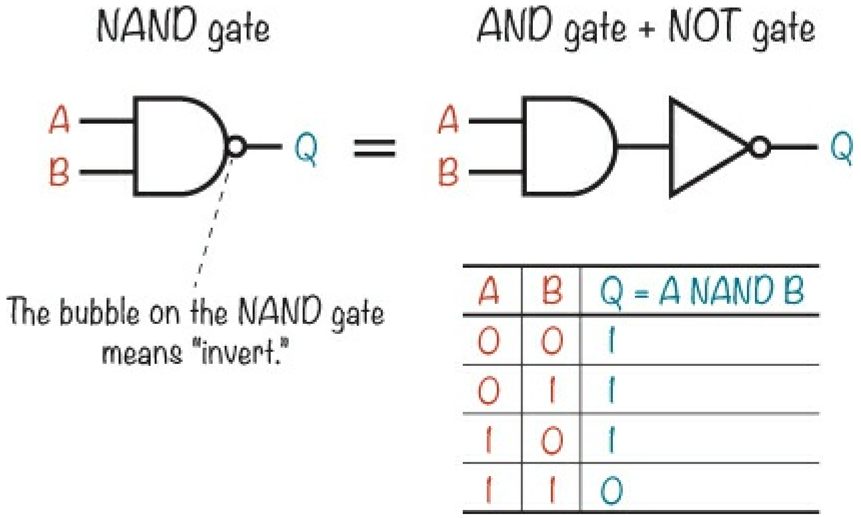
- **The circuit from "Project #2: Intruder Alarm" on page 11**
- **The circuit from "Project #21: A Secret Code Checker" on page 223**
- **A 5 V relay** (Jameco #842996, Bitsbox #SW073)

NEGATIVE LOGIC GATES

AND, OR, and NOT are basic logic gates, and you can combine them to create new ones. Let's look at two more gates that are created this way.

NAND Looks for One False Input

The *NAND gate* works like an AND gate with a NOT gate inverter on the output. The little circle on the output means NOT. That means the output from the NAND gate is 0 when both A and B are 1.

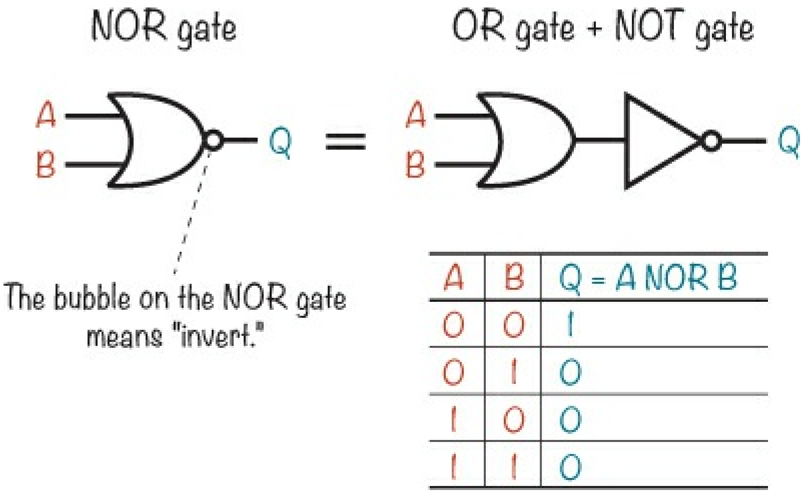


The bubble on the NAND gate means "invert."

A	B	Q = A NAND B
0	0	1
0	1	1
1	0	1
1	1	0

NOR Looks for Two False Inputs

The *NOR gate* works like an OR gate with an inverter on the output. The output is 1 when both A and B are 0.



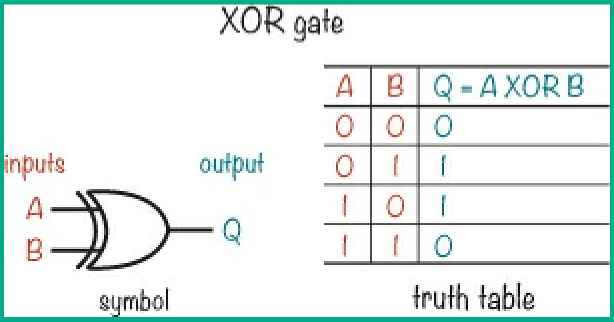
The bubble on the NOR gate means "invert."

A	B	Q = A NOR B
0	0	1
0	1	0
1	0	0
1	1	0

WHAT'S NEXT?

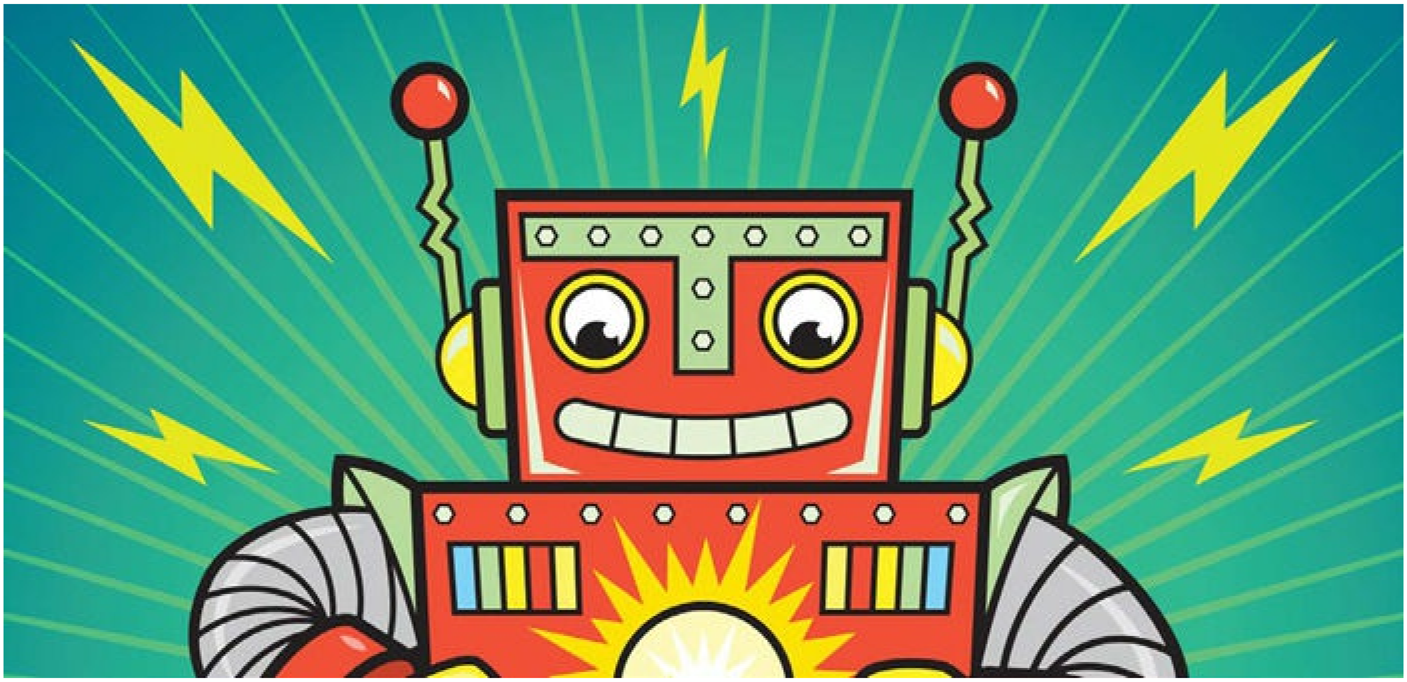
In this chapter, you learned how to use logic gates to build circuits that "decide" things, like whether a code is correct or not. And at the end, you got to see some negative logic gates as well. Understanding how negative logic gates work is helpful, because they are often used in real-life circuits. In fact, you'll use them in Chapter 11.

If you want to explore gates a bit further, I suggest you try combining some logic gates you've learned about on paper to create an *XOR gate*. An XOR gate gives out 1 only if the inputs are different from each other.



A	B	Q = A XOR B
0	0	0
0	1	1
1	0	1
1	1	0

By combining logic gates in different ways, you can create almost anything you can imagine. But that might be a bit hard to see right now, so in the next chapter, I'm going to show you some more building blocks you can create with logic gates. You'll learn how to build your own memory circuit, and then you'll build your own electronic coin tosser!



11

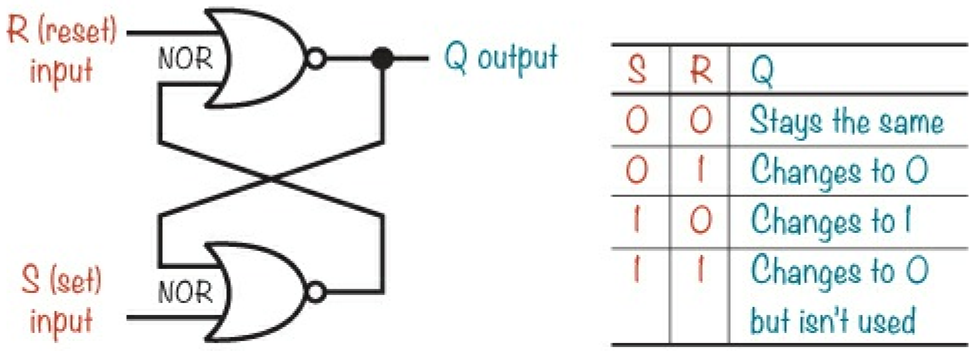
CIRCUITS THAT REMEMBER INFORMATION

In Chapter 9, you learned how to store bits using switches. As long as the switches don't change, the bits stay the same. But you have to manually set the switches, and that's not very efficient. In Chapter 10, you learned about logic gates and how you can use them to play with ones and zeroes. Now, I'll show you how to use logic gates to make electronic memory that saves bits, even after you change the input. At the end of this chapter, you'll build your own electronic coin tosser!

SAVING ONE BIT AT A TIME

One simple memory circuit is an *SR latch*. You can create an SR latch with two NOR gates, and one latch can store one bit of data.

SR latch

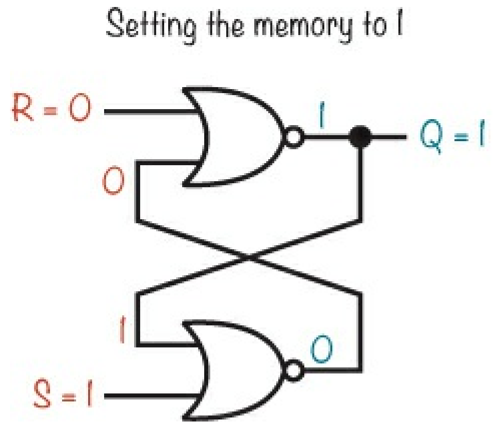


S	R	Q
0	0	Stays the same
0	1	Changes to 0
1	0	Changes to 1
1	1	Changes to 0 but isn't used

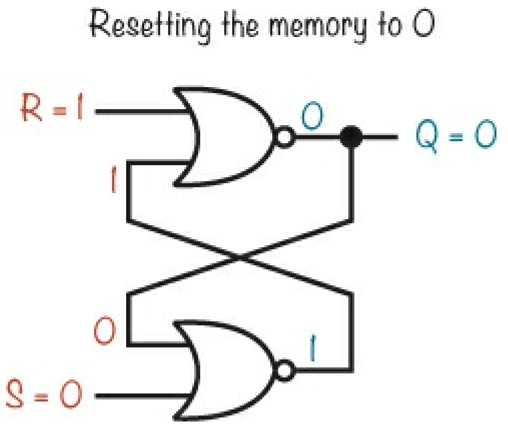
symbol

truth table

Q starts at 0, and this circuit won't update its output until you use R or S to tell it to, which is called *latching* the bit. S and R stand for *set* and *reset*, respectively: when you set the latch, Q changes to 1. When you reset it, Q changes to 0. As the SR latch truth table describes, you can set the latch by putting a 1 on the S input and a 0 on the R input. To reset it, you'd put a 1 on the R input and a 0 on the S input. Let's look at how setting Q to 1 works.



Setting the memory to 1



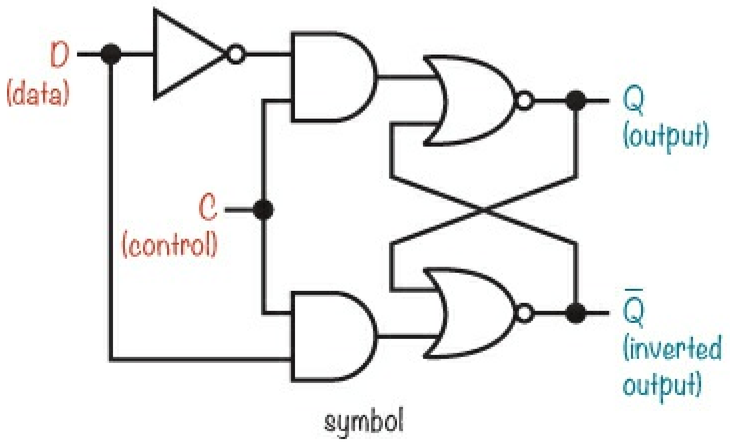
Resetting the memory to 0

The output from a NOR gate is 1 when all inputs are 0. When S (set) is 1, the output of the lower NOR gate is 0, no matter what that gate's other input is. The output is connected to an input on the other NOR gate, together with R (reset). Because R is 0, you have two 0s into the upper NOR gate, which makes Q output 1.

A BETTER MEMORY CIRCUIT

If you add a few more gates to the SR latch, you can create a *D latch*, which sets the output Q to whatever the D input is when the C input is 1.

D latch



symbol

D	C	Q
0	0	Doesn't change
0	1	Changes to 0
1	0	Doesn't change
1	1	Changes to 1

truth table

The D latch is an improvement over the SR latch because you can change D, the *data input*, as much as you want, and Q won't change unless you set C, the *control input*, to 1. The lower NOR gate output will always be the opposite of the output Q, and that output is labeled $\bar{Q}$ to show this.

MEMORY THAT CHANGES ONLY AT A CERTAIN TIME

The D latch has one weakness: when C is 1, changing D also changes the output Q. What if you don't want the output to change immediately?

Computers use a *clock signal* to tell the circuits inside when something should happen, like when to store new data from a wire. A clock signal is just a voltage that turns on and off continuously—that is, it keeps switching between 1 and 0. This signal is similar to the one you sent to the speaker in "Project #16: Make Your Own Sound with the 555 Timer" on page 167.

To reduce the chance of errors, actions like calculations or storing data happen only when the clock signal switches from off to on or from on to off. This is called *edge-triggering*. If a circuit does something when the clock signal changes from off to on, then that action happens on the rising edge, and the circuit is *positive edge-triggered*. A circuit that triggers an action on the falling edge, when the clock changes from on to off, is *negative edge-triggered*.

A *flip-flop* is a latch that updates its output when triggered by the edge of a clock signal, and you can create one by combining two D latches and a NOT gate. This is called a *D flip-flop*.

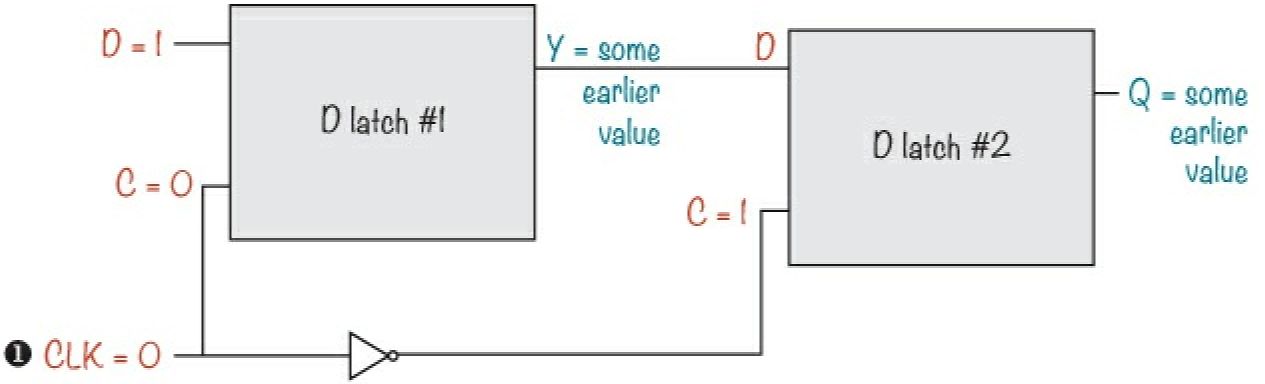
The output voltage Q can change only when the CLK voltage changes from high to low, from 1 to 0. Here's how that works.



D = 1

C = 0
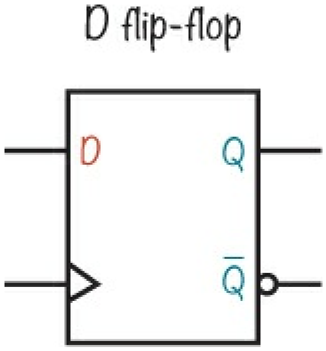
❸ CLK changes from 1 to 0
Y stays equal to 1
D
D latch #2
C = 1
Q changes to 1

When CLK is 0, Y and Q don't change ❶. When CLK changes to 1 ❷, Y changes to match the D input to D latch #1. But the NOT gate inverts the 1, setting C on D latch #2 to 0 so Q doesn't change. As CLK goes back to 0 ❸, C on D latch #2 changes to 1, the value on Y is saved in latch #2, and Q changes to match Y.

NOTE

Q updates when the clock signal changes from high to low voltage, so this flip-flop is negative edge-triggered.

This is the circuit diagram symbol for a positive edge-triggered D flip-flop:



D flip-flop
D
Q
$\overline{Q}$

Instead of writing CLK for the clock input, the D flip-flop symbol has a > marking. Notice the bubble on the $\overline{Q}$ output. Just like on the NOT gate symbol, the bubble means $\overline{Q}$ is the inverted version of Q.

AN OUTPUT THAT TOGGLES

With a simple wire, you can turn a D flip-flop into a circuit that toggles another circuit on and off. For example, imagine you want to turn a light on and off. The D flip-flop stores a value on its input, D, when its clock goes from low to high voltage (if positive edge-triggered). If you connect the D flip-flop's inverted output $\overline{Q}$ to D, the flip-flop's input will always be the opposite of Q. Every time the clock input triggers, the output will change to the opposite value, and the light will toggle.

PROJECT #22: AN ELECTRONIC COIN TOSSER

For this project, you'll build an electronic coin tosser with a 555 timer, a D flip-flop, a push button, and two LEDs.

In Chapter 8, you built several 555 timer circuits that switched voltages on and off. A circuit that turns a voltage on and off continuously is called an *oscillator*, and in this project, you're going to use an oscillator circuit as an input to the toggling D flip-flop. The 555 timer oscillator circuit creates a clock signal that goes to the D flip-flop, causing the output to switch on and off, or *toggle*, continuously as long as you press a push button. The changing output from the D flip-flop turns the LEDs on and off.

When you let go of the push button, the clock signal from the 555 timer stops. The flip-flop output will stop alternating, and only one of the two LEDs will be on: one for heads or the other for tails.

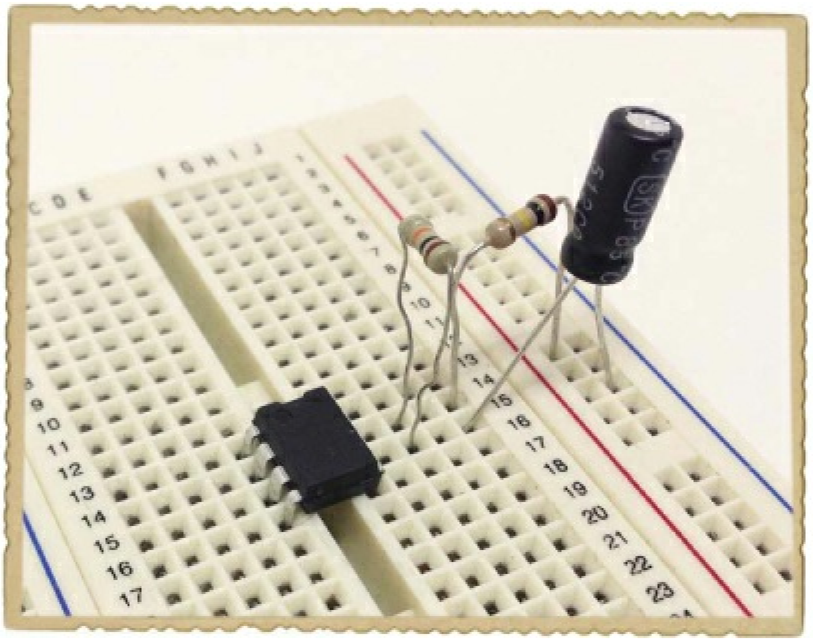
- **A 1 kΩ resistor** (Jameco #690865, Bitsbox #CR251K) to use as a pull-down resistor for the start button.
- **A 1 µF capacitor** (Jameco #29831, Bitsbox #EC1U063) to help set the frequency of the sound.
- **A push button** (Jameco #119011, Bitsbox #SW087) to "toss the coin."
- **A 5 V DC wall adapter** (Jameco #2126125, Bitsbox #TF010) to power the circuit.
- **A DC barrel jack adapter** (Jameco #2227209, Bitsbox #CN424) to connect the wall adapter to the breadboard.

This circuit uses the positive and negative supply columns on both sides of the breadboard. When I say to connect a component to the negative or positive supply column “on the left,” that means you should use one of the supply columns on the left side of the breadboard. On both sides, the positive column is marked with a red line to the left, and the negative is marked with a blue line to the right.

Step 1: Build the Oscillator Circuit

First, let’s wire up the 555 timer:

1. Plug the 555 timer into the breadboard near the middle.
2. Connect R1, the 100 kΩ resistor, from pin 7 of the 555 timer to the positive supply column on the right.
3. Connect R2, the 10 kΩ resistor, from pin 6 to pin 7.
4. Connect C1, the 1 µF capacitor, from pin 6 to the negative supply column on the right. If you’re using a polarized capacitor like the one I suggest in the Shopping List, make sure you connect the negative leg to the negative supply column. The negative leg should be marked with a minus or a zero on the capacitor itself.
5. Connect a jumper wire from pin 2 to pin 6 of the 555 timer.

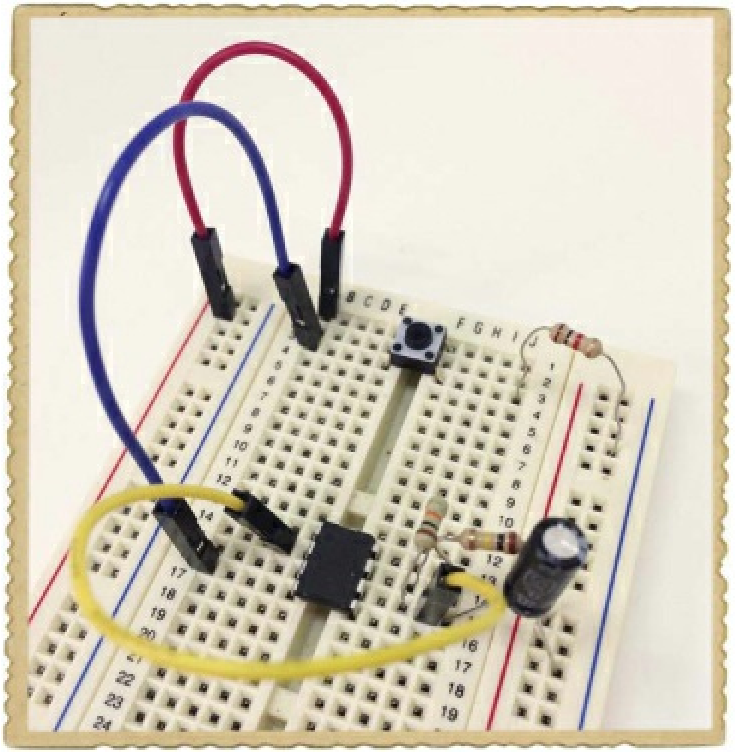


Step 2: Add the Start Button

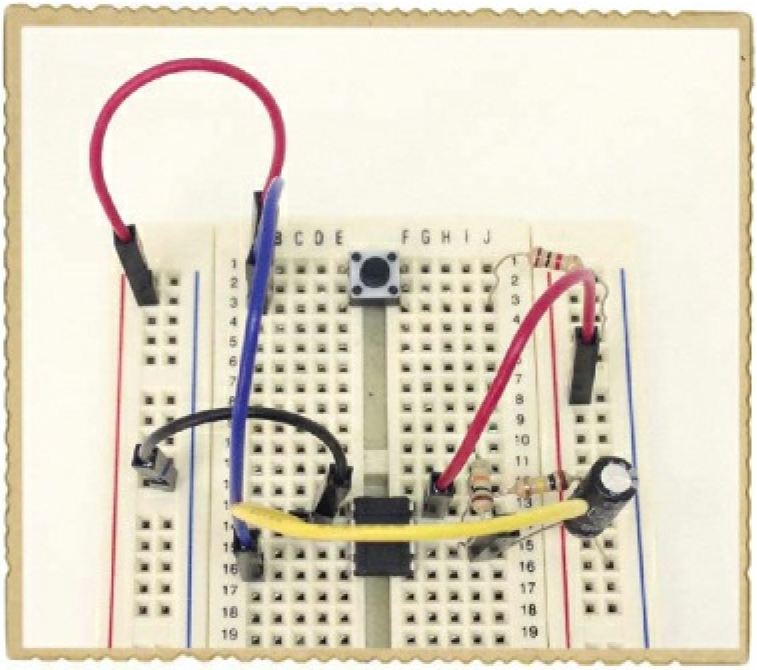
Now, connect the push button between pin 4 on the 555 timer and the positive supply column as follows:

1. Place the push button at the very top of the breadboard, across the notch in the middle. By connecting it like this, you should have one side of the switch on the top row and the other side on row 3.
2. Connect a wire from pin 4 of the 555 timer to the lower pins of the push button (row 3). Connect a wire from the upper pins of the push button (row 1) to the positive supply column on the left.
3. Connect R5, the 1 kΩ pull-down resistor, from the lower pins of the push button to the negative

supply column on the right.



The 555 timer also needs to be powered. Connect a jumper wire from pin 1 to the negative supply column on the left. Use another jumper wire to connect pin 8 to the positive supply column on the right.



Step 3: Build the Toggle Circuit

Place the IC with the D flip-flops—marked *74LS74*—below the 555 timer so that it straddles the notch in the breadboard, with the notch pointing to the top of the breadboard. This IC contains two D flip-flops, but you'll use only the D flip-flop on pins 1 to 6.

Run a jumper wire from the inverted output $\overline{Q}$ on pin 6 of the 74LS74 D flip-flop to the D-input at pin 2. Connect the output from pin 3 on the 555 timer to pin 3 on the D flip-flop, which is the clock input.

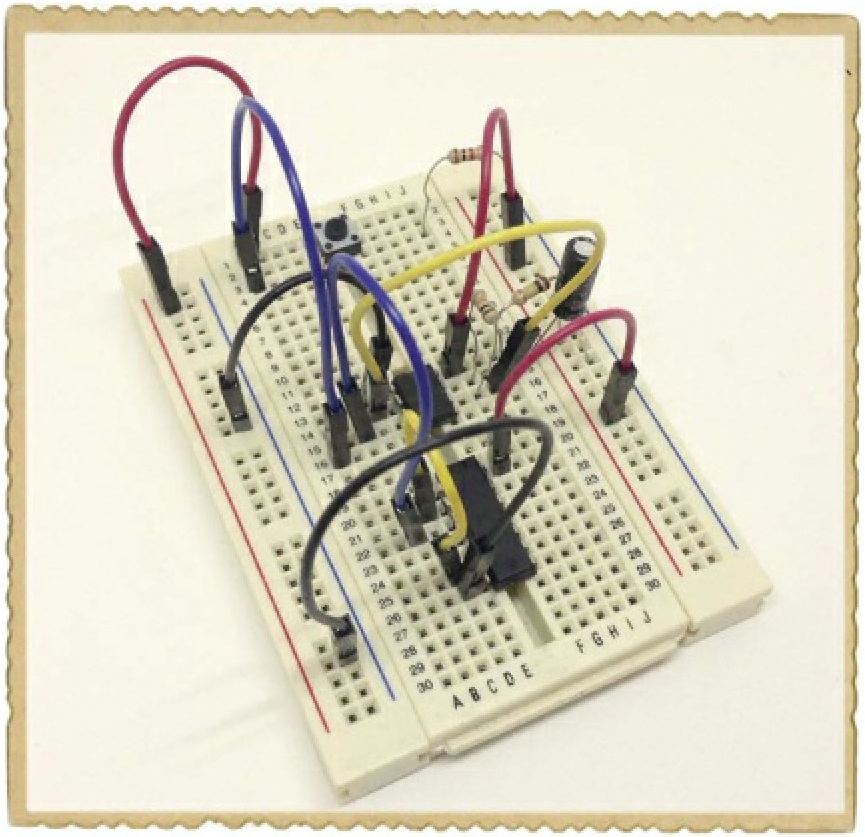
The D flip-flop needs power, too. Connect pin 14 to the positive supply column on the right and connect pin 7 to the negative supply column on the left.



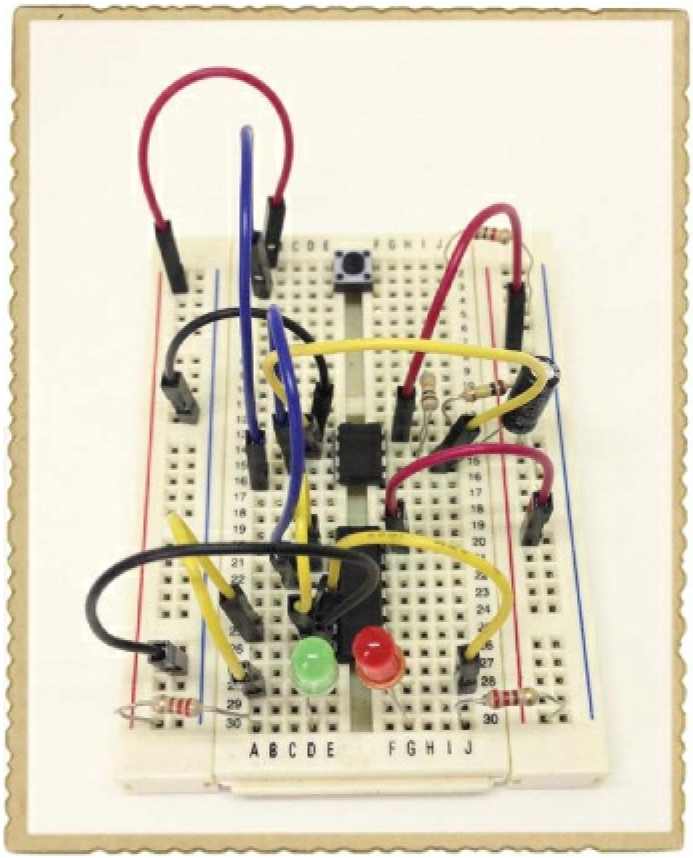
Step 4: Add the Heads and Tails LEDs

In the previous project, you used a transistor to power an LED from a logic gate output because the gate couldn't provide enough current. This circuit has the same challenge because D flip-flops are just a few logic gates in an IC, but there's a little trick you can use to get around that limitation.

The 74LS74 D flip-flop's datasheet says this IC will allow only about 0.5 mA to flow when the output voltage is high, but it allows 8 mA when the output voltage is low. (Search online for *74LS74 datasheet* if you're curious to read the datasheet for yourself.) If you connect the LEDs and resistors to the positive supply column on one side and to the flip-flop output on the other, the LEDs should get 8 mA of current when the output is low, turning them on. It may seem strange to connect the LEDs like this, instead of connecting them to the negative supply column, but doing so makes the LEDs light when the output from the gate is 0 instead of 1.

Whatever value Q has, $\bar{Q}$ will always be the opposite. If you connect an LED to each output, one will light up and the other won't. Add the heads and tails LEDs as follows:

1. Plug the two LEDs into the bottom of the breadboard, with the red LED on the right side of the middle notch and the green LED on the left side. Place the longer leads (the anodes) in the bottom row and the shorter leads (the cathodes) a couple of rows above.
2. Connect one jumper wire from pin 5 of the D flip-flop to the short leg of the red LED. Then connect another jumper wire from pin 6 of the D flip-flop to the short leg of the green LED.
3. Connect a resistor from each bottom row to the positive supply column on each side (R3 and R4 from the circuit diagram).

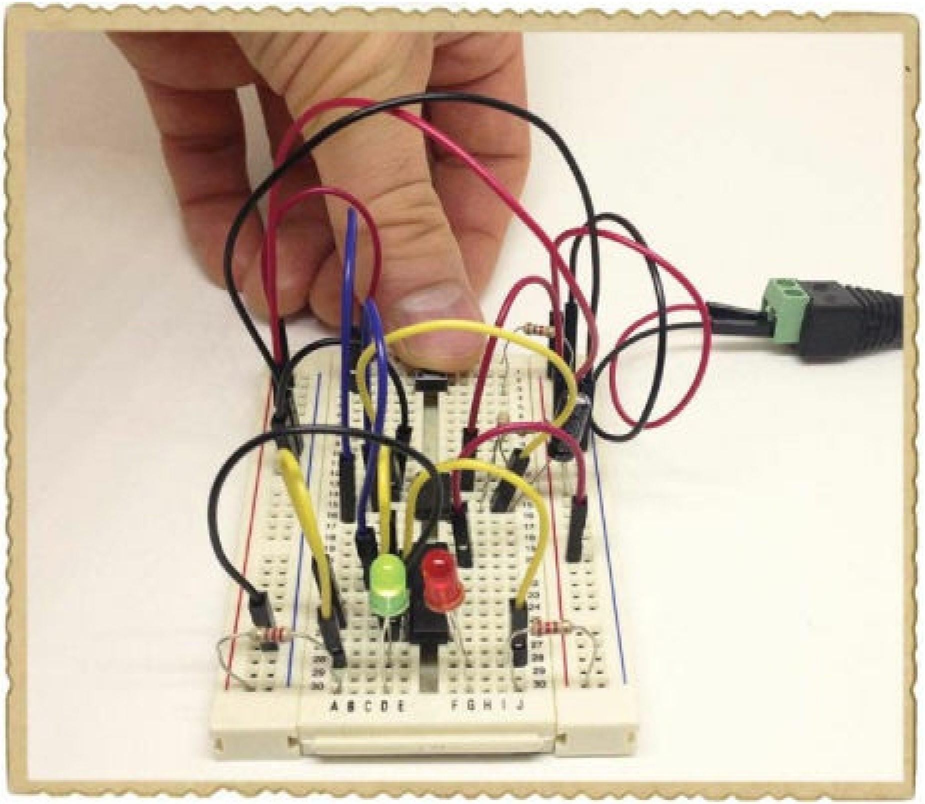


Step 5: Toss that "Coin"!

Use a jumper wire to connect the left negative supply column to the one on the right, and do the same for the two positive supply columns. Then, connect two jumper wires to your barrel jack adapter—connect the plus side to one of the positive supply columns and connect the minus side to one of the negative supply columns.

Finally, plug the wall adapter into the barrel jack adapter first and then into the wall socket. One LED should light up right away. When you push the button, the LEDs should alternate quickly between on and off. Release the button, and only one should be lit.

Now, you can use this circuit to make decisions. For example, say you ask yourself, "Should I go out and play football this weekend, or should I play baseball?" Green means go out and play football; red means baseball. Or, if you're arguing with one of your friends about who gets the last cookie, then let the coin tosser decide!



Step 6: What If the Coin Tosser Doesn't Work?

First, check that you're using a 5 V wall adapter. Any other voltages might not work.

Then, if one LED is lit but nothing happens when you push the button, check that the D flip-flop is connected correctly. If no LEDs are lit, there's definitely something wrong with the D flip-flop and LED parts of the circuit. Carefully compare your connections with the circuit diagram at the beginning of this project. If your circuit isn't working after you know the LED and flip-flop circuits are connected correctly, then check the 555 timer connections.

To help you avoid the same mistakes, I'll share the problems I had when building this for the first time:

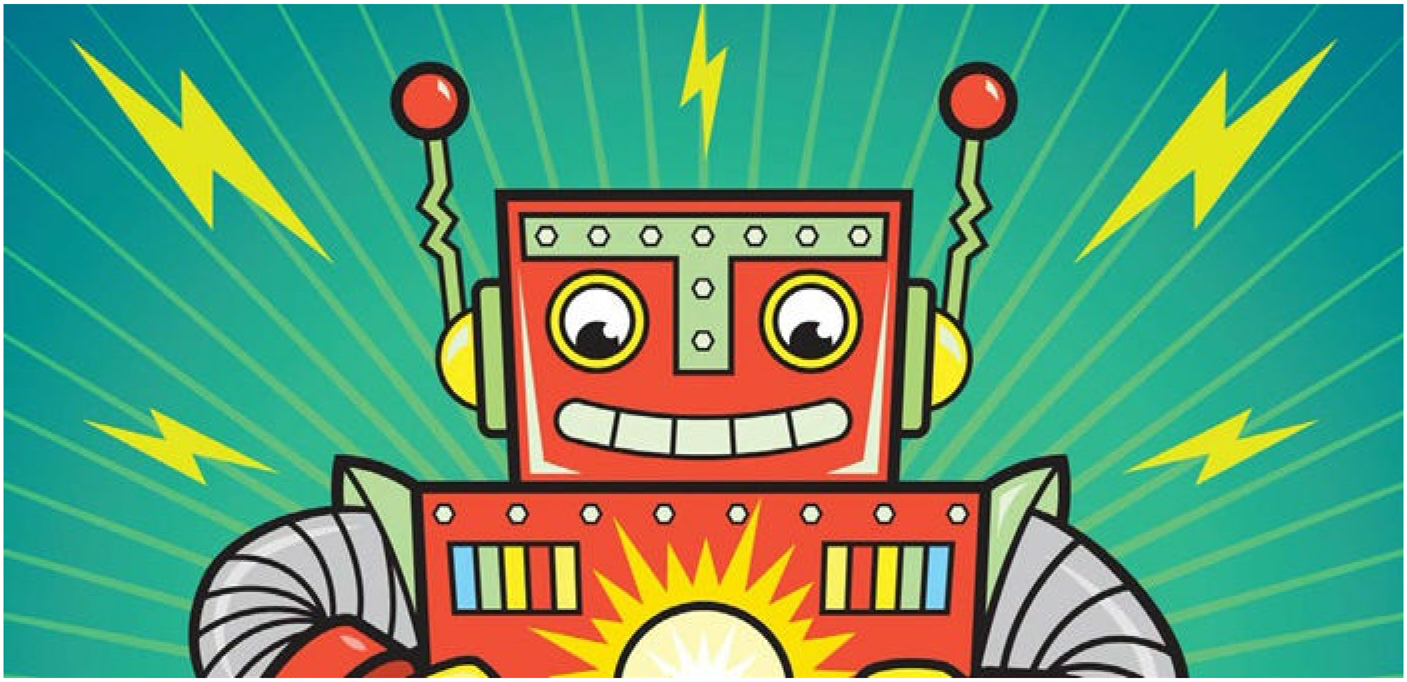
- I connected the LEDs to pins 4 and 5 of the D flip-flop instead of pins 5 and 6.
- I connected the capacitor to pin 5 of the 555 timer instead of pin 6.
- I forgot to connect the positive supply column on the left to the one on the right.

WHAT'S NEXT?

You've built a lot of different circuits in this book! At this point you have a solid foundation in electronics, both in theory and practical experience. Now, the next step is to focus on what you think is fun. Find a project you really want to build—and go make it!

The best way to continue learning is to build lots of circuits and read about anything you're curious about. Follow tutorials online and find more books on different topics in electronics.

In Chapter 12, the final chapter, I'll show you how to build one last project: a really cool game where you have to test your reaction speed by "catching" a light. After that, I hope you'll continue exploring, playing, and having fun with electronics. There are so many great things you can build!



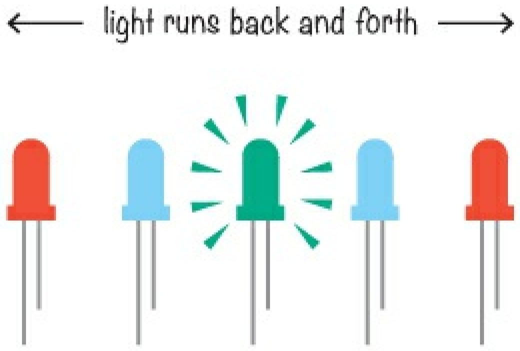
12

LET’S MAKE A GAME!

You’ve built all sorts of small circuits in this book, and each circuit was designed to teach you a particular concept. In this chapter, you’ll combine all your new skills to build a reaction game. The game has a row of five LEDs that light up one at a time so that a light appears to run back and forth.

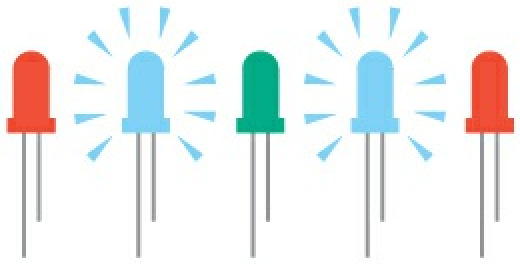
The goal of the game is to stop the light when it’s in the middle of the five LEDs. That gives you 10 points. If you stop it on an LED next to the middle one, you get 5 points. But if you stop it on one of the end LEDs, you lose all your points and have to start over from 0. Try to reach 50 points!

You can play this game by yourself to practice your reaction time, or with as many friends as you want. If you’re competing with friends, I suggest giving each player only one attempt at stopping the light before the next player gets a turn.

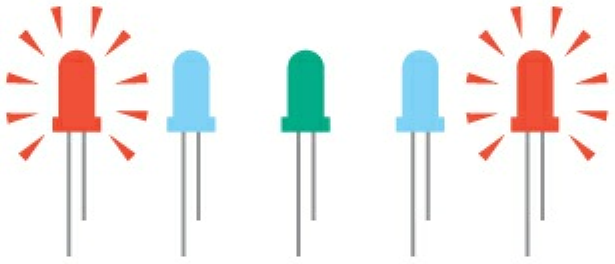


← light runs back and forth →

If you stop on the green light, you get 10 points!



If you stop on a blue light, you get 5 points!



If you stop on a red light, you lose all your points!

MEET THE REACTION GAME CIRCUITS

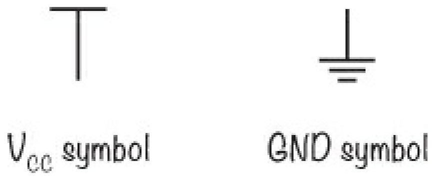
The reaction game will consist of three circuits:

- A 555 timer circuit that determines the speed of the game
- A counter that controls which LED light to turn on
- An SR latch that will add a reset button and an action button

This section explains each circuit, but to help you understand their diagrams, let's meet two new circuit symbols.

Meet the V_{CC} and GND Symbols

Circuit diagrams don't always use a battery symbol like the one used throughout this book. Sometimes they use the V_{CC} (or V_{DD}) and *GND* symbols instead.



If nothing in the circuit diagram or its description says otherwise, you can assume that V_{CC} represents the positive side of the battery and that GND represents the negative side, or ground. The symbols sometimes look a little different, but the V_{CC} symbol usually shows a wire connecting down from its symbol to the circuit, while the GND symbol shows a wire connecting up from the symbol to the circuit.

In bigger circuit diagrams, like the one you're going to build from in this chapter, these symbols make the diagram much easier to draw and understand.

WHY IS IT CALLED V_{CC}?

The positive voltage symbol is called V_{CC} because of old naming conventions. V_{CC} was the voltage supplied to the collector side of a transistor in common transistor circuits, usually through a resistor or some other components. The collector is where the "CC" comes from.

You've used a bipolar junction transistor throughout this book, but there's another type of transistor called a *field-effect transistor (FET)*. The pin that equals the collector on this type of transistor is called the *drain*, so the voltage that was supplied to the drain side of the FET was called V_{DD}.

A 555 Timer to Set the Light Speed

The circuit that sets the reaction game's speed will be built around a 555 timer, and it's similar to the circuits you built in Chapter 8. The components in this circuit diagram will set the game to a "medium" speed: it's not super fast, and it's not super slow.

pin 1
pin 5

Every time the output from the 555 timer goes from low to high, the light moves one step to the side. The number of times the output from the 555 timer goes high per second is the frequency of the output. As I showed in Chapter 8, the formula for calculating the frequency of the output of the 555 timer is

$$\text{Frequency} = \frac{1.44}{(\text{R1} + \text{R2} + \text{R2}) \times \text{C1}}$$

The following values from the 555 timer circuit diagram correspond to that formula:

R1 = 100 kΩ
R2 = 10 kΩ
C1 = 1 μF

Plug these into the formula, keeping in mind that 1 μF = 0.000001 F and 120 kΩ = 120,000 Ω, and you get this:

$$\text{Frequency} = \frac{1.44}{(100\ \text{k}\Omega + 10\ \text{k}\Omega + 10\ \text{k}\Omega) \times 1\ \mu\text{F}}$$

$$\text{Frequency} = \frac{1.44}{120\ \text{k}\Omega \times 1\ \mu\text{F}}$$

$$\text{Frequency} = \frac{1.44}{120{,}000\ \Omega \times 0.000001\ \text{F}}$$

$$\text{Frequency} = 12\ \text{Hz}$$

This means the output will go high 12 times per second and the light will change places 12 times per second. You can experiment with the component values for R1, R2, and C1 later to speed up or slow down the game.

A Counter to Turn the LEDs On

To control the LEDs, you'll use a *decade counter*, which is an IC that counts input pulses. Every time the clock input on pin 14 goes from low to high, the counter increments by one. It counts from 0 to 9, and it has 10 outputs marked 0 to 9.

For example, when the counter has counted three input pulses, output 3 (that is, pin 7) is high, and the other pins are low. If you connect an LED to output 3, then when the counter is at three, the LED will turn on.

If you connect LEDs to several output pins, then as the counter increases, the LEDs turn on in order, according to their output pins. When the counter is at 9 and receives a 10th input pulse, it goes back to 0 and turns the output pins on in order again.

But the counter counts pulses only if pin 13 is low. This means you can use pin 13 to tell the game when to start moving the light across the LEDs and when to stop the light.

Each output has a resistor to reduce the current through the LED and make sure the LED doesn't get destroyed. Because two output pins connect to each LED, the resistors keep the voltage to each LED high, even though one output will be low and one will be high. The resistors also ensure that two outputs aren't connected directly together, which could damage the IC when one output is high and the other low.

A Latch to Start and Stop the Light

Do you remember the SR latch from "Saving One Bit at a Time" on page 240? The start/stop circuit for this game is a similar SR latch but built with two NAND gates. (The SR latch in Chapter 11 used NOR gates.)

The SR latch is a circuit that can remember a single bit. Its output is either 0 or 1, and it keeps that number until it gets set or reset with a new input.

You can create a circuit that tells the latch what to output with two buttons: one for setting the output to 1 and one for setting the output to 0. Using NAND gates instead of NOR gates means the buttons must make the inputs low to output a 1.

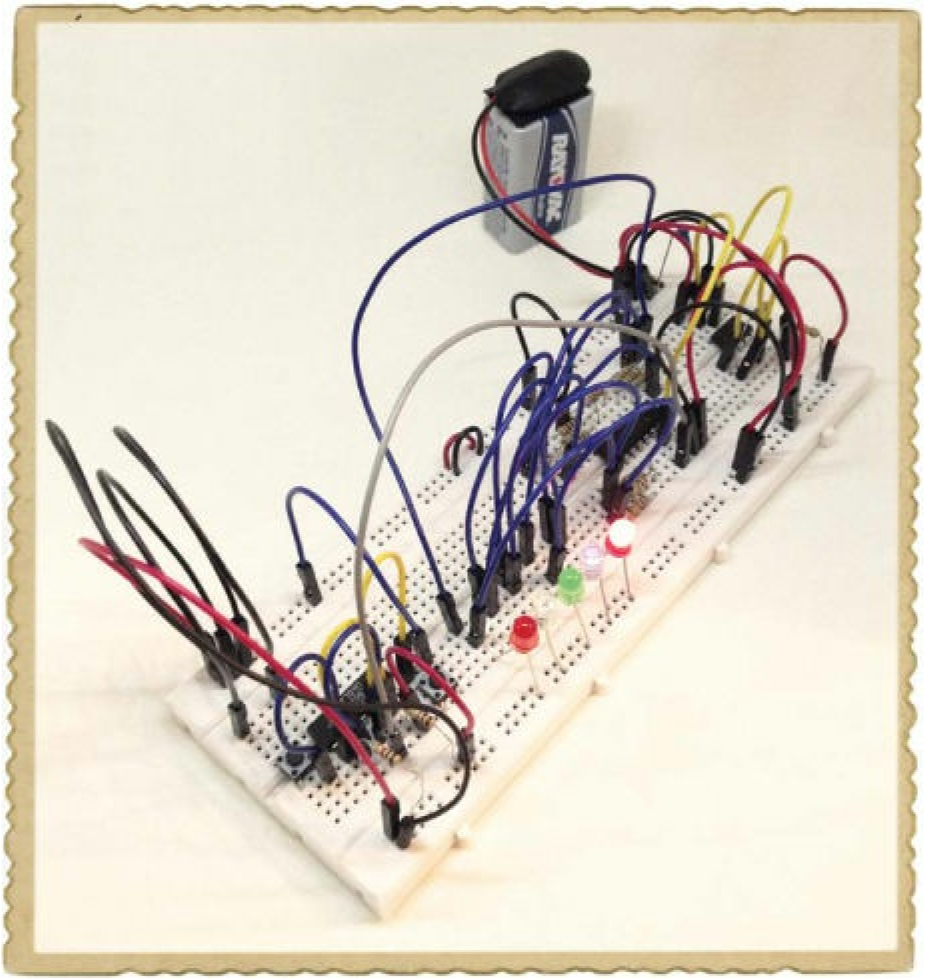
In this circuit, it doesn’t matter whether you click the buttons quickly or slowly. The 1-button always sets the output to 1, and the 0-button always sets the output to 0.

That’s perfect for the reaction game! Connecting the output to the start/stop pin, or pin 13, on the decade counter gives you a button for starting and stopping the LEDs.

PROJECT #23: AN LED REACTION GAME

It’s time to put all the pieces I showed you together to build the reaction game. This circuit has a lot of connections, but I know you can make it. Just don’t rush. Take your time and test each part of the circuit after the step where I explain how to build it.



I also recommend using a bigger breadboard than you've used in the previous projects, because this circuit is huge!

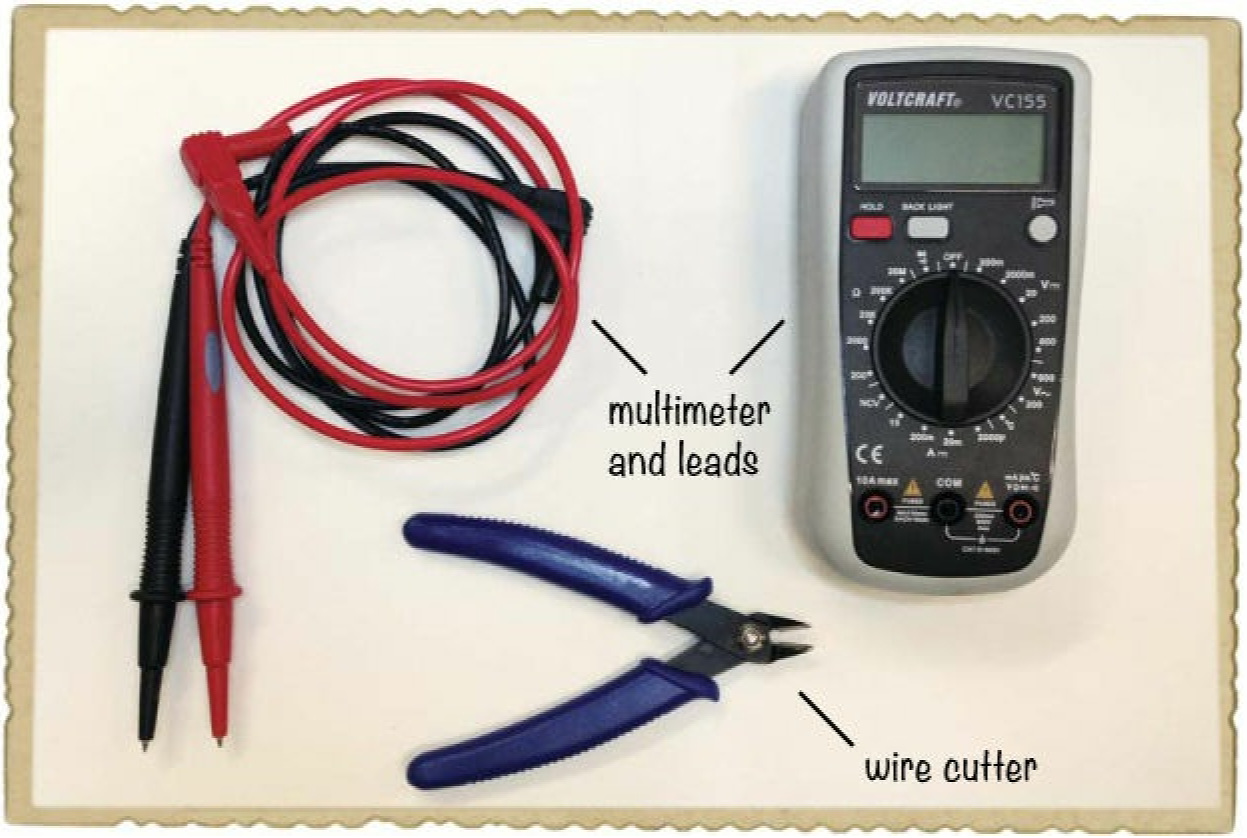
- **Two push buttons** (Jameco #119011, Bitsbox #SW087), one for resetting the game and one for

playing.

Tools

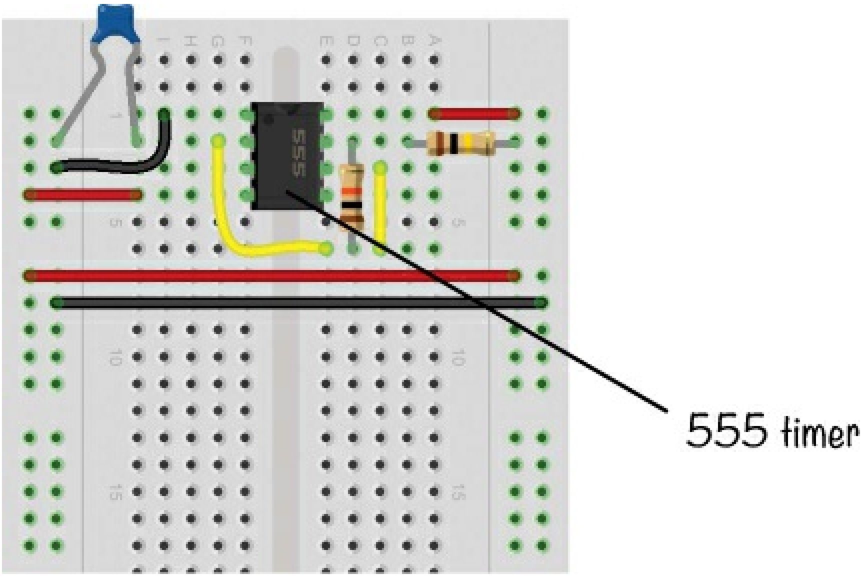


- **A wire cutter** (Jameco #35482, Bitsbox #TL008) to cut small pieces of wire.
- **A multimeter** (Jameco #2206061, Bitsbox #TL057, Rapid Electronics #55-6662) to debug your circuit if it's not working correctly.

Step 1: Build the 555 Timer Circuit

Plug the 555 timer into the breadboard all the way at the top so that you'll have room for the other parts of the circuits farther down. Then, connect the capacitors and resistors to the IC according to this project's circuit diagram. The capacitor I suggest in this project's Shopping List is a nonpolarized capacitor, so it doesn't matter which way you connect it. If you use a polarized capacitor instead, connect it according to the plus marking in the circuit diagram.

Use wires to make connections as needed, as I show in this breadboard diagram.



In this project, it’s best to use the supply column pairs on both sides to make connections easier and keep everything as tidy as possible. The breadboard that I recommend in this project’s Shopping List doesn’t have blue and red markings, but the positive and negative columns are the same as in breadboards with the stripes. The left and right sides of the breadboard each have a pair of supply columns. The positive supply column is the left column in each pair, and the negative supply column is the right column in each pair. Use a red wire to connect the positive column on one side to the positive column on the other side, and do the same using a black wire with the negative columns.

As you follow my instructions, connect everything in the 555 timer circuit that should connect to V_{CC} to one of the positive supply columns, and connect everything that should connect to GND to one of the negative supply columns.

NOTE

This circuit connects the 555 timer in astable mode, just like the 555 timer circuits in Chapter 8. Read “Meet the 555 Timer” on page 164 for a description of exactly how this IC works. You can also build the projects in Chapter 8 to practice using the 555 timer.

Before you move on to the next step, check that this circuit is working by connecting an LED with a resistor to the output of the 555 timer as follows:

1. Connect the negative side (short leg) of an LED to the output on pin 3 of the 555 timer.
2. Connect the positive side (long leg) of the LED to a 100 Ω resistor, and connect the other side of this resistor to the positive supply column.
3. Connect your battery clip to one of the supply column pairs as usual. Then plug in the battery to check that the circuit works.

If your LED blinks really fast, then you’re ready to move on. If not, recheck your connections to find out where the error is.

When you know the 555 timer circuit works, unplug the LED, 100 Ω resistor, and battery clip.

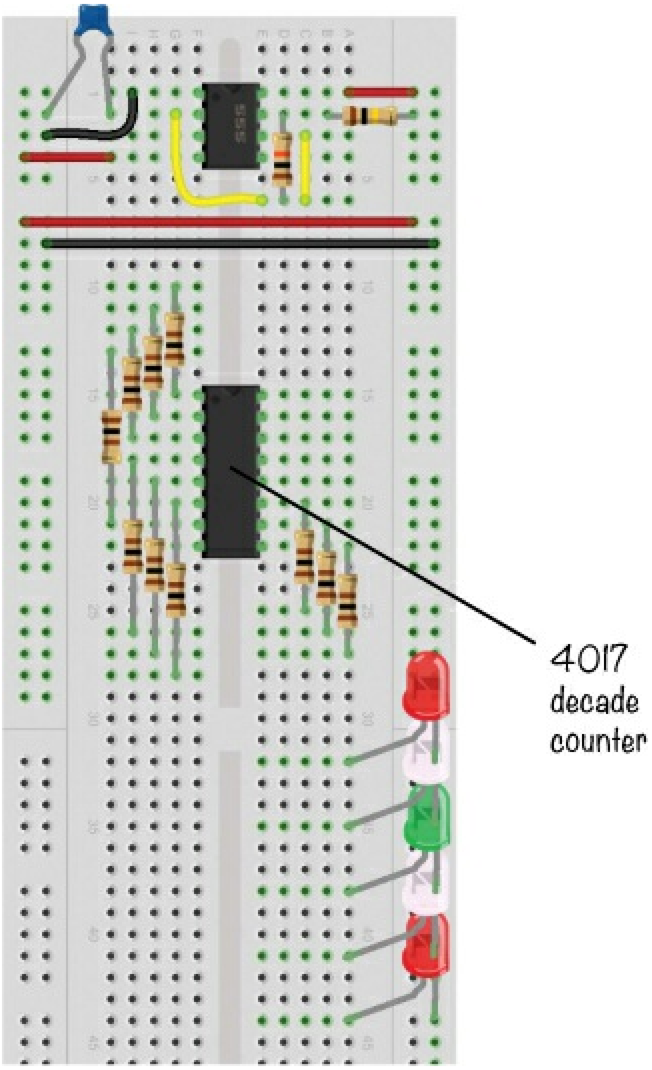
Step 2: Build the LED-Controlling Circuit

Now, you're going to connect the 4017 decade counter with resistors and LEDs. There are a lot of connections, so take as much time as you need to get them all correct.

Plug the 4017 decade counter into the breadboard so that the middle of the decade counter is around row 20, with the chip marker pointing up toward row 1. Then, take out five LEDs and ten 100 Ω resistors.

Connect each LED's negative (short) leg to the negative supply column on the right, and connect each positive (long) leg to its own empty row in the component area on the right. Place the green LED in the middle, the two blue ones on each side of the green LED, and the red ones on each end.

Then, connect the ten 100 Ω resistors. In the circuit diagram, notice that pins 1 to 7 and pins 9 to 11 of the 4017 decade counter each connect to one side of a resistor. The other side of each resistor needs to be on a row by itself. Take care to ensure the resistor legs don't accidentally touch one another. Look at the following breadboard circuit to see how I connected them:

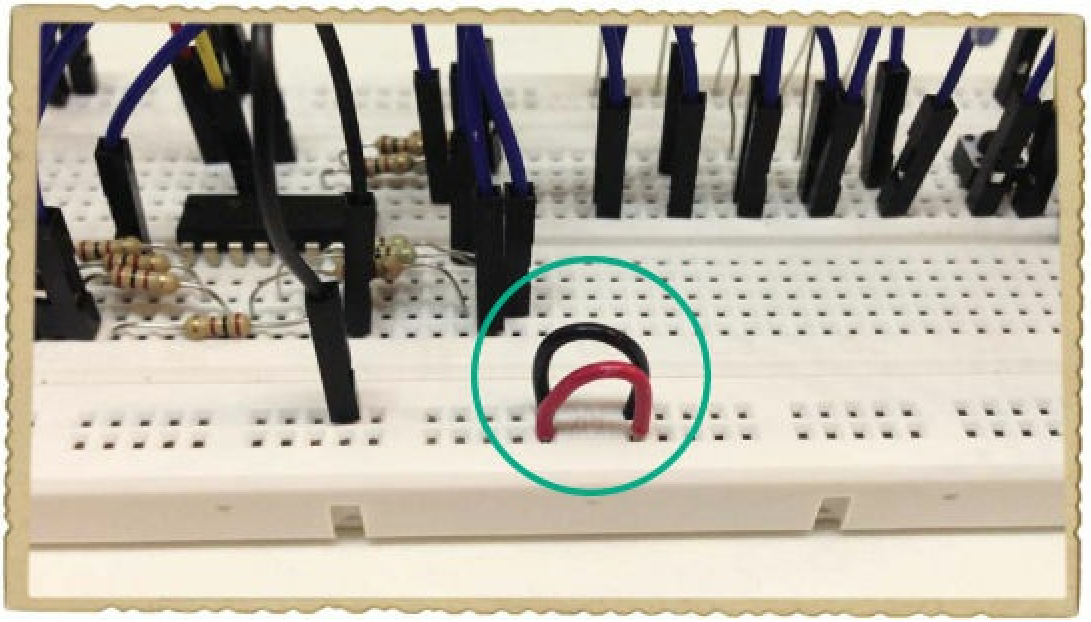


Now, connect the LEDs to the resistors on the 4017 decade counter, and connect the decade counter circuit to the 555 timer circuit according to the circuit diagram. Jumper wires are the best way to make those connections.

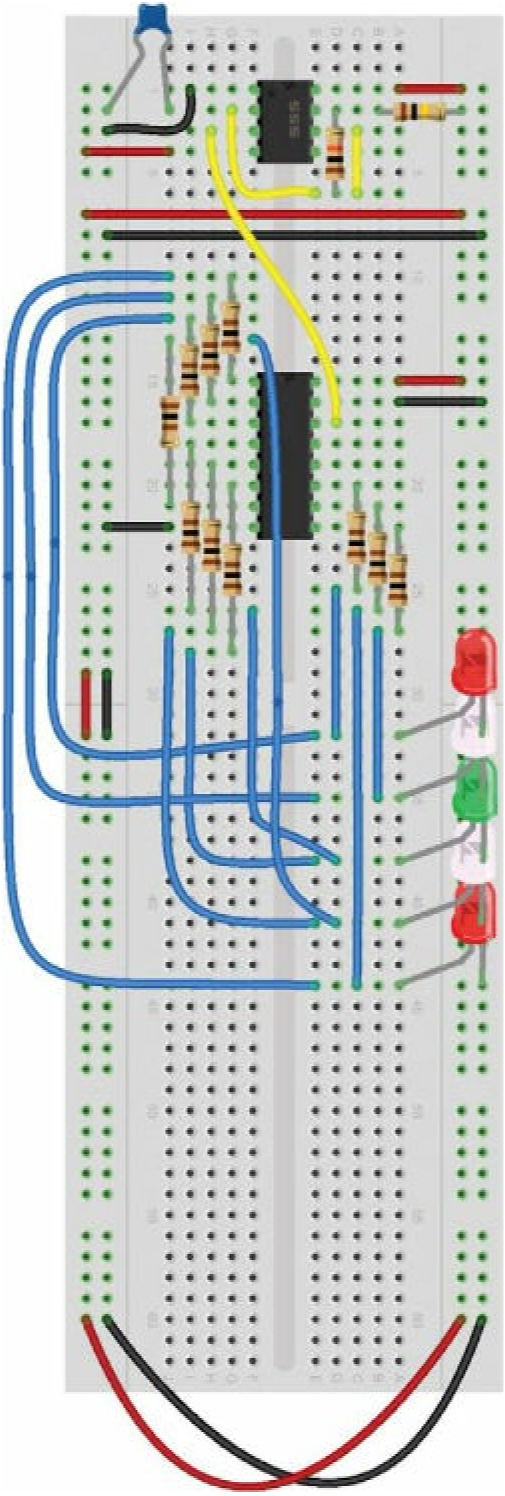
From each resistor, connect a jumper wire to the corresponding LED. Look at the circuit diagram and notice, for example, that the other side of the resistor connected to pin 4 of the 4017 decade counter should connect to the positive pin of the green LED in the middle. Go through the pins in the circuit diagram to figure out which LED to connect each resistor to.

Connect pins 8 and 15 of the 4017 decade counter to the negative supply column, and connect pin 16 to the positive supply column. Use a wire to connect the output from the 555 timer (pin 3) to the clock input of the 4017 decade counter (pin 14).

Make sure that you have positive and negative connections in all of your power supply columns. The breadboard I recommend in this project's Shopping List (page 267) divides its power supply columns into two sections, one upper and one lower. Just connect each of the upper and lower halves on the left side with a wire to bridge the gap, as shown. Do the same on the right side. Alternatively, use two jumper wires from the left columns to the right columns.



You can use a jumper wire, or you can cut off a small piece of wire, as I've done in this photo. Then, use two long jumper wires to connect the lower-left power supply columns with the two lower-right columns. When you're done connecting the two circuits and all the power supply columns, your breadboard should look like this:



Before building the next part of the circuit, check that your LED-controlling circuit is working correctly, too. To test it, just connect pin 13 on the 4017 decade counter—that is, the "disable" pin—to the negative supply column with a jumper wire, and plug your battery clip and battery into the breadboard as usual. You should see a light "running" back and forth across the row of LEDs.

If no LEDs light up, first check that you've connected the 4017 decade counter with the notch pointing upward. Connecting the chip the wrong way is an easy mistake to make. I've done it many times!

Next, check that pin 16 of the 4017 decade counter is connected to the positive supply column and that pins 8 and 15 connect to the negative supply column. Also, confirm that you've connected the LEDs with their short legs in the negative supply column.

If some LEDs work and some don't, or if the light doesn't run smoothly back and forth, look over all the connections of resistors and jumper wires to find the fault.

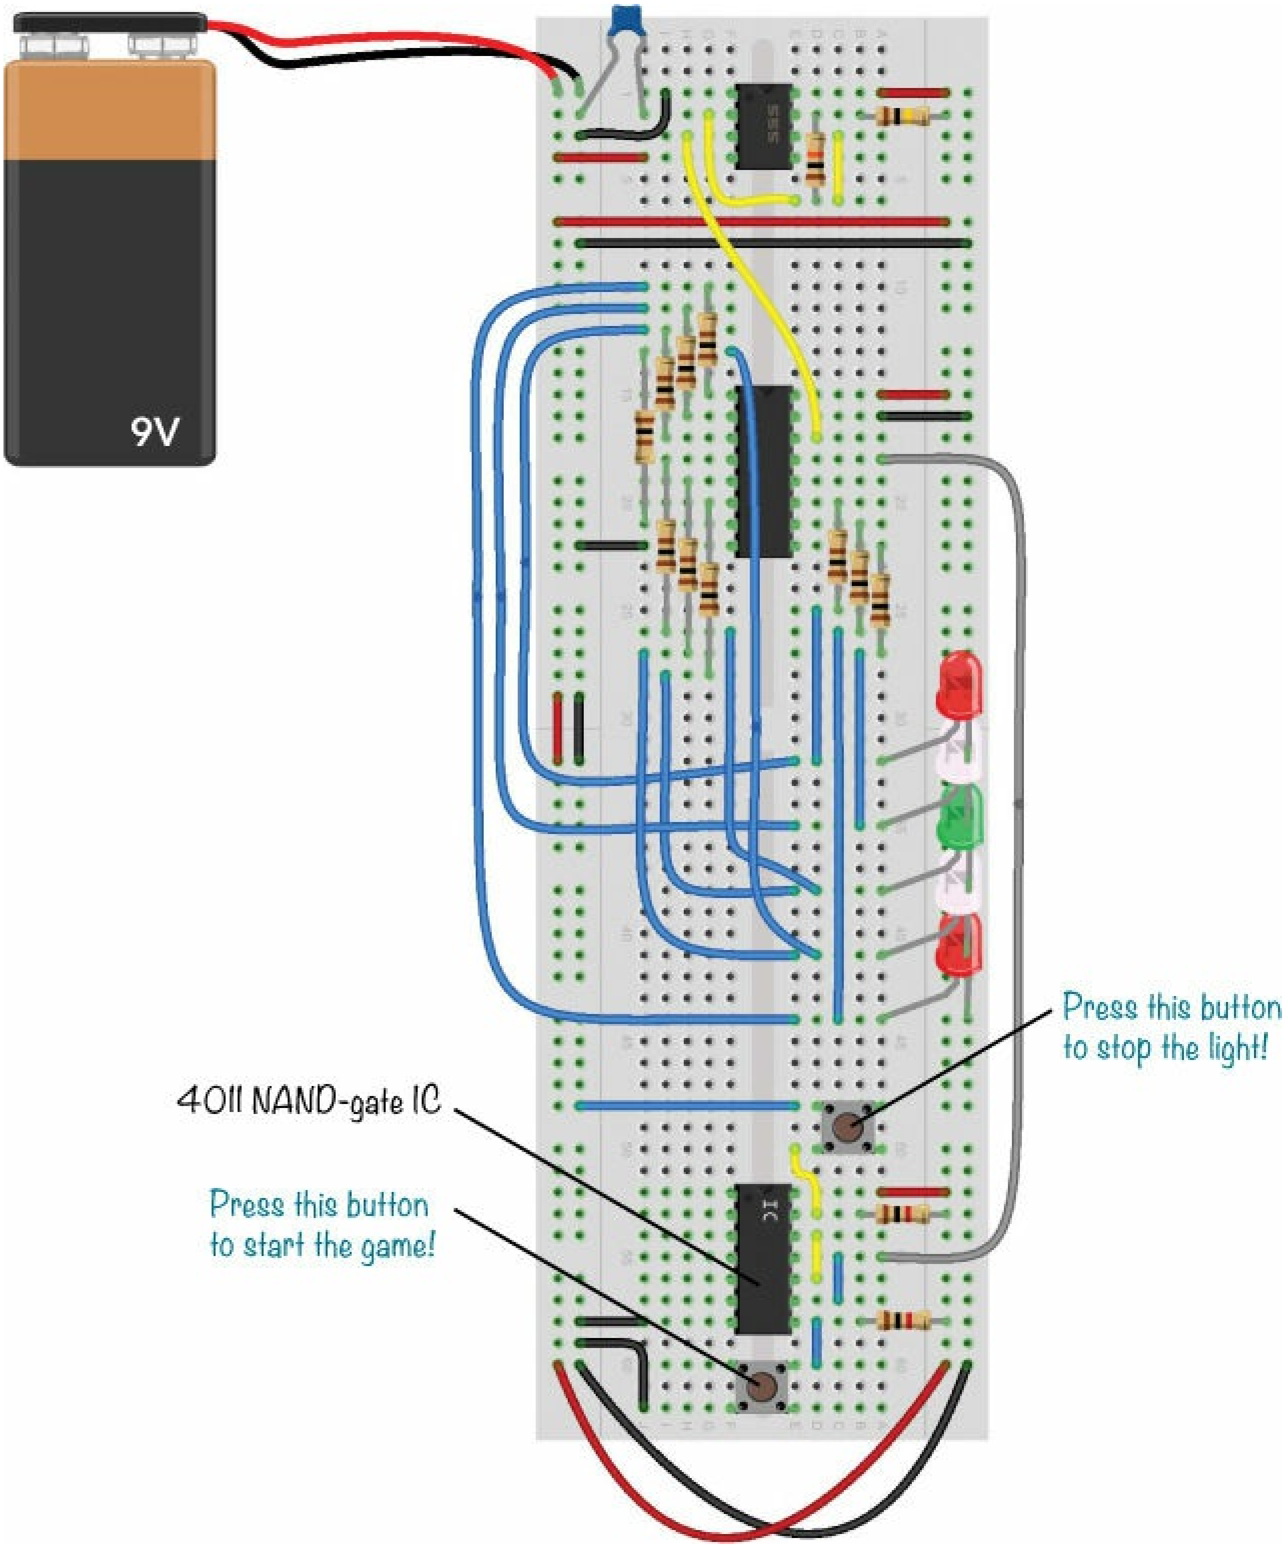
After verifying that your circuit works, remove the wire connecting pin 13 of the 4017 decade counter to the negative supply column, and disconnect the battery from the breadboard.

Step 3: Build the Start and Stop Circuit

The last piece of this project is the button circuit that starts and stops the LEDs. Make these connections now:

1. Connect one push button at the bottom of the breadboard, across the notch in the middle. Plug the 4011 NAND-gate IC into the breadboard, a couple of rows above the button. Make sure its chip marking points toward row 1 on the breadboard.
2. Place the second button above the IC on the right component side so that it’s easy to reach it with your finger.
3. Connect the two resistors, R13 and R14, as shown in the circuit diagram. Then, use jumper wires to make the remaining connections in the SR latch circuit, as shown in the following breadboard diagram. Connect the positive and negative supply columns to the NAND-gate IC (pins 14 and 7, respectively), and connect the wire from pin 11 of the NAND-gate IC to pin 13 of the 4017 decade counter.

Compare your connections to the following image.



9V
555
4011 NAND-gate IC
Press this button to start the game!
Press this button to stop the light!

Step 4: Practice Your Reaction Time!

All that's left is to connect the battery to the supply columns. The button at the bottom of the board is the Reset button. Use this to start the game and to restart the game after each player attempts to stop the light.

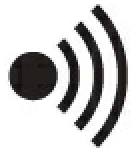
The button next to the LEDs should stop the light when the game is running. See how many turns it takes you to get to 50 points!

Step 5: What If the Game Isn't Working?

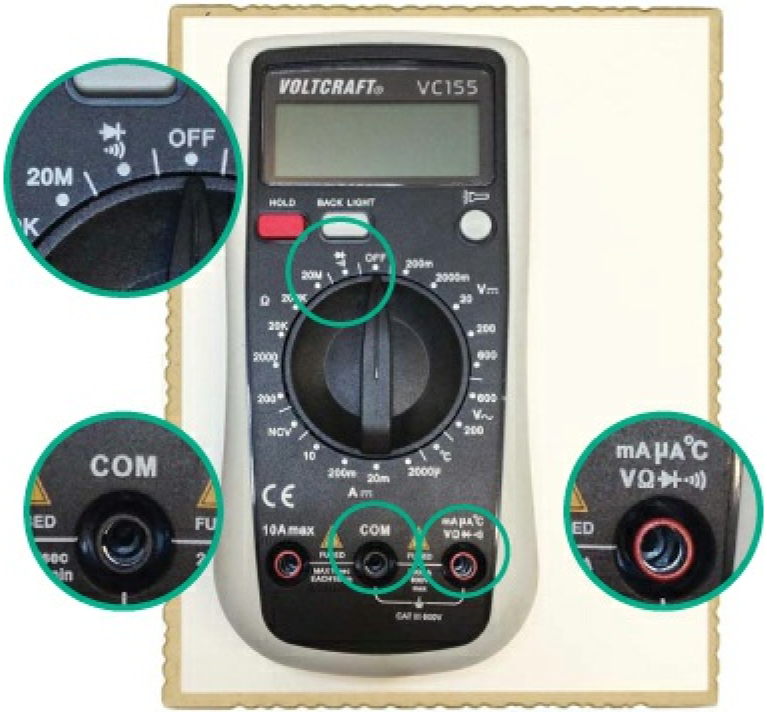
If you've followed my instructions so far, the circuits from Steps 1 and 2 should be working. If your circuit isn’t working, the only sources of error left are the start/stop circuit you just built and the connection from this circuit to the 4017 decade counter.

A. Check the Continuity

First, check that you don’t have a short circuit between the positive and negative columns. To do this, use the *continuity* function on your multimeter. A continuity test checks for a direct connection between two points in a circuit. The symbol for the continuity tester usually looks like the one shown here.



continuity
symbol



You don’t want a direct connection between the positive and negative columns because that would short-circuit the battery and stop the game from working. Use the continuity tester to check for short circuits.

Turn the dial on your multimeter so that it points toward the continuity symbol. Plug the black measurement lead into the multimeter’s COM socket, and plug the red measurement lead into the multimeter’s V socket. Touch the tip of the black and red measurement leads to each other, and you should hear a beep to indicate that there’s a direct connection.

NOTE

Many electronics enthusiasts also call continuity mode beep mode.

B. Check for Bad and Good Beeps

Now, plug your battery clip into the breadboard as you would normally, but without the battery. Touch one measurement lead tip to the positive connector and the other to the negative connector. If you hear a beep, there's a short circuit, and you need to fix it! Check all your connections to the positive and negative supply columns.

Next, check the connection between pin 11 on the 4011 NAND-gate IC and pin 13 on the 4017 decade counter to make sure they're connected correctly. Use the continuity tester to check that you have a connection by carefully touching the lead tips on the IC pins. There isn't much space between IC pins, so take care to be sure each tip only touches the correct pin. This time, a beep is a good sign.

C. Check for Power

If the connection to the NAND-gate IC is correct, use a multimeter to measure the output voltage from the start/stop circuit to see whether it's working correctly. Set your multimeter to measure voltage. Make sure the black measurement lead is connected to the multimeter's COM socket, and the red measurement lead is connected to the V socket.

Touch the tip of the black lead of the multimeter to the negative side of the battery, and touch the red lead to pin 11 on the 4011 NAND-gate IC. You should see a high signal—about 9 V—after clicking the stop button and a low signal—about 0 V—after pushing the start button. If not, check the connections of the SR latch circuit to find the error.

TRY IT OUT: CHANGE THE LIGHT'S SPEED

To change the speed and difficulty of the game, play around with different values for R1, R2, and C1 around the 555 timer. Smaller values will make the game go faster. Larger values will make the game go slower. Flip to "How to Set the Output Speed of the 555 Timer" on page 166 for the calculations to figure out specific resistor and capacitor values based on the frequency you want.

Note that R1 should not be less than 1 kΩ, as lower values might damage the 555 timer.

But what if you want to change the difficulty on the go? Just replace resistor R2 with a potentiometer. Then you can change that resistance value by rotating the potentiometer shaft, which changes the speed!

ADD A BUZZER TO YOUR GAME

Congratulations: You've finished the last project in the book! Now, it's up to you to decide what to make next. If you're not sure where to start, why not add more circuits to your reaction game?

The LED in the middle is where you want the light to stop, and I suggest adding a sound circuit to bring some excitement to hitting your target. To do this, you could use an active buzzer like the one in "Project #2: Intruder Alarm" on page 11, as shown in this partial circuit diagram.

The darker part of this circuit shows new components you'd need in order to add a buzzer to the reaction game project. The lighter components are just a section of the original circuit diagram.

Connect the positive leg of the middle LED through a 1 kΩ resistor to the base of an NPN transistor. Then connect the buzzer to the transistor's collector. Connect the positive side of your battery to the other side of the buzzer, and connect the negative side of the battery to the transistor's emitter.

You should end up with a circuit that makes a little beep every time the light passes the middle LED. If you can stop the light on the middle LED, the buzzer should beep continuously to indicate that you've hit the main target.

When you've customized the game to your liking, solder it onto a prototyping board. Maybe you'll even want to place it in a nice box to hide the electronics and show only the buttons and LEDs.

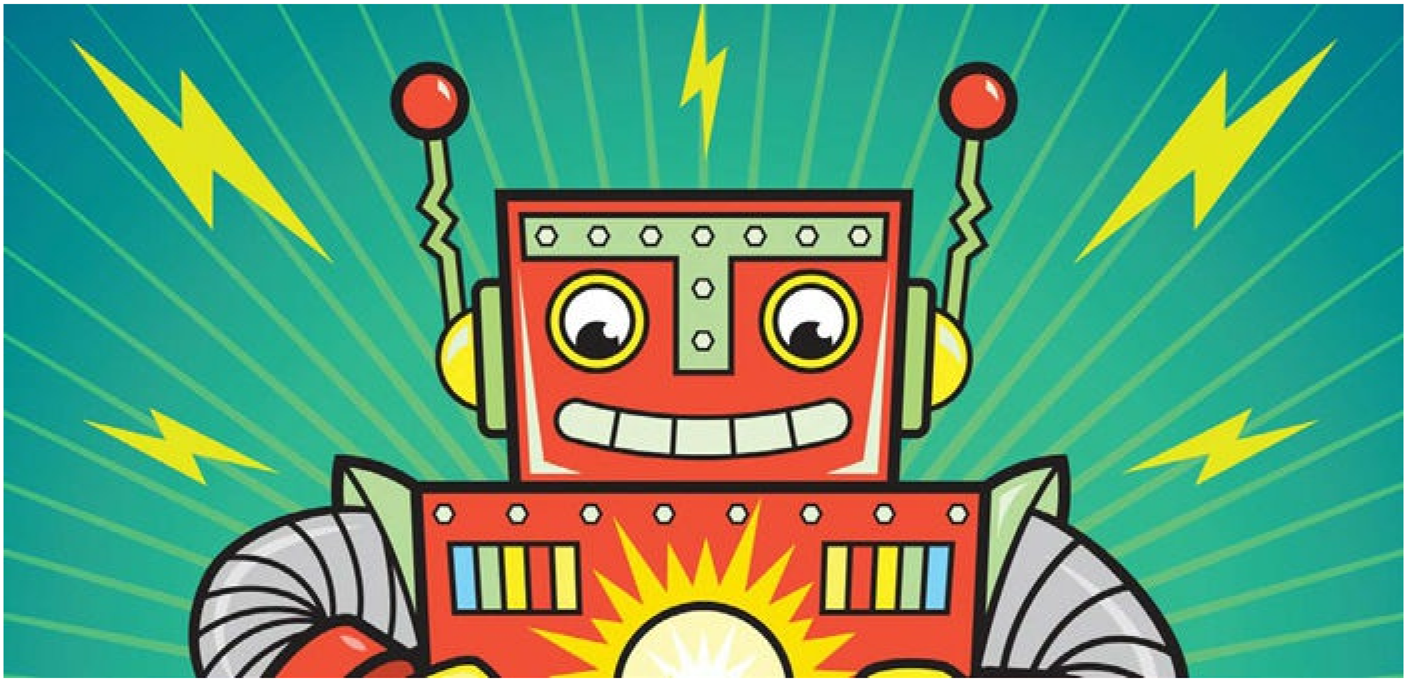
WHAT'S NEXT? GO MAKE COOL STUFF!

I'm so happy you've read the book all the way to the end! I hope you've enjoyed the projects, and I hope you'll continue building cool things with electronics. One way to practice is to find a circuit diagram for something exciting, buy the components, and build the circuit. You can find circuit diagrams for almost anything online.

I'd also like to invite you to continue learning on my website, *http://www.ohmify.com/*. You can watch video courses, read lots of project tutorials, and visit a discussion forum where you can ask questions and make friends with people from all over the world who also like to build electronics.

Just make sure to ask your parents' permission to join the site, as it's subscription based. If they say yes, then use the following link for a special offer available only to the owners of this book: *http://ohmify.com/e4k/*.

Also be sure to check out the "Online Resources" on page 286—you'll find loads of tutorials and more circuits to build at those websites. Have fun!



HANDY RESOURCES

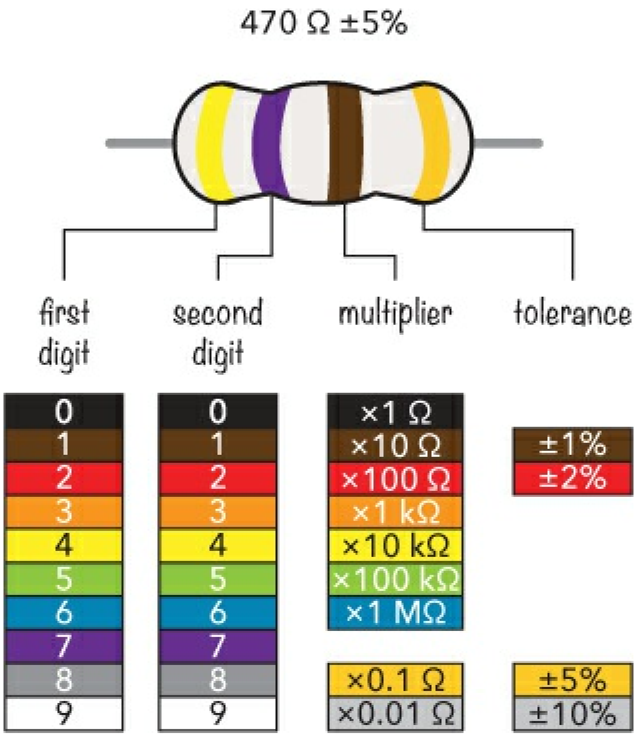
Here are some resources that you'll find useful when building projects with electronics. Use this as a reference when, for example, you need to figure out what the color bands of a specific resistor mean. I've also listed some websites where you can continue learning and find more projects to build.

COMPONENT AND UNIT VALUE CHEAT SHEETS

Throughout this book, you'll use lots of components, and there are as many ways to read those components as there are component types. Here are some handy cheat sheets to help you read resistors and capacitors and to help you remember what the different prefixes on units like volts and amperes mean.

Resistor Color Codes

Most of the resistors in this book have four color bands. To determine a resistor's value, just look up its colors in the following diagram and multiply accordingly. For example, to get 470 Ω, you'd multiply the number 47 (given by the yellow and purple bands) by 10 (given by the brown band). For more details on resistors, see "Meet the Resistor" on page 70.



first digit	second digit	multiplier	tolerance
0	0	×1 Ω	
1	1	×10 Ω	±1%
2	2	×100 Ω	±2%
3	3	×1 kΩ	
4	4	×10 kΩ	
5	5	×100 kΩ	
6	6	×1 MΩ	
7	7		
8	8	×0.1 Ω	±5%
9	9	×0.01 Ω	±10%

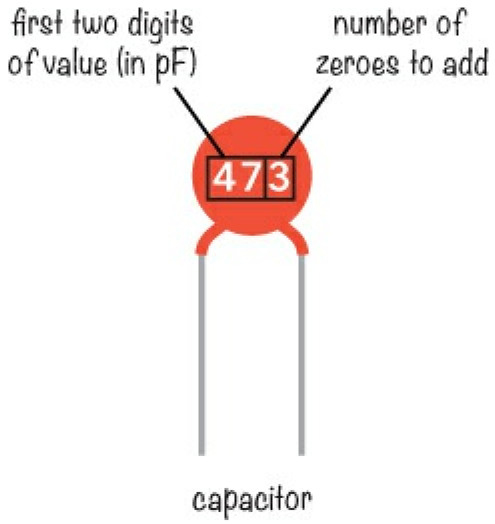
Capacitor Codes

In the following table, I've listed the most common capacitor codes. Refer to this table when you're using ceramic or tantalum capacitors because, unlike the electrolytic capacitors used in much of this book, those won't have their capacitance written straight out for you.

Code	Picofarad (pF)	Nanofarad (nF)	Microfarad (µF)

101	100	0.1	0.0001
102	1,000	1	0.001
103	10,000	10	0.01
104	100,000	100	0.1
105	1,000,000	1,000	1

If you have a capacitor with a different code from those listed here, you can find the value in picofarads by taking the first two digits and adding the number of zeros of the third digit.



In this example, the capacitor has the code 473. Take the first two digits, 47, and add the number of zeros specified by the third digit, 3. That gives you 47,000 pF, which is 47 nF, or 0.047 µF.

Standard Prefixes

When building electronics projects, as in many areas of science, we sometimes have to deal with really small or really big numbers. Fortunately, there’s a set of standard prefixes in the International System of Units to make those numbers easier to write. The prefixes are multipliers, as shown in the table.

Prefix	Name	Multiply value by	Example usage
p	pico	× 0.000 000 000 001	Capacitor values (example: 47 pF capacitor)
n	nano	× 0.000 000 001	Capacitor values (example: 100 nF capacitor)
µ	micro	× 0.000 001	Capacitor values (example: 10 µF capacitor)
m	milli	× 0.001	Currents in a circuit (example: 20 mA current)

-	-	× 1	Voltages often don't have a prefix (example: 9 V battery)
k	kilo	× 1,000	Resistor values above 1,000 (example: 10 kΩ resistor)
M	mega	× 1,000,000	File sizes (example: 2MB photo)
G	giga	× 100,0000,000	File sizes (example: 1GB video)
T	tera	× 1,000,000,000,000	Hard disk sizes (example: 2TB hard drive)

A QUICK REVIEW OF OHM'S LAW

Ohm's law is such an essential part of calculating values in circuits that you'll keep coming back to it again and again as you build more projects. Whenever you need a refresher on figuring out a voltage, current, or resistance in a circuit, just flip to this section.

$V = I \times R$ Voltage (in volts) equals the current (in amps) multiplied by the resistance (in ohms)

$I = \frac{V}{R}$ Current (in amps) equals the voltage (in volts) divided by the resistance (in ohms)

$R = \frac{V}{I}$ Resistance (in ohms) equals the voltage (in volts) divided by the current (in amps)

In the Ohm's law equation, you must use volts (V), amps (A), and ohms (Ω), so remember to convert units if necessary: 1 mA = 0.001 A and 1 kΩ = 1,000 Ω.

A BASIC VOLTAGE DIVIDER CIRCUIT

The voltage divider is a circuit that is very useful, for example, when you have a sensor based on resistance, such as a thermistor, which senses temperature, or a photoresistor, which senses light. See "Project #15: Build a Sunrise Wake-Up Alarm" on page 148 for a project that uses a voltage divider like this. You can also use your knowledge of the voltage divider to calculate voltages within a circuit in order to understand what's going on.

When you have two resistors in series, they form a voltage divider. The input voltage gets divided between the two resistors, and the output voltage (across R2) is given by the formula:

$$V_{out} = V_{in} \times \frac{R2}{R1 + R2}$$

Electronics for Kids is set in Century Schoolbook, Filmotype Candy, Housearama Kingpin, TheSansMono Condensed, and Billy the Flying Robot. The book was printed and bound by TC Transcontinental Printing in Beauceville, Québec, Canada. The paper is 70# Husky Offset, which is certified by the Forest Stewardship Council (FSC).

The book uses an Otabind binding, in which the pages are bound together with a cold-set, flexible glue, and the first and last pages of the resulting book block are attached to the cover. The cover is not actually glued to the book's spine, and when open, the book lies flat and the spine doesn't crack.

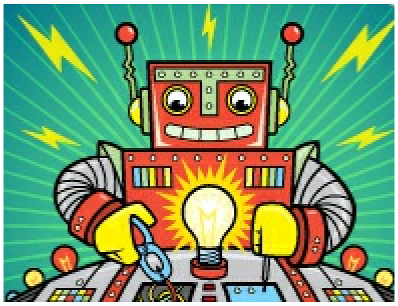
REAL ELECTRONICS.
REAL EASY.



Why do the lights in a house turn on when you flip a switch? How does a remote-controlled car move? And what makes lights on TVs and microwaves blink? The technology around you may seem like magic, but most of it wouldn't run without electricity.

Electronics for Kids demystifies electricity with a collection of awesome hands-on projects. In Part 1, you'll learn how current, voltage, and circuits work by making a battery out of a lemon, turning a metal bolt into an electromagnet, and transforming a paper cup and some magnets into a spinning motor. In Part 2, you'll make even more cool stuff as you:

- Solder a blinking LED circuit with resistors, capacitors, and relays
- Turn a circuit into a touch sensor using your finger as a resistor
- Build an alarm clock triggered by the sunrise
- Create a musical instrument that makes sci-fi sounds

Then, in Part 3, you'll learn about digital electronics—things like logic gates and memory circuits—as you make a secret code checker and an electronic coin flipper. Finally, you'll use everything you've learned to make the LED Reaction Game—test your reaction time as you try to catch a blinking light!

With its clear explanations and assortment of hands-on projects, *Electronics for Kids* will have you building your own circuits in no time.

ABOUT THE AUTHOR

Øyvind Nydal Dahl built his first circuit at 14 and has been passionate about electronics ever since. He has a master's degree in electronics from the University of Oslo, helps companies develop new products, and travels the world while teaching electronics workshops. He also writes beginner-friendly tutorials at *http://www.build-electronic-circuits.com/*.

Footnotes

Chapter 1: What Is Electricity?

* The electron is a negative particle, but in some materials the current is made up of positive particles instead, and they flow in the opposite direction. So, at the atomic level, the particles can flow in either direction.

Chapter 9: How Circuits Understand Ones and Zeros

* Sometimes kilobyte refers to 1024 bytes (2^10).

About the Author

Jonathan Bartlett is a senior software R&D specialist at Specialized Bicycle Components, focusing on creating initial prototypes for a variety of IoT (Internet of Things) projects. Jonathan has been educating the tech community for well over a decade. His first book, *Programming from the Ground Up*, is an Internet classic and was endorsed by Joel Spolsky, co-founder of Stack Exchange. It was one of the first open source books and has been used by a generation of programmers to learn how computers work from the inside out, using assembly language as a starting point. He recently released *Building Scalable PHP Web Applications Using the Cloud* as well as the calculus textbook *Calculus from the Ground Up*. Jonathan also writes a mix of technical and popular articles for a number of websites, including the new MindMatters.ai technology blog. His other articles can be found on IBM's DeveloperWorks website, Linux.com, and Medium.com. He is also the head of Tulsa Open Source Hardware, a local group focusing on do-it-yourself electronics projects.

Jonathan also participates in a variety of academic work. He is an associate fellow of the Walter Bradley Center for Natural and Artificial Intelligence. There, he does research into fundamental mathematics and the mathematics of artificial intelligence. He also serves on the editorial board for the journal *BIO-Complexity*, focusing on reviewing information-theoretic papers for the journal and assisting with LaTeX typesetting.

Additionally, Jonathan has written several books on the interplay of philosophy, math, and science, including *Engineering and the Ultimate* and *Naturalism and Its Alternatives in Scientific Methodologies*. Jonathan served as editor for the book *Controllability of Dynamic Systems: The Green's Function Approach*, which received the RA Presidential Award of the Republic of Armenia in the area of “Technical Sciences and Information Technologies.”

Jonathan serves on the board of Homeschool Oklahoma along with his wife, Christa, of 20 years. They inspire their community in several ways including writing educational material, creating educational videos, tutoring students through Classical Conversations, and sharing their own stories of tragedy and success with others.

Acknowledgments

I would like to thank, first and foremost, my homeschool co-op community. This book originally started from a series of classes that I taught in our local co-op, and my students were the guinea pigs for this content. I received a lot of encouragement from that class, with both the students and the parents enjoying the material. I want to thank my wife who put up with me always typing on my computer to put this together. I also want to thank the Tulsa Open Source Hardware community (as well as the larger Tulsa WebDevs community), who gave me a lot of encouragement while putting together this book and who also sat through many presentations based on this material.

CHAPTER 1

Introduction

Welcome to the world of electronics! In the modern world, electronic devices are everywhere, but fewer and fewer people seem to understand how they work or how to put them together. At the same time, it has never been easier to do so as an individual. The availability of training, tools, parts, instructions, videos, and tutorials for the home experimenter has grown enormously, and the costs for equipment have dropped to almost nothing.

However, what has been lacking is a good guide to bring students from *wanting* to know how electronic circuits work to actually understanding them and being able to develop their own. For the hobbyist, there are many guides that show you how to do individual projects, but they often fail to provide enough information for their readers to be able to build projects of their own. There is plenty of information on the physics of electricity in physics books, but they fail to make the information practical. One exception to this is Horowitz and Hill's *The Art of Electronics*. This book is a wonderful reference guide for practical circuit design. However, its target audience is largely electrical engineers or other very advanced circuit designers. Not only that, the book itself is prohibitively expensive.

What has been needed for a long time is a book that takes you from knowing nothing about electronics to being able to build real circuits that you design yourself. This book combines theory, practice, projects, and design patterns in order to enable you to build your own circuits from scratch. Additionally, this book is designed entirely around safe,

low-current DC (direct current) power. We stay far away from the wall outlet in this book to be sure that you have a fun and largely worry-free experience with electronics.

This book is written with two groups of people in mind. First, this book can be used as a guide for hobbyists (or wannabe hobbyists) to learn on their own. It has lots of projects to work on and experiment with. Second, this book can also be used in electronics classes for high school and college students. It has problems to be worked, activities to do, and reviews at the end of each chapter.

The needs of these groups are not so different from each other. In fact, even if you are a hobbyist and plan on using this book to learn on your own, I suggest that not only do you read the main parts of the chapter but that you also do the activities and homework as well. The goal of the homework is to train your mind to think like a circuit designer. If you work through the example problems, it will make analyzing and designing circuits simply a matter of habit.

1.1 Working the Examples

In this book, all examples should be worked out using decimals, not fractions. This is an engineering course, not a math course, so feel free to use a calculator. However, you will often wind up with very long strings of decimals on some of the answers. Feel free to round your answers, but always include at least a single decimal point. So, for instance, if I divide 5 by 3 on my calculator, it tells me 1.66666667. However, I can just give the final answer as 1.7. This only applies to the final answer. You need to maintain your decimals while you do your computations.

Also, if your answer is a decimal number that *begins* with a zero, then you should round your answer to include the first two to four nonzero digits. So, if I have an answer of 0.0000033333333, I can round that to 0.00000333. If you want to be precise about the proper way to round results, see the section on significant figures in the next chapter.

For beginners and hobbyists, this is less of a concern, and we will generally be in a hobbyist mindset for the book.

In short, as engineers, we wind up being, at minimum, as precise as we *need* to be or, at maximum, as precise as we *can* be. The amount of precision we need will vary from project to project, and the amount of precision that we can be will depend on our tools, our components, and other things we interact with. Therefore, there is not a lot of focus on this book on how many decimals exactly to use. You can get more detailed descriptions in other science books for dealing with significant figures. In the problems in the chapters, if you are off by a single digit due to rounding errors, don't worry about it.

1.2 Initial Tools and Supplies

You can get started in electronics with a minimum set of tools, but you can also be as fancy as you have money to afford. This book will focus on the more modest tools that are within the reach of pretty much every budget.

While the book will walk you through a wide variety of parts for different types of circuits, every electronics hobbyist should start out with the following components:

1. Multimeter: Multimeters will measure voltage, current, resistance, and other important values. For these projects, the cheapest digital multimeter you can find will work just fine. You only need one of these.

2. Solderless Breadboards: Solderless breadboards will hold your projects in place and connect your components together. Breadboards are sold based on the number of holes, known as "tie points," the breadboard contains. If you want to keep your projects around, you should have a separate breadboard for each project. However, the beauty of solderless breadboards is that they are in fact reusable if you want.

3. Jumper Wires: Jumper wires are just like normal insulated wires, except that their ends are solid and strong enough to be pushed into your breadboard. The wires themselves may be flexible or rigid. Jumper wires with female ends (a hole instead of a wire) also exist for plugging into circuits which have metal pins sticking out of them (known as headers) to connect to. Every hobbyist I know has a huge mass of jumper wires. They usually come in bundles of 65 wires, which is plenty to get started.

4. Resistors: Resistors do a lot of the grunt work of the circuit. They resist current flow, which, among other things, prevents damaging other parts of the circuit. Resistors are measured in ohms (Ω). Most hobbyists have a wide variety of resistors. You should have a range of resistors from 200 Ω to 1, 000, 000 Ω. However, if you had to pick one value for your resistors, 1, 000 Ω resistors work in a wide variety of situations. Resistors for this book should be rated for 1/4 watt of power.

5. LEDs: LEDs (light-emitting diodes) are low-power lights often used in electronic devices. I recommend getting a variety of colors of LEDs just because it makes life more fun. Most standard single-color LEDs have about the same specifications, so the main difference is the color.

6. Buttons and Switches: Buttons and switches will be the primary method of input and output in these circuits. You should buy buttons and switches *which are specifically made to go on breadboards*.

7. Power Regulator: While most of these projects can be operated directly from a battery, a power regulator board will make sure that, no matter how well charged or drained the battery is, you get a predictable voltage from your battery. The YwRobot breadboard power supply is extremely cheap (cheaper than most batteries) and also provides your project with an on/off switch. You should buy one of these for each breadboard you have. Other breadboard power supplies are available as well (make sure they output 5 volts), but our drawings will assume the YwRobot one.

8. 9 V Battery and Connector: The easiest way to supply power to the power regulator is with a 9 V battery with a standard barrel plug (2.1 mm × 5.5 mm), which will fit into the YwRobot power supply.

Later projects will require specialized components, but these are the components that are needed for nearly every project you will encounter or design yourself. If you would like to order a kit with all of the components you need for this book, you can find them at `www.bplearning.net`.

1.3 Safety Guidelines

This book deals almost entirely with direct current from small battery sources. This current is inherently fairly safe, as small batteries are not capable of delivering the amount of current needed to injure or harm. For these projects, you can freely touch wires and work with active circuits without any protection, because the current is incapable of harming you. The main issue that sometimes arises is that, in poorly made circuits, components can overheat and occasionally (but rarely) catch fire.

Additionally, the battery itself may become overheated/compromised, and batteries are often made from potentially toxic chemicals.

Please follow the following safety guidelines when working on projects (both projects from this book and projects you build yourself). They will help keep you safe and help prevent you from accidentally damaging your own equipment:

1. If you have any cuts or other open areas on your skin, please cover them. Your skin is where most of your electric protection exists in your body.
2. Before applying power to your circuit, check to be sure you have not accidentally wired in a short circuit between your positive and negative poles of your battery.
3. If your circuit does not behave as you expect it to when you plug in the battery, unplug it immediately and check for problems.
4. If your battery or any component becomes warm, disconnect power immediately.
5. If you smell any burning or smoky smells, disconnect power immediately.
6. Dispose of all batteries in accordance with local regulations.
7. For rechargeable batteries, follow the instructions on the battery for proper charging procedures.

Please note that if you ever deal with alternating current (AC) or large batteries (such as a car battery), you must exercise many more precautions than described in this book, because those devices generate sufficient power in themselves and within the circuits to harm or kill you if mishandled (sometimes even after the power has been disconnected).

1.4 Electrostatic Discharge

If you have ever touched a doorknob and received a small shock, you have experienced electrostatic discharge (ESD). ESD is not dangerous to you, but it can be dangerous to your equipment. Even shocks that you can't feel may damage your equipment. With modern components, ESD is rarely a problem, but nonetheless it is important to know how to avoid it. You can skip these precautions if you wish, just know that occasionally you might wind up shorting out a chip or transistor because you weren't careful. ESD is also more problematic if you have carpet floors, as those tend to build up static electricity.

Here are some simple rules you can follow to prevent ESD problems:

1. When storing IC components (i.e., electronics chips), store them with the leads enmeshed in conductive foam. This will prevent any voltage differentials from building up in storage.
2. Wear natural 100% cotton fabrics.
3. Use a specialized ESD floor mat and/or wrist strap to keep you and your workspace at ground potential.
4. If you don't use an ESD strap or mat, touch a large metal object before starting work. Do so again any time after moving around.

1.5 Using Your Multimeter Correctly

Even though we haven't covered the details we need to use our multimeter yet, since we are covering proper handling of devices, I am including this section here with the others. Feel free to skip over this until we start using multimeters in the book.

In order to keep your multimeter functioning, it is important to take some basic precautions. Multimeters, especially cheap ones, can be easily broken through mishandling. Use the following steps to keep you from damaging your multimeter or damaging your circuit with your multimeter:

1. Do not try to measure resistance on an active circuit. Take the resistor all the way out of the circuit before trying to measure it.
2. Choose the appropriate setting on your multimeter *before* you hook it up.
3. Always err on the side of choosing high values first, especially for current and voltage. Use the high value settings for current and voltage to give your multimeter the maximum protection. If you set the value too large, it is easy enough to set it lower. If you had it set too low, you might have to buy a new multimeter!

CHAPTER 2

Dealing with Units

Before we begin our exploration of electronics, we need to talk about **units of measurement**. A unit of measurement is basically a standard against which we are measuring something. For instance, when measuring the length of something, the units of measurement we usually use are feet and meters. You can also measure length in inches, yards, centimeters, kilometers, miles, and so on. Additionally, there are some obscure units of length like furlongs, cubits, leagues, and paces.

Every type of quantity has its own types of units. For instance, we measure time in seconds, minutes, hours, days, weeks, and years. We measure speed in miles per hour, kilometers per hour, meters per second, and so on. We measure mass in pounds, ounces, grams, kilograms, grains, and so on. We measure temperature in Fahrenheit, Celsius, Kelvin, and Rankine.

Units for the same type of quantity can all be converted into each other using the proper formula.

2.1 SI Units

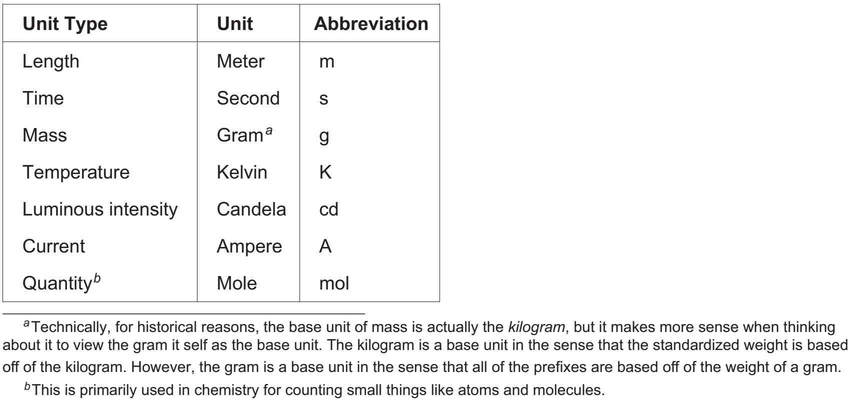
The scientific community has largely agreed upon a single standard of units known as the **International System of Units**, abbreviated as **SI Units**. This is the modern form of the metric system. Because of the large number of unit systems available, the goal of creating the SI standard was

© Jonathan Bartlett 2020
J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_2

to create a single set of units that had a basis in physics and had a standard way of expressing larger and smaller quantities.

The imperial system of volumes illustrates the problem they were trying to solve. In the imperial system, there were gallons. If you divided a gallon into four parts, you would get quarts. If you divided quarts in half, you'd get pints. If you divided a pint into twentieths, you'd get ounces.

The imperial system was very confusing. Not only were there an enormous number of units but they all were divisible by differing amounts. The case was similar for length—12 inches in a foot, but 3 feet in a yard and 1,760 yards in a mile. This was a lot to memorize, and doing the calculations was not easy.



Unit Type	**Unit**	**Abbreviation**
Length	Meter	m
Time	Second	s
Mass	Gram[a]	g
Temperature	Kelvin	K
Luminous intensity	Candela	cd
Current	Ampere	A
Quantity[b]	Mole	mol

[a] Technically, for historical reasons, the base unit of mass is actually the *kilogram*, but it makes more sense when thinking about it to view the gram it self as the base unit. The kilogram is a base unit in the sense that the standardized weight is based off of the kilogram. However, the gram is a base unit in the sense that all of the prefixes are based off of the weight of a gram.

[b] This is primarily used in chemistry for counting small things like atoms and molecules.

Figure 2-1. *SI Base Units*

The imperial system does have some benefits (the quantities used in the imperial system match the sizes normally used in human activities—few people order drinks in milliliters), but for doing work which requires a lot of calculations and units, the SI system has largely won out. Scientific quantities are almost always expressed in SI units. In engineering it is more of a mix, just as engineering itself is a mix between scientific inquiry and human usefulness. However, the more technical fields have generally moved to SI units and stayed with them.

There are only seven base units in the SI system. Other units are available as well, but they all can be measured in terms of these base units. The base units for the SI system are shown in Figure 2-1.

Many other units are derived from these and are known as SI derived units. For instance, for measuring volume, liters are often used.[1] A liter, however, is not defined on its own, but in terms of meters. A liter is a thousandth of a cubic meter. Thus, we can take the unit of length and use it to describe a unit of volume.

A more complicated example is the newton, which is a unit of force. In the SI system, the newton is defined as being a “kilogram-meter per second squared.” This is another way of saying that a newton is the amount of force which accelerates 1 kilogram 1 meter per second, per second.

All of the things of interest to us in this book are ultimately defined in terms of SI base units. For the purposes of this book, it is not important to know which units are base units or derived units, and it is especially unnecessary to know how they are derived. The important thing to keep in mind is that you will be using a well-thought-out, standardized system of units. If the units seem to fit together well, it’s because they were designed to do so.

---

[1] Technically, the liter is not defined by the SI, but it is listed here because it is the simplest illustration of the point.

Conversion Factor	Prefix	Abbreviation	Examples
1,000,000,000,000	Tera	T	Terameter, terasecond, teragram
1,000,000,000	Giga	G	Gigameter, gigasecond, gigagram
1,000,000	Mega	M	Megameter, megasecond, megagram
1,000	Kilo	K	Kilometer, kilosecond, kilogram
1			Meter, second, gram
0.001	Milli	m	Millimeter, millisecond, milligram
0.000001	Micro	μ or u	Micrometer, microsecond, microgram
0.000000001	Nano	n	Nanometer, nanosecond, nanogram
0.000000000001	Pico	p	Picometer, picosecond, picogram

Figure 2-2. *Common SI Prefixes*

2.2 Scaling Units

Now, sometimes you are measuring really big quantities, and sometimes you are measuring very small quantities. In the imperial system, there are different units altogether to reach a different scale of a quantity. For instance, there are inches for small distances, yards for medium-sized distances, and miles for large distances. There are ounces for small volumes and gallons for larger volumes.

In the SI system, however, there is a uniform standard way of expressing larger and smaller quantities. There are a set of modifiers, known as **unit prefixes**, which can be added to *any unit* to work at a different scale. For example, the prefix *kilo-* means thousand. So, while a meter is a unit of length, a kilometer is a unit of length that is 1,000 times as large as a meter. While a gram is a unit of mass, a kilogram is a unit of mass that is 1,000 times the mass of a gram.

It works the other way as well. The prefix *milli-* means thousandth, as in $\frac{1}{1000}$. So, while a meter is a unit of length, a millimeter is a unit of length that is $\frac{1}{1000}$ of a meter. While a gram is a unit of mass, a milligram is a unit of mass that is $\frac{1}{1000}$ the mass of a gram.

Therefore, by memorizing one single set of prefixes, you can know how to modify all of the units in the SI system. The common prefixes occur at every power of 1,000, as you can see in Figure 2-2.

To convert between a prefixed unit (i.e., kilometer) and a base unit (i.e., meter), we just apply the conversion factor. So, if something weighs 24.32 kilograms, then I could convert that into grams by multiplying by 1,000. $24.32 * 1000 = 24{,}320$. In other words, 24.32 kilograms is the same as 24,320 grams.

To move from the base unit to a prefixed unit, you *divide* by the conversion factor. So, if something weighs 35.2 grams, then I could convert that into kilograms by dividing it by 1,000. $35.2/1000 = 0.0352$. In other words, 35.2 grams is the same as 0.0352 kilogram.

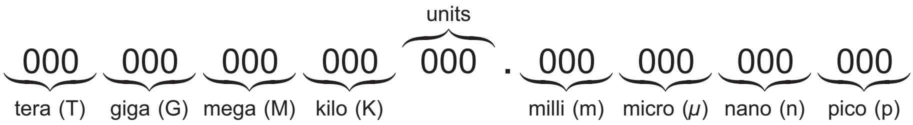


Figure 2-3. *Visualizing Common Unit Prefixes*

You can also convert between two prefixed units. You simply multiply by the starting prefix and divide by the target prefix. So, if something weighs 220 kilograms and I want to know how many micrograms that is, then I will multiply using the kilo- prefix (1,000) and divide by the micro- prefix (0.000001):

$$\frac{220 \cdot 1000}{0.000001} = 220000000000$$

In other words, 220 kilograms is the same as 220,000,000,000 micrograms.

You can do all of the unit scaling that you need just by knowing the multipliers. However, what usually helps me deal with these multipliers intuitively is to simply visualize where each one lands in a single number. Figure 2-3 shows all of the prefixes laid out in a single number.

So let's say that I was dealing with fractions of a meter and I had something that was 0.000000030 meter. If you line this number up with the chart in Figure 2-3, there are only zeros in the unit, the milli-, and the micro- areas. The first nonzero digits appear in the "nano-" group. When lined up with the chart, the number in the nano- area is 030. Therefore, the number under consideration is 30 nanometers.

2.3 Using Abbreviations

Typing or writing words like kilogram, microsecond, and micrometer isn't terribly difficult, but, when it occurs a lot (as what can happen in equations), it can get overwhelming. Therefore, every prefix and every unit has an abbreviation. Since the abbreviation for gram is g, and the abbreviation for kilo- is k, we can abbreviate kilogram as kg. Occasionally the abbreviation for the unit and the scaling prefix are identical, as in the case of meter (m) and milli- (also m). That's fine, as, when you put them together, you get millimeter, which is abbreviated as mm.

The hardest one to write is the one for micro-, μ. This is the Greek letter mu (pronounced "mew"). It's essentially the Greek way of writing the letter m, and it is used because we already have a lowercase m (milli-) and an uppercase M (mega-) in use. Since micro- begins with an m, lacking any additional English/Latin way of writing an m, it is written with the Greek μ. However, this is sometimes hard to type. Therefore, since the squashed way that it is written makes it look kind of like a u, sometimes people will write u instead of μ if they don't know how to type out μ with their computer/keyboard. In this book, we never use u for this purpose, but, if you are reading elsewhere something like 100 us, that means 100 microseconds.

2.4 Significant Figures

Significant figures are the bane of many science books. Nearly everything in science has to be rounded, and significant figures are basically the rounding rules for science. We need to talk about them simply so that you are aware of how I achieve the rounding that I do in my exercises.

These rules aren't hard, but they can cause some newer students to stumble. If you just are wanting to play with electronics, you can skip this section; just be aware that I may have rounded the answers to problems differently than you do.

The goal of significant figures is to prevent us from thinking that we are being more precise than we really are. Let's say that I measured a piece of wood to be 1 meter long, but I wanted to cut that wood into thirds. How should I report the distance, in decimal, of the length of each desired piece? Well, 1 divided by 3 is 0.33333333333… I can keep writing three's until the cows come home. But do I really need the length to be that precise? Is my measurement of the initial length of the wood precise enough to warrant that sort of precise request? Significant figures allow us to answer that question and report numbers with a justifiable precision.

So, for any measured quantity, we need to count the number of significant figures. For the most part, the number of significant figures in a number is the same as the number of digits, with a few exceptions. First, significant figures ignore all leading zeros. So, if I measured something as being 102 feet, it has three signficant figures, even if I add leading zeros. So 102 feet and 0000000000102 feet both have three significant figures. Additionally, these leading zeros are still ignored even if they are after the decimal point. So the number 0.00042 has two significant figures.

The second rule in counting is that trailing zeros aren't counted as significant if the measuring device isn't capable of measuring that accurately (or the quantity isn't reported that accurately). For instance, the value 1 meter and the value 1.000 meter refer numerically to the same number. However, the second one is usually used to indicate that we can actually measure that precisely. We wouldn't report 1.000 meter unless our scale can actually report accurately to a thousandth of a meter.

The situation is a little more complicated with zeros on the left side of the decimal. If I say, "1,000 people attended the event," how precise is that number? Did you count individuals and get exactly 1,000? Is it possibly estimated to the tens or hundreds place? This gets murky. To simplify the issue for this book, you can assume that all digits on the right count as significant figures. So, if we say "1,000 people" attended the event, that is a number with four significant digits. However, if we say "1 kilopeople" attended the event, that is a number with one significant digit. If we say " 1.03 kilopeople" attended the event, that is a number with three significant digits. We will use this convention when writing down problems, but results may just be a rounded number with trailing zeros (i.e., instead of writing "1.03 kilopeople," we might write the result as 1,030 people).

One other small rule: If a number is exact, then it is essentially considered to have infinite significant digits. So, for instance, it takes two people to have a baby. This is an exact number. It isn't 2.01 or 2.00003 people, it is exactly two. So, for the purposes of significant figures, this value has an infinite number of digits. Conversion factors are generally considered to be exact values.

So that is how to count significant digits. This is important because the significant digits affect how caclulations are rounded. There are two rules—one for multiplying and dividing and another for adding and subtracting.

For multiplying and dividing, you should find the input value with the fewest significant figures. The result should then be rounded to that many significant figures. For instance, if we had $103 * 55$, then the result should be rounded to two significant figures. So, even though the result is 5,665, we should report it as 5,700. Let's say we have 55.0 ÷ 3.00. Since both of the input values have three significant figures, then the result should have three significant figures. Therefore, the result is 18.3.

For addition and subtraction, instead of using significant figures, the decimal points for the numbers are lined up, the operation is performed, and the result is rounded to the number of decimal places available in the input value that has the least precision (fewest numbers to the right of the decimal). So, for instance, if I have 1.054 + 0.06, the result is 1.104. However, this would be rounded to 1.10 because that is how many digits to the right the decimal 0.06 had.

If there are a series of operations, significant figures are usually applied at the end of the whole calculation, or when necessary to limit the complication of intermediate results. Calculators will round for you at some point anyway, so there is no getting around some amount of intermediate rounding. Therefore, you should recognize that if your answer differs from the book's answer by the least significant digit, it is likely that you are correct, but that you rounded in different stages in your calculation.

In professional science and engineering data reporting, significant figures are important. In playing around with electronics, they are much less so. Additionally, even the rules for significant figures aren't perfect—there are places where their usage leads to problematic results. Entire books have been written on the subject.[2] Significant figures are there not because they are perfect, but so that we all have a common, straightforward way of communicating the precision of our results. The most important thing to keep in mind is that the degree to which you are precise in your measurements affects the degree to which you can be precise in your calculations.

CHAPTER 3

What Is Electricity?

The first thing to tackle in the road to understanding electronics is to wrap our minds around what electricity is and how it works. The way that electricity works is very peculiar and unintuitive. We are used to dealing with the world in terms of physical objects—desks, chairs, baseballs, and so on. Even if we never took a class in physics, we know the basic properties of such objects from everyday experience. If I drop a rock on my foot, it will hurt. If I drop a heavier rock, it will hurt more. If I remove an important wall from a house, it will fall down.

However, for electricity, the only real experience we have is that we have been told to stay away from it. Sure, we have experience with computers and phones and all sorts of devices, but they give us the result of processing electricity a million times over. But how does electricity itself work?

3.1 Charge

To answer this question, we need to answer another question first: What *is* electricity? Electricity is the flow of **charge**. So what is charge?

Charge is a fundamental quantity in physics—it is not a combination (that we know of) of any other quantity. A particle can be charged in one of three ways—it can be positively charged (represented by a + sign), negatively charged (represented by a – sign), or neutrally charged (i.e., has no charge). Figure 3-1 shows what an atom looks like. In the center of the atom are larger, heavier particles called **protons** and **neutrons**. Protons are positively charged particles, and neutrons are neutrally charged particles.

© Jonathan Bartlett 2020

J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_3

Together, these form the **nucleus** of the atom and determine *which* atom we are talking about. If you look on a periodic table, the large printed number associated with an element is known as its **atomic number**. This number refers to how many protons it has in its nucleus. Sometimes, there is a number in smaller print as well. This is the total number of protons and neutrons combined.[1] Note that the number of neutrons in an element can vary, so this number is often a decimal representing the average number of combined protons and neutrons in any particular element.

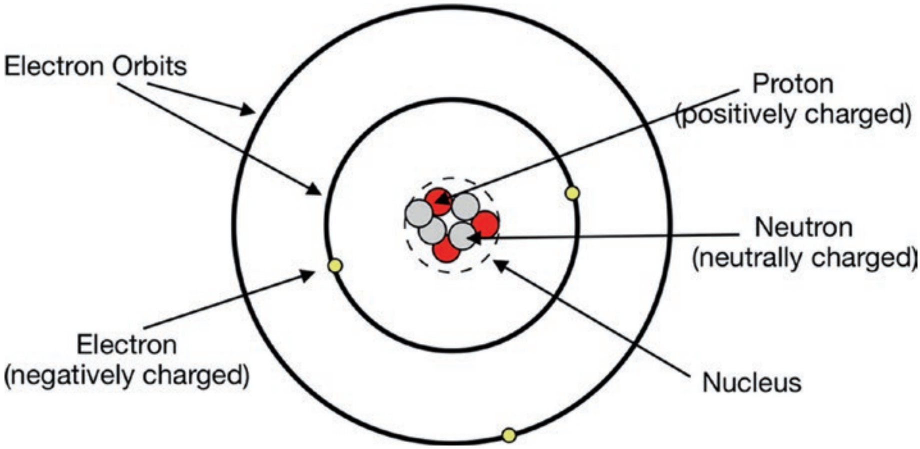

Figure 3-1. *Charged Particles in an Atom*

Circling around the nucleus are **electrons**. Electrons are negatively charged particles. Even though electrons are much smaller and lighter than protons, the amount of negative charge of one electron is equal to the amount of positive charge of one proton. Positive and negative charges attract each other, which is what keeps electrons contained within the atom.

---

[1] This is technically the *atomic mass* of the element, given in special units called atomic mass units (AMUs). However, the weights of protons and neutrons are each extremely close to 1 AMU, and the weight of electrons is extremely close to zero, so the atomic mass and the combined number of protons and neutrons are nearly identical.

Electrons are arranged in shells surrounding the nucleus. The outermost shell, however, is the most important one when thinking about how atoms work.

When we think about individual atoms, we think about them when they are isolated and alone. In these situations, the number of electrons and the number of protons are equal, making the atom as a whole electrically neutral. However, especially when atoms interact with other atoms, the configuration of their electrons can change. If the atoms gain electrons, then they are negatively charged. If the atoms lose electrons, then they are positively charged. Free electrons are all negatively charged.

If there are both positively and negatively charged particles moving around, their opposite charges attract one another. If there is a great imbalance of positive and negative charges, usually you will have a *movement* of some of the charged particles toward the particles of the opposite charge. This is a *flow* of charge, and this flow is what is referred to when we speak of electricity.

The movement of charge can be either positively charged particles moving toward negatively charged ones, negatively charged particles moving toward positively charged ones, or both. Usually, in electronics, it is the electrons which are moving through a wire, but just know that this is not the only way in which charge can move.

Electricity can be generated by a variety of means. The way that electricity is generated in a battery is that a chemical reaction takes place, but the reactants (the substances that react together) are separated from each other by some sort of medium. The positive charges for the reaction move easiest through the medium, but the negative charges for the reaction move easiest through the wire. Therefore, when the wire is connected, electricity moves through the wire to help the chemical reaction complete on the other side of the battery.

This flow of electric charge through the wire is what we normally think of as electricity.

MAKING YOUR OWN BATTERY

You can make a simple battery of your own out of three materials: thick copper wire or tubing, a galvanized nail (it *must* be galvanized), and a potato or a lemon. This battery operates from a reaction between the copper on the wire and the zinc on the outside of the galvanized nail. The electrons will flow from the zinc to the copper through the wire, while the positive charge will flow within the lemon or potato.

To build the battery, you must insert the thick copper and the nail into the potato. They should be near each other, but *not touching*. This battery will not produce very much current—less than a milliamp of current at less than 1 volt (we will discuss milliamps later in this chapter and volts in Chapter 4). This is not quite enough to light up an LED, but it should register on a multimeter. See Chapter 6 for how to measure voltage with a multimeter.

Note that the lemon/potato is not actually supplying the current. What the lemon/potato is doing is creating a barrier so that only the positive charges can flow freely in the potato, and the negative charges have to use the wire.

3.2 Measuring Charge and Current

Atoms are very, very tiny. Only in the last few years have scientists even developed microscopes that can see atoms directly. Electrons are even tinier. Additionally, it takes a *lot* of electrons moving to have a worthwhile flow of charge. Individual electrons do not do much on their own—it is only when there are a very large number of them moving that they can power our electronics projects.

Therefore, scientists and engineers usually measure charge on a much larger scale. The **coulomb** is the standard measure of electric charge. One coulomb is equivalent to the electric charge of about

6,242,000,000,000,000,000 protons. If you have that many electrons, you would have a charge of −1 coulomb. That's a lot of particles, and it takes particles on that scale to do very much electrical work. Thankfully, protons and electrons are very, very small. A typical 9-volt battery can provide about 2,000 coulombs of charge, which is over 10,000,000,000,000,000,000,000 charged particles (ten thousand billion billion particles).

However, electricity and electronics are not about electric charge sitting around doing nothing. Electricity deals with the *flow* of charge. Therefore, when dealing with electricity, we rarely deal with coulombs. Instead, we talk about how fast the electric charge is flowing. For that, we use **amperes**, often called amps and abbreviated as A. One ampere is equal to the movement of 1 coulomb of charge out of the battery each second.

For the type of electronics we will be doing, an ampere is actually a lot of current. In fact, a full ampere of current can do a lot of physical harm to you, but we don't usually deal with full amperes when creating electronic devices. Power-hungry devices like lamps, washers, dryers, printers, stereos, and battery chargers need a lot of current—that's why we plug them into the wall. Small electronic devices don't usually need so much current. Therefore, for electronic devices, we usually measure current in **milliamperes**, usually called just milliamps and abbreviated as mA. Remember that the prefix *milli-* means one-thousandth of (i.e., $\frac{1}{1000}$ or 0.001). Therefore, a milliamp is one-thousandth of an amp. If someone says that there is 20 milliamps of current, that means that there is 0.020 amp of current. This is important, because the equations that we use for electricity are based on amps, but since we are dealing with low-current devices, most of our measurements will be in milliamps.

So, to go from amps to milliamps, multiply the value by 1,000. To go from milliamps to amps, divide the value by 1,000 (or multiply by 0.001) and give the answer in decimal (electronics always uses decimals instead of fractions).

Example 3.1 If I were to have 2.3 amps of electricity, how many milliamps is that? To go from amps to milliamps, we multiply by 1,000. 2.3 ∗ 1,000 = 2,300. Therefore, 2.3 amps is the same as 2,300 milliamps.

Example 3.2 If I were to have 5.7 milliamps of electricity, how many amps is that? To go from milliamps to amps, we divide by 1,000. 5.7/1,000 = 0.0057. Therefore, 5.7 milliamps is the same as 0.0057 amp.

Example 3.3 Now, let's try something harder—if I say that I am using 37 milliamps of current, how many coulombs of charge has moved after 1 minute? Well, first, let's convert from milliamps to amps. To convert from milliamps to amps, we divide by 1,000. 37/1000 = 0.037. Therefore, we have 0.037 amp. What is an amp? An amp is 1 coulomb of charge moving per second. Therefore, we can restate our answer as being 0.037 coulomb of charge moving each second.

However, our question asked about how much has moved after 1 *minute*. Since there are 60 seconds in each minute, we can multiply 0.037 by 60 for our answer. 0.037 ∗ 60 = 2.22. So, after 1 minute, 37 milliamps of current moves 2.22 coulombs of charge.

3.3 AC vs. DC

You may have heard the terms AC and DC when people talk about electricity. What do those terms mean? In short, DC stands for **direct current**, and AC stands for **alternating current**. So far, our descriptions of electricity have dealt mostly with DC. With DC, electricity makes a route from the positive terminal to the negative. It is the way most people envision electricity. It is “direct.”

However, DC, while great for electronics projects, very quickly loses power over long distances. If we were to transmit current that simply flows from the positive to the negative throughout the city, we would have to have power stations every mile or so.

So, instead of sending current in through one terminal and out through another, your home is powered with **alternating current**. In alternating current, the positive and negative sides continually reverse, switching back and forth 50–60 times per second. So the current direction (and thus the direction the electrons are moving) continually switches back and forth, over and over again. Instead of moving in a continuous flow, it is more like someone is pushing and pulling the current back and forth. In fact, at the generator station, that is almost exactly what is going on! This may seem strange, but this push and pull action allows for much easier power generation and also allows much more power to be delivered over much longer distances.

AC, such as the current that comes out of a wall socket, is much more powerful than we require for our projects here. In fact, converting high-power AC to low-power DC voltage used in electronic devices is an art in itself. This is why companies charge so much money for battery chargers—it takes a lot of work to get one right!

Now, not all AC is like this. We call this current AC “mains,” because it comes from the power mains from the power stations. It is supposed to operate at about 120 volts, and the circuits are usually rated for about 15–30 amps (that’s 15,000–30,000 milliamps). That’s a lot of electricity!

In addition to AC mains, there are also ACs which we will call AC “signal.” These currents come from devices like microphones. They are AC because the direction of current does in fact alternate. When you speak, your voice vibrates the air back and forth. A microphone converts these air vibrations into small vibrations of electricity—pushing and pulling a small electric current back and forth. However, these ACs are so low powered as to be almost undetectable. They are so small we have to actually amplify these currents (see Chapter 25) just to work with them using our DC power!

So, in short, while we will do some work with AC signal voltages later in the book, all of our projects will be safe, low-power projects. We will often touch wires with our projects active or use multimeters to measure currents and voltages in active circuits. This is perfectly safe for battery-operated projects. But *do not* attempt these same maneuvers for anything connected to your wall outlet unless you are properly trained.

3.4 Which Way Does Current Flow?

One issue that really bungles people up when they start working with electronics is figuring out which way electric current flows. You hear first that electric current is the movement of electrons, and then you hear that electrons move from negative to positive. So one would naturally assume that current flows from negative to positive, right?

Good guess, but no—or, at least, not quite.

Current is not the flow of physical stuff like electrons, but the flow of *charge*. So, when the chemical reaction happens in the battery, the positive side gets positively charged, and the influence of that charge moves down the wires. The electrons are a negative charge that moves toward that positive charge. The positive charge is just as real as the negative charge, even though physical stuff isn't moving with the positive charge.

Think about it this way. Have you ever used a vacuum cleaner? Let's say we are tracing the action of a vacuum cleaner. Where do you start? Usually, you start at the inside where the suction happens and then trace the flow of suction through the tube. Then, at the end of the tube, the dust comes into the tube.

Engineers don't trace their systems from the dust to the inside, they trace their systems from the suction on the inside out to the dust particles on the outside. Even though it is the dust that moves, it is the suction that is interesting.

Likewise, for electricity, we usually trace current from positive to negative even though the electrons are moving the other way. The positive charge is like the suction of a vacuum, pulling the electrons in. Therefore, we want to trace the flow of the vacuum from positive to negative, even though the dust is moving the other way.

The idea that we trace current from positive to negative is often called **conventional current flow**. It is called that way because we conventionally think about circuits as going from the positive to the negative, and it is the common convention to draw them that way (any arrow in an electronics diagram is pointing toward the movement of *positive* charge).

If you are tracing charge the other way, that is called **electron current flow**, but it is rarely used.

Review

In this chapter, we learned the following:

1. Electric current is the flow of charge.
2. Charge is measured in coulombs.
3. Electric current flow is measured in coulombs per second, called amperes or amps.
4. A milliampere is one-thousandth of an ampere.
5. In an atom, protons are positively charged, electrons are negatively charged, and neutrons are neutrally charged.

6. Batteries work by having a chemical reaction which causes electricity to flow through wires.
7. In DC, electricity flows continuously from positive to negative.
8. In AC, electricity flows back and forth, changing flow direction many times every second.
9. Even though electrons flow from negative to positive, in electronics, we usually think about circuits and draw circuit charges as flowing from positive to negative.
10. AC mains (the kind in your wall outlet) is dangerous, but battery current is relatively safe.
11. Small signal AC (like that generated by a microphone) is not dangerous.

Apply What You Have Learned

1. If I have 56 milliamps of current flowing, how many amps of current do I have flowing?
2. If I have 1,450 milliamps of current flowing, how many amps of current do I have flowing?
3. If I have 12 amps of current flowing, how many milliamps of current do I have flowing?
4. If I have 0.013 amp of current flowing, how many milliamps of current do I have flowing?
5. If I have 125 milliamps of current flowing for 1 hour, how many coulombs of charge have I used up?

6. What is the difference between AC and DC?
7. In AC mains, how often does the direction of current go back and forth?
8. Why is AC used instead of DC to deliver electricity within a city?
9. In working with electronic devices, do we normally work in amps or milliamps?

CHAPTER 4

Voltage and Resistance

In Chapter 3, we learned about current, which is the rate of flow of charge. In this chapter, we are going to learn about two other fundamental electrical quantities—**voltage** and **resistance**. These two quantities are the ones that are usually the most critical to building effective circuits.

Current is important because limiting current allows us to preserve battery life and protect precision components. Voltage, however, is usually the quantity that has to be present to do any work within a circuit.

4.1 Picturing Voltage

What is voltage? Voltage is the amount of power each coulomb of electricity can deliver. If person A has 1 coulomb of charge at 5 volts and person B has 1 coulomb of charge at 10 volts, that means that person B's coulomb can deliver twice as much power as person A's.

A good analogy to electronics is the flow of water. When comparing water to electricity, *coulombs* are a similar unit to *liters*—coulombs measure the amount of electric charge present just like a liter is the amount of water volume present. Both charge and water move as a flow. In water, we can measure the flow of a current of a stream in liters per second. Likewise, in electronics, we measure the flow of charge through a wire in coulombs per second, which are also called amperes.

Now, I want you to image the end of a hose through which water is flowing. Normally, the water just falls out of the hose, especially if the hose is just sitting on the ground. That hose just sitting on the ground is like a current with 0 volt—each unit of water or charge is just not doing that much.

Let's pretend we added a spray nozzle to the hose. What happens now? Water shoots out of the nozzle forcefully. We haven't added any more water—it is actually the same amount of water (i.e., current) flowing. Instead, we increased the pressure of the water, which is just like increasing the voltage on an electric charge. By increasing the pressure, we changed the amount of work that each liter of water is available to perform.

Likewise, when we increase voltage, we change the amount of work that each coulomb of electricity can do.

One way we might measure the pressure of water coming out of a hose is to measure how far up it can shoot out of the hose. By doubling the pressure of the water, we can double how far out of the hose it can shoot. Similarly, with voltages, large enough voltages can actually jump air gaps across circuits. However, to do this, it takes a lot of voltage—about 30,000 volts per inch of gap. If you have been shocked by static electricity, though, this is what is happening! The power of the charge is extreme (thousands of volts), but the amount of charge in those shocks is so small that it doesn't harm you (about 0.00000001 coulomb).

4.2 Volts Are Relative

While charge and current are fairly concrete ideas, voltage is a much more relative idea. You can actually never measure voltage absolutely. All voltage measurements are actually relative to other voltages. That is, I can't actually say that my electric charge has exactly 1, 2, 3, or whatever volts. Instead, what I have to do is say that one charge is however many volts more or less than another charge. So let's take a 9-volt battery. What that means is not that the battery is 9 volts in any absolute sense, but rather that there is a 9 -volt *difference* between the charge at the positive terminal and the charge at the negative terminal. That is, the pressure with which charge is trying to move from the positive terminal to the negative terminal is 9 volts.

4.3 Relative Voltages and Ground Potential

When we get to actually measuring voltages on a circuit, we will only be measuring voltage *differences* on the circuit. So, to measure voltage, I can't just put a probe on one place on the circuit. Instead, I have to put my probe on two *different* places on the circuit and measure the voltage difference (also called the **voltage drop**) between those two points.

However, to simplify calculations and discussions, we usually choose some point on the circuit to represent "0 volt." This gives us a way to standardize voltage measurements on a circuit, since they are all given relative to the same point. In theory, this could be any point on the circuit, but, usually, we choose the negative terminal on the battery to represent 0 volt.

This "zero point" goes by several names, the most popular of which is **ground** (often abbreviated as **GND**). It is called the ground because, historically, the physical ground has often been used as a reference voltage for circuits. Using the physical ground as the zero point allows you to also compare voltages between circuits with different power supplies. However, in our circuits, when we refer to the ground, we are referring to the negative terminal on the battery, which we are designating as 0 volt.

Another, lesser-used term for this designated 0-volt reference is the **common** point. Many multimeters label one of their electrodes as **COM**, for the common electrode. When analyzing a circuit's voltage, this electrode would be connected to whatever your 0-volt point is.

This “ground” analogy also makes sense with our water hose analogy. Remember that a voltage is the potential for a charge to do work. What happens to water after it lands on the ground? By the time the water from my hose lands on the ground, it has lost all its energy. It is just sitting there. Sure, it may seep or flow around a bit, but nothing of consequence. All of its ability to do work—to move quickly or to knock something over—has been drained. It is just on the ground. Likewise, when our electric charge is all puttered out, we say that it has reached “ground potential.”

So, even though we could designate any point as being zero, we usually designate the negative terminal of the battery as the zero point, indicating that by the time electricity reaches that point, it has used up all of its potential energy—it now has 0 volt compared to the end destination (i.e., the other battery terminal).

4.4 Resistance

Resistance is how much a circuit or device resists the flow of current. Resistance is measured in **ohms** and is usually represented by the symbol Ω. Going back to our water hose analogy, **resistance** is how small the hose is, because a smaller hose will resist the flow of water more than a larger hose will. Think about a 2-liter bottle of pop. The bottle has a wide base, but the opening is small. If I turn the bottle upside down, the small opening limits the amount of liquid that flows out at one time. That small opening is giving *resistance* to the flow of liquid, making it flow more slowly. If you cut off the small opening, leaving a large opening, the liquid will come out much faster because there is less resistance.

Ohm’s law, which we will use throughout this book, tells us about the relationship between resistance, voltage, and current flow. The equation is very simple. It says

$$V = I * R \tag{4.1}$$

In this equation, V stands for voltage, I stands for current (in *amperes*, not milliamperes), and R stands for resistance (in ohms). To understand what this equation means, let's think again about water hoses. The water that comes out of the faucet of your house has essentially a constant current. Therefore, according to the equation, if we add resistance, it will increase our voltage.

We know this to be true from experience. If we have a hose and just point it forward, water usually comes out about a foot or two. Remember, voltage is how much push the water has, which determines how far the water will go when it leaves the hose. However, if my children are on the other side of the yard and I want to hit them with a water spray, what do I do? I put my thumb over the opening. This increases the resistance, and, since the current is relatively constant, the voltage (the force the water will have when it leaves the hose) will increase, and this force will cause the water to spray further.

However, in circuits, we usually don't have a constant current source. Instead, batteries provide a constant voltage source. A 9-volt battery will provide 9 volts in nearly every condition. Therefore, for electronics work, we usually rearrange the equation a little bit. Using a little bit of algebra, we can solve our equation for either current or resistance, like this:

$$I = \frac{V}{R} \tag{4.2}$$

$$R = \frac{V}{I} \tag{4.3}$$

Equation 4.2 is the one that is usually most useful. To understand this equation, think back to the example of the bottle turned upside down. There, the liquid had a constant amount of push/voltage (from gravity), but we had different resistances. With the small opening, we had a large resistance, so the liquid came out slower. With the large opening, we had almost no resistance, so the liquid came out all at once.

> **Example 4.4** Let's put Ohm's law to use. If I have a 5-volt voltage source with 10 ohms of resistance in the circuit, how much current will flow? Since we are solving for current, we should use Equation 4.2. This says $I = \frac{V}{R}$. Therefore, plugging in our voltage and resistance, we have $I = \frac{5}{10}$, which is $I = 0.5$ ampere (remember, Ohm's law always uses amperes for current).

> **Example 4.5** Now let's say that we have a 10-volt source and we want to have 2 amps worth of current flowing. How much resistance do we need in order to make this happen? Since we are now solving for resistance, we will use Equation 4.3, which says $R = \frac{V}{I}$. Plugging in our values, we see that $R = \frac{10}{2} = 5\ \Omega$. Therefore, we would need 5 Ω of resistance.

> **Example 4.6** Now let's say that I have a 9-volt source and I want to limit my current to 10 *milliamps*. This uses the same equation, but the problem I have is that my units are in milliamps, but my equation uses amps. Therefore, before using the equation, I have to convert my current from milliamps to amps. Remember, to convert milliamps to amps, we just divide by 1,000. Therefore, we take 10 milliamps and divide by 1,000, and we get 0.010 amp. Now we

can use Equation 4.3 to find the resistance we need. $R = \frac{V}{I} = \frac{9}{0.010} = 900\Omega$. Therefore, with 900 Ω of resistance, we will limit our current to 10 milliamps.

Review

In this chapter, we learned the following:

1. Voltage is the amount of power that each coulomb of charge delivers.
2. The volt is the electrical unit that we use to measure voltage.
3. Voltage is always given relative to other voltages—it is not an absolute value.
4. The ground of a circuit is a location on the circuit where we have chosen to use as a universal reference point—we define that point as having zero voltage for our circuit to make measuring other points on our circuit easier.
5. In DC electronics, the chosen ground is usually the negative terminal of the battery.
6. Other terms and abbreviations for the ground include common, GND, and COM.
7. Resistance is how much a circuit resists the flow of current and is measured in ohms (Ω).
8. Ohm's law tells us the relationship between voltage, current, and resistance: $V = I * R$.

9. Using basic algebra, we can rearrange Ohm's law in two other ways, depending on what we want to know. It can be solved for current, $I = \frac{V}{R}$, or it can be solved for resistance, $R = \frac{V}{I}$.

Apply What You Have Learned

1. If I have a 4-volt battery, how many volts are between the positive and negative terminals of this battery?
2. If I choose the *negative* terminal of this battery as my ground, how many volts are at the *negative* terminal?
3. If I choose the *negative* terminal of this battery as my ground, how many volts are at the *positive* terminal?
4. If I choose the *positive* terminal of this battery as my ground, how many volts are at the *negative* terminal?
5. If I have a Point A on my circuit that is 7 volts above ground and I have a Point B on my circuit that is 2 volts above ground, what is the voltage difference between Point A and Point B?
6. Given a constant voltage, what effect does increasing the resistance have on current?
7. Given a constant current, what effect does increasing the resistance have on voltage?

8. If I have a 10 V battery, how much resistance would I need to have a current flow of 10 amps?
9. If I have a 3-volt battery, how much resistance would I need to have a current flow of 15 amps?
10. Given 4 amps of current flow across 200 ohms of resistance, how much voltage is there in my circuit?
11. If I am wanting to limit current flow to 2 amps, how much resistance would I need to add to a 40-volt source?
12. If I am wanting to limit current flow to 2 milliamps, how much resistance would I need to add to a 9-volt source?
13. If I am wanting to limit current flow to 20 milliamps, how much resistance would I need to add to a 5-volt source?

CHAPTER 5

Your First Circuit

In the last two chapters, we have learned about the fundamental units of electricity—charge, current, voltage, and resistance. In this chapter, we are going to put this information to use in a real circuit.

5.1 Circuit Requirements

For a circuit to function properly, you usually need several things:

1. A source of power which provides electricity for your circuit (this is usually a combination of both a source *and destination* for the electricity)
2. A network of wires and components that ultimately lead from the source to the destination
3. Some amount of resistance in your circuit

We need the source because, without a source of power, the charge won't move! If we have a circuit, but no electrical power, it will just sit there. In our circuits, batteries will usually provide the power we need. They will do this by providing a (relatively) constant voltage to our circuits.

We need the wires because unless we provide a *complete pathway* from a higher voltage (the source) to a lower voltage (the destination), the electricity won't be able to move. If we want the charge to move, we have to

© Jonathan Bartlett 2020

J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_5

make a *pathway* from the higher voltage to the lower voltage. Without this pathway, we have what is known as an **open circuit**. No electricity flows in an open circuit.

The components in the pathway from the source to the destination do the "electrical stuff" that we want to accomplish, whether that is turning on a light, running a motor, running a computer, or whatever else it is we want to do. In order for them to take advantage of the electrical power, they have to be in the pathway in which the current is moving. Think of this like a watermill—those structures that sit near a river and use the power of the water moving through the river to turn a wheel and therefore operate whatever is inside the house. In order for that to work, the water must flow through the watermill-connected structure. If the watermill is not built next to the river or if the river runs dry, the watermill doesn't work. Similarly, if the components are not in the flow of moving electric charge, they will not operate.

However, in addition to the wires and components, we must also have resistance (though sometimes this is added by the components themselves). Without resistance, the current would be too high. If you had zero resistance, the current would be so high that it would immediately drain your battery and likely destroy all of your components that you have connected. You can actually see this using Ohm's law. If we have a 10-volt source with no resistance, the current is given by the equation $I = V/R = 10/0 \approx \infty$. Dividing by zero gives you, essentially, infinite current. Now, wires and batteries *themselves* have some amount of resistance, so the current wouldn't be infinite, but it would be very, very large and would quickly drain your battery and destroy any sensitive components you had connected. Therefore, every pathway from the positive side of the battery to the negative *must* have some measurable amount of resistance. When a pathway from positive to negative occurs without resistance, this is known as a **short circuit**.

In other words, to accomplish real tasks with electricity, we must control its flow. If it doesn't flow (as in an open circuit), it can't do anything. If it flows without resistance (as in a short circuit), it does damage rather than work. Therefore, the goal of electronics is to provide a controlled route for electric charge to follow so that the power of electricity does the things we want it to do on its way from the source to the destination.

SHORTING OUT

If you've ever heard the phrase "shorting out," that refers to the fact that if you have a short circuit, it will often run too much current through a component and break the component. Sometimes this causes sufficient damage to actually damage the connections within the circuit. So, although the *original problem* was that there was a short circuit (i.e., something that created a pathway which bypassed resistance in the circuit), the *resulting problem* is that the damage leaves you with a permanent open circuit.

Interestingly, shorting out is actually usually a better result than having a permanently short circuit, which would leave you open to your project heating up and potentially catching on fire. This is why many projects which have larger power sources often use fuses. The goal of the fuse is to break either before other parts of the circuit break or before something catches fire.

5.2 Basic Components

The first circuits that we will build will only use four basic types of components:

- Batteries (9-volt)
- Battery regulator
- Resistors
- LEDs

As we have discussed, batteries provide a relatively constant amount of voltage between the positive and negative terminals. A 9-volt battery, therefore, is supposed to have a 9-volt difference between the positive and negative terminals. However, there is an actual range that 9-volt batteries have. A 9-volt battery, depending on the battery chemistry, will deliver between 7 and 10 volts. Additionally, when the battery is worn out, its voltage will decrease as well.

Therefore, in order to make the projects operate more uniformly across different power sources, our projects will often include a regulator, which will take the battery's voltage (which can vary from 7 to 10 volts) and return a constant 5-volt output. So keep in mind that if the project does not have a regulator attached, the actual voltages in the circuit may vary depending on the battery. If the project does have a regulator attached, it should be reliably yielding a 5-volt difference from the positive to the negative. We will treat the regulator just like a battery, but one that is more stable and reliable than a battery.

A resistor is a device that, as its name implies, adds resistance to a circuit. Resistors have colors that indicate how much resistance they add to the circuit. You don't need to know the color codes yet, but if you are curious, you can see the resistor datasheet in Appendix E. So, if we want to add 100 Ω to our circuit, we just find a resistor with a value of 100 Ω. Resistors are not the only devices that add resistance to a circuit, but they are usually what are used when you want to add a fixed amount of resistance. Resistors have two terminals (connecting points), but they both function identically—unlike other components, there is no backward or forward for a resistor. You can put them in your circuit either way, and they will function just fine.

Of the components in this section, the LED is probably the strangest. LED stands for "light-emitting diode." A diode is a component that only allows current to flow in one direction. It blocks the flow of electricity in the other direction. However, more importantly, LEDs emit light when current passes through them. However, LEDs do not resist current, so they must be used with a resistor to limit the amount of current flowing through them (most of them will break at 20–30 milliamps). Also, since LEDs only allow current to flow one way, they have to be wired in the correct direction. To find out which way to wire an LED, look at the legs of the LED—one is longer than the other. To allow current flow, the longer leg of the LED should be on the more positive side of the circuit.

Most of your components (especially your resistors) come with very long legs. You can feel free to bend or cut these legs however you please to better fit in your circuit. However, on LEDs (and any other component where leg length matters), be sure to keep the longer legs longer so you don't get confused about which way it should be inserted in your circuit.

5.3 Creating Your First Circuit

Now we will put together a simple first circuit. What you will need is

- One 9-volt battery
- One red LED (other colors will work too)
- One 1,000 Ω resistor (anything from 400 ohms to 2,000 ohms should work)

If you already have resistors, you can use a multimeter to determine the resistance, or you can use the color chart in Appendix E. Most electronics enthusiasts I know don't actually use the color codes, because they are too small. If you have better vision than we do, then the color chart may work great. Otherwise, use a multimeter to check the resistance, or, better yet, keep your resistors organized so it is easy to find the value you want. If you don't have resistors, it is even easier—just buy a resistor with the resistance you are looking for!

READING A RESISTOR'S VALUE FROM A MULTIMETER

Multimeters are incredibly flexible tools, and they are pretty cheap too. For the purposes of this book, you don't need anything fancy—the cheapest one will do just fine! Be sure that the resistor is not connected to anything else before testing.

To find the value of the resistor, look for values on the multimeter marked with the ohm sign (Ω). Set the dial to the lowest resistance value it has (remember to think about the metric suffixes from Chapter 2—for instance, 10 M means 10,000,000). Then, test the resistor by putting the two multimeter probes on the two legs of the resistor. It is okay to hold the probes on the resistor legs with your fingers. Many multimeters require you to only use the pointed tips of the probes in order to measure values accurately.

If the screen shows a 0 or 1, that means that the resistor's value is actually too large for it to register at that setting. In that case, move the dial on the multimeter to the next setting higher and try again. If the screen shows a more precise value, then use that value plus whatever metric suffix the multimeter is set to. For instance, if the multimeter is set to 10 M, then you would add the M suffix to whatever value is shown on the screen. That is the value of the resistor.

If you did buy a fancy, expensive multimeter, it may only have one spot for measuring resistance, marked as ohm without listing any number by it. In this case, it will automatically do that same process internally and report the results to you like magic.

More information about multimeter use is found in Chapter 6.

To make this circuit, take one leg of the resistor and twist it together with the *short* leg of the LED. It should look like Figure 5-1.

Now, take the long leg of the LED and touch it to the positive terminal of the battery. Nothing happens—why not? Nothing happens because, even though we have connected the wires to the positive side of the battery, the electricity has nowhere to go to, so the current won't move. We have an open circuit because there is not a complete path from positive to negative.

Now, touch the long leg of the LED to the battery and, at the same time, touch the unattached end of the resistor to the battery. The LED should give a nice glow of its color. Congratulations! You have built your first circuit!

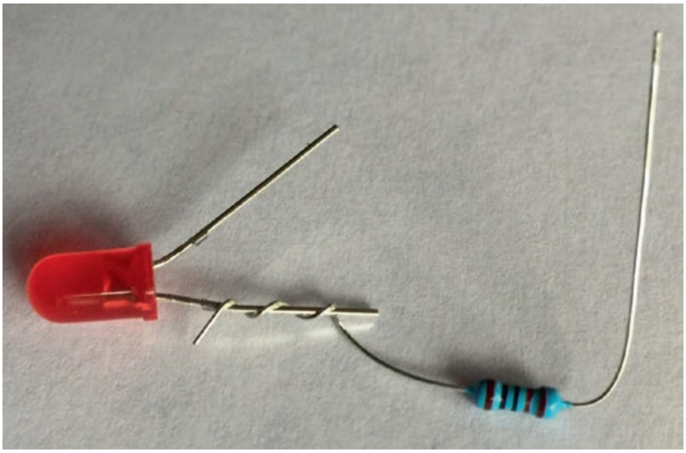

Figure 5-1. *Wrapping the Resistor Around the LED's Short Leg*

Even though we can't see the electricity moving, I hope you understand how it will flow through the circuit. We can trace the current flow from the positive terminal of the battery through the LED. The resistor limits the amount of current flowing through the circuit and therefore through our LED (the resistor can actually go on either side of the LED; it will limit the flow no matter which side it is on). Without the resistor, the battery would easily go over the 30-milliamp rating of our LED, and it would short out and no longer work. If you connected it without a resistor, you might see it turn on for a moment and then very quickly turn off, and then it would never work again. If you have an extra LED, you can try this out if you want. It is not dangerous—it will just cost you the price of an LED.

If your LED is backward, no current will flow at all. It won’t hurt the LED, but it won’t turn on unless it is oriented in the right direction.

5.4 Adding Wires

We are not going to physically add wires to our circuit at this time, but I did want to make a note on wires. Changing the lengths of wires will not affect our circuits in any way. On advanced projects (usually projects with extremely high precision or extremely long wires), the length of a wire will sometimes have an effect on such circuits. We are not doing any high-precision circuits, and our wire lengths are all less than a meter. Therefore, for the electronics we are doing, we can totally ignore wire length.

Therefore, if we connected our components using wires rather than directly wrapping their legs around each other directly, it would have no effect on the circuit at all. What is important is not the wires but the connections—what components are connected together and how are they connected. The length of the wire used to connect them is not important. You can connect them with a really long wire or directly touch the legs of each component together with no wires. It doesn’t matter because the result is the same—the components are connected.

Symbol	Component	Description
	Battery	A battery is represented by a long line and a short line stacked on top of each other. Sometimes, there are two sets of long and short lines. The long line is the positive terminal and the short line is the negative terminal (which is usually used as the ground).
	Resistor	A resistor is represented by a sharp, wavy line with wires coming out of each side. This represents that the resistor is not an easy way for current to flow.
	LED	An LED is represented by an arrow with a line across it, indicating that current can flow from positive to negative in the direction of the arrow, but it is blocked going the other way. The LED symbol also has two short lines coming out of it, representing the fact that it emits light.

Figure 5-2. *Basic Component Diagram Symbols*

5.5 Drawing Circuits

So far, we have only described circuits in words or by showing you pictures. This, however, is a lousy way of describing circuits. In complicated circuits, trying to trace the wires in a photograph is difficult. If you wanted to draw a circuit that you wanted built, you would have to be an artist to render it correctly. Likewise, reading through text describing a circuit takes a long time, and it is easy to get lost when discussing large circuits.

Therefore, in order to communicate information about how a circuit is put together in a way that is easy to read and write, engineers have developed a way of drawing circuits called **circuit diagrams** or **electronic schematics** (often just called *diagrams* or *schematics*). In a circuit diagram, each component is represented by an easy-to-draw symbol that helps you remember what the component does. Figure 5-2 shows the symbols for the components we have used so far. Note that everybody draws the symbols slightly differently and some components have more than one symbol. However, these are the symbols we will use in this book. For more symbols, see Appendix B.

Then, the components are connected together using lines to represent the wires and connections between the components.

Therefore, we can redraw our original circuit using these symbols as you see in Figure 5-3.

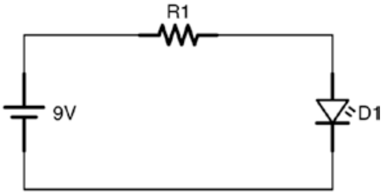

Figure 5-3. *Basic LED Circuit Drawn as a Diagram*

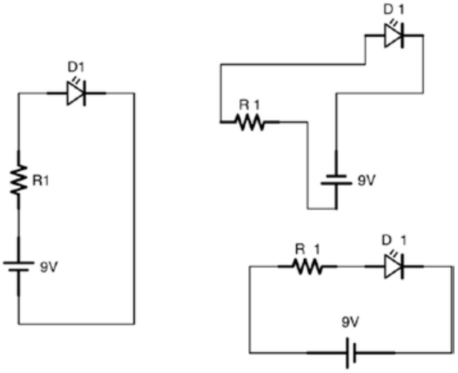

Figure 5-4. *Alternative Ways of Drawing the Basic LED Circuit*

Notice that our components are laid out on the diagram with wires connecting them. Remember that it doesn't matter if we have very long wires or very short wires or if the components are directly placed end to end—the resulting circuits will operate identically. Also notice that each component is labeled (R1 and D1) because, as we make more complicated circuits, it is important to be able to refer back to them.

It does not matter in a diagram which way you have your components turned, how long or short your wires are, or what the general spacing looks like. When you actually wire it, all of those things will change. The important part of a circuit diagram is to convey to the reader what the parts are, how they are connected, and what the circuit does in the way that is easiest to read.

For instance, all of the circuits in Figure 5-4 are equivalent to the circuit in Figure 5-3, they are just drawn differently. All of them have the positive terminal of a battery connected to a resistor, with the other leg of the resistor connected to the positive end of an LED, with the other leg of the LED connected to the negative side of the battery. Since the connections are identical, the circuits are identical. Schematics don't care how long the lines are that you draw or how the components are oriented or even where the components are drawn on the page. The only thing important in the schematic is how the components are connected.

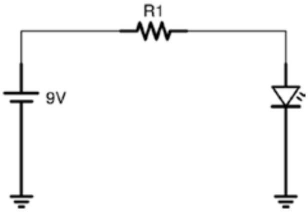

Figure 5-5. *Basic LED Circuit Drawing Using the Ground Symbol*

For consistency, I like to draw all of my batteries to the left of the drawing with the positive side on top. By keeping the battery positive-side-up, components with higher voltage are usually closer to the top, and components with lower voltages are usually closer to the bottom, with the ground (i.e., 0 volt) coming back into the negative terminal. I also try to make my wire lines as simple as possible in order to make following them easier.

By keeping some amount of consistency, it is easier to look at a drawing and see what is happening.

5.6 Drawing the Ground

Remember that for electricity to move, every circuit must be fully connected from the positive side to the negative side. That means that in larger circuits, there are numerous connections that come from the positive or go back to the ground/negative. Because of this, a special symbol has been adopted to refer to the ground point in a circuit. This symbol, the ground symbol, has three lines, each shorter than the next. Points on a circuit that have this symbol connected to them are connected to each other (usually they are all connected to the negative side of the battery).

Therefore, the circuit in Figure 5-5 is the same circuit as before, just drawn using the ground symbol. Since points with the ground symbol are all connected together, using this symbol on both the negative terminal and the negative side of the LED means that they are wired together.

This doesn't help us a lot for this circuit (and, in fact, it makes it a little less easy to read). However, in complex circuits, it is much easier to write the ground symbol than trying to have 20 lines drawn back to the negative terminal.

Additionally, the same is true with the positive side of the battery. Many components require a direct connection to a specific voltage to work correctly. These are usually marked with just a disconnected wire with the end of the wire marking what voltage it requires. We make less use of that symbol in this book than the ground symbol, but it does come in handy sometimes.

So, using both the voltage source and ground symbols, we could rewrite the same circuit again in the manner shown in Figure 5-6. This circuit, again, is not *wired* any differently than before. We are just *drawing* it differently. For this circuit, it doesn't matter, but in more complex circuits, if we need a specific voltage at a specific location, this symbol tells us to put it there.

Review

In this chapter, we learned the following:

1. Every circuit requires a source of power (usually a battery), wires and components, some amount of resistance, and a complete path back to the negative side of the power source.
2. An open circuit is one that does not connect back to the negative side (and thus does not provide any electricity), and a short circuit is one that connects back to the negative side without any resistance (and thus overwhelms the circuit with current).
3. A battery supplies a fixed voltage between its two terminals.
4. A resistor provides a fixed resistance (measured in ohms) within your circuit.
5. An LED allows current to flow in only one direction, gives off light when current is flowing, but is destroyed when the current goes above 20–30 milliamps.

6. The longer leg of the LED should be on the positive side of the circuit.
7. Wires on simple circuits can be almost any length (from zero to a few meters) without changing the functionality of the circuit.
8. A circuit diagram is a way of drawing a circuit so that it is easy to read and understand what the circuit is doing.
9. Each component has its own symbol in a circuit diagram.
10. Components labeled with the ground symbol are connected together, usually at the negative side of the battery.
11. Voltage sources can be similarly labeled by a wire connected on one side labeled with the voltage that it is supposed to be carrying.

Apply What You Have Learned

Special Note: In the following problems, since we have not yet studied LED operation in depth, we are ignoring the electrical characteristics of the LED and just focusing on the resistor. If you know how to calculate the circuit characteristics using the LED, please ignore it anyway for the purpose of these exercises.

1. Calculate the amount of current running in the circuit you built in this chapter using Ohm's law. Since Ohm's law gives the results in amps, convert the value to milliamps.

2. Let's say that the minimum amount of current needed for the LED to be visibly on is 1 milliamp. What value of the resistor would produce this current?
3. Let's say that the maximum amount of current the LED can handle is 30 milliamps. What value of the resistor would produce this current?
4. Draw a circuit diagram of a short circuit.
5. Take the circuit drawing in this chapter, and modify it so that it is an open circuit.
6. Draw a circuit with just a battery and a resistor. Make up values for both the battery and the resistor and calculate the amount of current flowing through.

CHAPTER 6

Constructing and Testing Circuits

In Chapter 5, we learned how a circuit works. However, the method of putting together a circuit in the chapter doesn't translate to the real world well. In this chapter, we will learn how to use solderless breadboards to construct circuits in a more robust manner. Additionally, we will put our understanding of Ohm's law to the test as we learn how to measure voltages in circuits using our multimeter.

6.1 The Solderless Breadboard

The most important piece of equipment to use for making circuits is the **solderless breadboard**. Before solderless breadboards, if you wanted to put together a circuit, you had to attach them to a physical piece of wood to hold them down and then **solder** the pieces together. Soldering is a process where two wires are physically joined using heat and a type of metal called solder, which melts at much lower temperatures than other types of metal. So what you would have to do is attach the electrical components to the board, wrap the components' legs around each other, and then heat them up with a soldering iron and add solder to join them permanantly.

This was an involved process, and, though it was sometimes possible to get your components back by reheating the soldered joints, you were generally stuck with your results. The solderless breadboard is an amazing

invention that allows us to quickly and easily create and modify circuits without any trouble at all. Figure 6-1 shows what a solderless breadboard looks like, and Figure 6-2 has the different parts of the breadboard labeled.

The solderless breadboard has a number of spring clips (usually about 400 or 800 of them) called **connection points** which will allow you to insert wires or component leads and will hold them in place. Not only that, the breadboard itself will connect the components for you!

The way that this works is that the breadboard is broken up into little half-rows called **terminal strips**. Each terminal strip has multiple connection points—usually five. Each connection point on a given terminal strip is connected by wire *inside* the breadboard. Therefore, to connect two wires or leads together, all you need to do is connect them to the same terminal strip. Any two wires or leads connected to the same terminal strip are themselves connected.

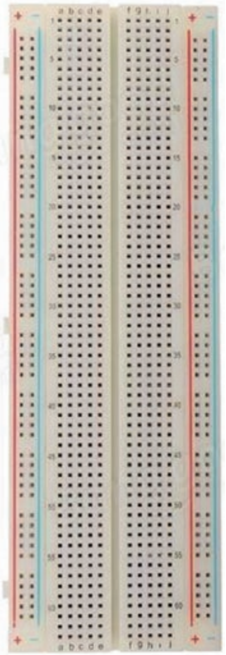

Figure 6-1. *A Solderless Breadboard*

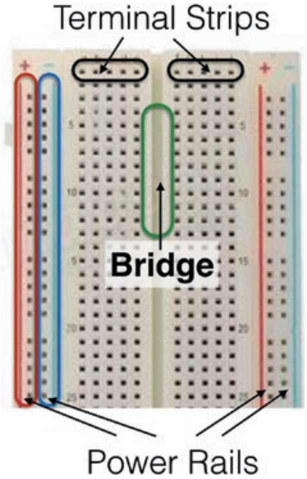

Figure 6-2. *Parts of a Solderless Breadboard*

In most breadboards, the two sides of the breadboard are separated by a gulf known as the **bridge**. The bridge is a visual indication that the two sets of terminal strips are not connected, but it also serves a practical purpose. If you have an integrated circuit (a small chip), the bridge is the right width so that you can place your integrated circuit right over the bridge, and each leg of the chip will receive its own terminal strip for you to easily connect them to what you need. We will cover this in more depth in later chapters.

In addition to the terminal strips, most breadboards have two strips running down each side, one with a red line and one with a blue line. These are known as **power rails** (some people call them **power buses**).

Power rails are very similar to terminal strips, with a few exceptions. The main difference is that, in terminal strips, only the five connection points grouped together are connected. On power rails, many more of the connection points are connected together, even when there are short gaps. Some boards will split the power rails at the halfway point, but others go all the way down the board. A split in the power rails is usually visually indicated by a break in the red and blue lines that indicate the power rails.

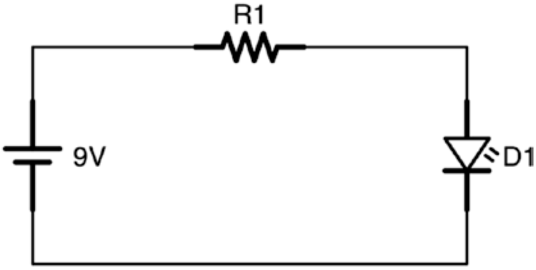

Figure 6-3. *Basic LED Circuit*

Note that the positive and negative are *not* connected to each other (that would create a short circuit) and they are *not* connected to the power rails on the other side of the breadboard (unless you connect them manually). On some breadboards, even a single side isn't connected all the way down, but may be broken into sections at the halfway point.

In many projects, many components need direct access to the positive or negative power supply. Power rails make this easy by providing a connection point with positive and negative power a very short distance away from wherever you need it on the breadboard. If you plug your power source's positive and negative terminals into the positive and negative rails on the breadboard, then any time you need a connection to the positive or negative terminal, you can just bring a wire to the closest connection point on the appropriate power rail.

6.2 Putting a Circuit onto a Breadboard

To see how a simple circuit works on a breadboard, let's go back to the circuit we first looked at in Chapter 5. Figure 6-3 has the drawing again for ease of reference.

So how do we translate what we see in the drawing to what we need to put in the breadboard? Well, let's take a look at what is in the circuit—a 9-volt battery, an LED (we will go with a red LED), and a 1,000 Ω resistor.

Let us not concern ourselves with the battery at the moment. So, without the battery, we have a resistor connected to an LED.

Let us start out by simply placing our components onto the breadboard. What you will want is to place them on the breadboard so that each of their legs is on a *different* terminal strip. It doesn't matter *which* terminal strips you use—just make sure the legs all get plugged into different ones. Figure 6-4 shows how your breadboard should look so far. Note that the longer leg of the LED is closer to the resistor. The longer leg is depicted in the diagram as having an extra bend in the leg.

Figure 6-5 shows the *wrong* way to do it. In that figure, the legs of both the components are on the same row, which is the same thing as placing a wire between the legs, creating a short circuit. Don't do that! Make sure each leg goes into its own row.

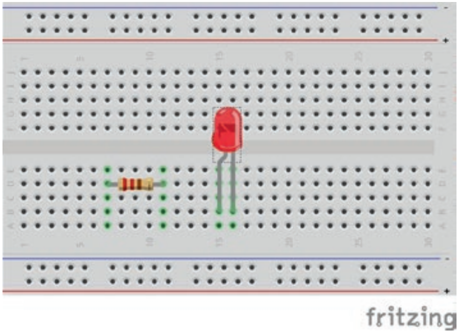

Figure 6-4. *Putting the Components onto the Breadboard*

Now, to connect the resistor to the LED, we need to add a wire. So all we need to do is connect a wire to any empty connection point that is on the same terminal strip of the right leg of the resistor and connect the other side of that wire to the left leg of the LED as shown in Figure 6-6.

Note that wires used on breadboards are often called "jumper wires." The difference between these and other kinds of wires is that jumper wires usually have solid, hard ends, making them easier to push into the breadboard. If you use regular wire or speaker wire, the ends are flexible, and it is almost impossible to get them into the breadboard properly to connect.

A common mistake that people will make is to connect the wire to the row right before or after the component. Take some time and be extra certain that the wire is connected to the *very same* row as the leg of your components.

Now, we need to connect our project to the power rails. So take a red wire from the left leg of the resistor to the positive power rail (remember, as long as it is in the same terminal strip as the resistor, they will be connected). Likewise, take a black wire from the right leg of the LED to the negative power rail. I always use red wires for connecting to the positive power rail and black wires for connecting to the negative/ground rail, as it makes it more clear when I am looking at my project what wire carries what. Your project should look like Figure 6-7.

Now your project is almost done. All you need to do now is to connect your power rails to a power supply. Connect a T-connector to a 9-volt battery, and then connect the red (positive) wire to the positive power rail on the breadboard.[1] You can plug it in anywhere on the rail, but I usually connect the power to the edge of the rail to leave more room for components. Then, connect the black (negative) wire to the negative power rail on the breadboard. As soon as you do this, the LED should light up! Figure 6-8 shows the final circuit.

---

[1] A T-connector is just a cap on the battery that has wires coming out of it. If you don't have a T-connector, you can manually plug a jumper wire into the breadboard and hold the other end on the battery terminal. T-connectors have their own drawbacks, as most of them have flexible ends, making them difficult to plug into breadboards. Shortly, we will move to an easier way of handling power with power regulators.

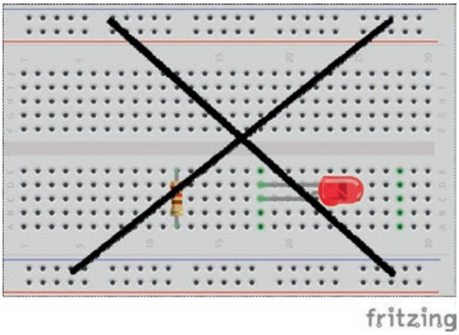

Figure 6-5. *The Wrong Way to Put Components onto the Breadboard*

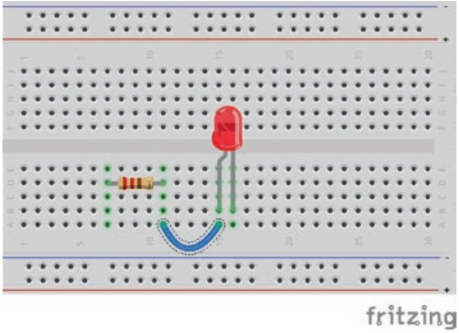

Figure 6-6. *Adding a Wire to Connect the Components*

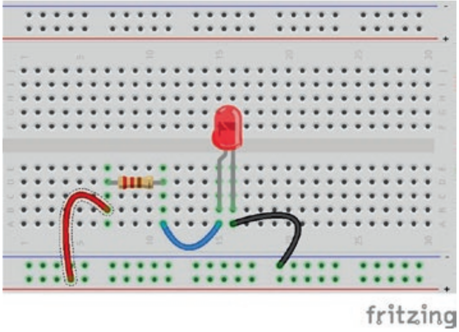

Figure 6-7. *Adding Wires to the Power Rails*

Note that many T-connectors for 9-volt batteries have very flimsy wires that are difficult to insert into a breadboard. Usually, as long as you can get both terminals in far enough to touch the metal within the connection point, it will work. We will move to using power regulators shortly, which makes the process a bit easier.

If your circuit doesn't work, here is a list of things to check:

1. Make sure your battery is properly connected to the breadboard—the red should go to positive and the black to negative.
2. Make sure there are *no* wires directly connecting positive to negative on the board. Any direct pathway from positive to negative without going through a component will cause a short circuit and can destroy your components and battery.
3. Make sure that your wires are connected to the same terminal strip as the component lead that they are supposed to be connected to. If they are on a different row, *they are not connected*!
4. Make sure the LED is inserted in the right way. The longer leg should be connected to the resistor, and the shorter leg should be connected to the negative power supply.
5. Make sure your components are good. Try replacing your LED with another LED to see if it works.
6. If all of those things fail, take a picture of your project and post it to an online forum. Someone will likely be able to spot your problem and/or lead you in the right direction. Many forums are also available on the Web for this.

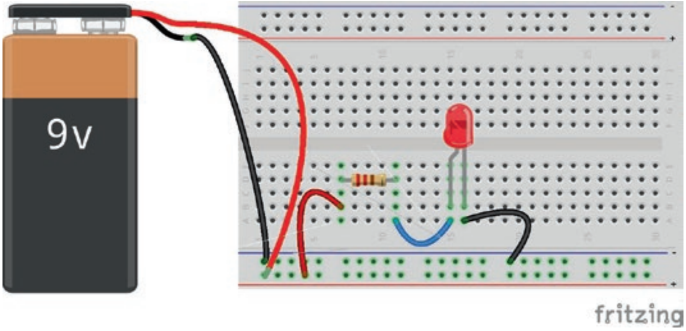

Figure 6-8. *Final LED Circuit with Power Connected*

6.3 Using Fewer Wires

In the previous section, we used three wires to connect our components, plus two more wires from the battery. We can improve our project by reworking it so that most of the wires are not necessary.

Remember that any two leads or wires plugged in next to each other on the same terminal strip are connected. Therefore, we can remove the wire that goes from the LED to the resistor simply by moving the LED and resistor so that the right leg of the resistor is on the same terminal strip. Figure 6-9 shows what this looks like.

However, that middle wire is not the only redundant wire. If you think about it, we could also save a wire by actually using the LED's own lead to go back to the negative rail. Figure 6-10 shows how this is set up. Now, in order to make the LED fit better, it is now on the *other* side of the resistor in the terminal strip. Remember that this does not matter at all! No matter where a component is connected on the terminal strip, it is joined with a wire to every other component on the same terminal strip.

Now, there is one last wire that we can get rid of. Can you think of which one it is? If you said the wire going from the positive rail to the resistor, you were right.

What we can do is to directly connect the resistor to the positive rail. Doing this gives us what is shown in Figure 6-11.

Therefore, as you can see, there are any number of ways that you can arrange parts on a breadboard to match a given schematic. All of these arrangements we have seen match the schematic given in Figure 6-3. As long as your circuit matches the configuration in the schematic, the specifics of where you put the wires and components is up to you. Some people like to place the components on their breadboard first, spaced out, and then add wires to connect them as needed. This works, though it does make for a messier board, with lots of wires going every which way. Other people like to use as few wires as possible and have their layouts as clean as possible (i.e., they don't like a tangled mess).

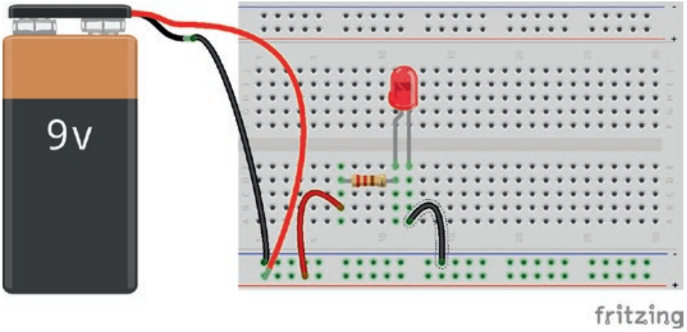

Figure 6-9. *Joining Components by Putting Their Leads on the Same Terminal Strip*

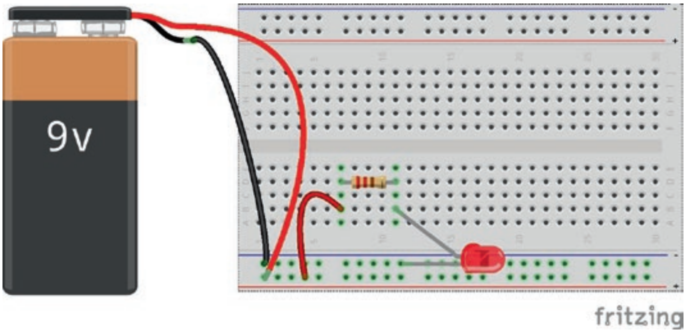

Figure 6-10. *Directly Connecting the LED to the Negative Rail*

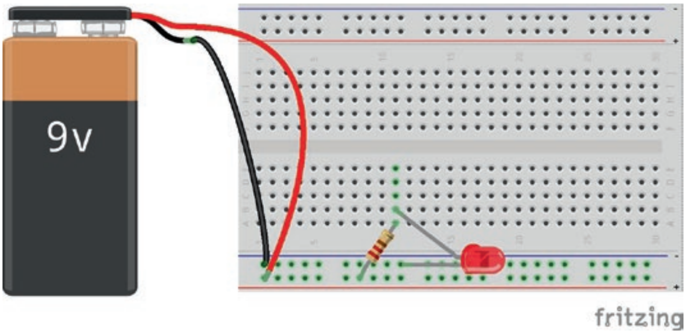

Figure 6-11. *Connecting the Resistor Directly to the Positive Rail*

Some people like to use flexible jumper wires that go up and over the board. Other people like to use rigid jumper wires that lie down close to the board and are the exact length needed. The flexible wire allows more flexibility in building your circuits (they are easier to move around and reconfigure), while the solid, rigid wire makes the final result a lot cleaner and easier to follow.

You can also trim the legs of your components to make them fit better, if you want. Some people like to leave their components as intact as possible, while others like to trim the legs of their leads to be the exact right size for their project. However, if you do trim the leads on your LEDs, be sure to keep the positive leg longer!

However you like to work with electronics is up to you. There are lots of options, and they all end up with the same circuit.

6.4 Testing Circuits with a Multimeter

Now that we know how to put circuits together, we need to know how to *test* our circuits. The main tool used to test simple circuits is the **multimeter**. It is called a multimeter because it measures *multi*ple different things about a circuit. Figure 6-12 shows a typical low-cost multimeter.

There are a lot of different multimeters around which have a lot of different functions. However, almost all of them will measure voltage, current, and resistance. Each of these values is measured by testing two different points on the circuit. Most multimeters have a red lead and a black lead. The red lead should connect to the more positive side of the circuit, and the black lead should connect to the more negative side of the circuit. However, if you get it reversed, it is usually fine—the multimeter may just report negative values if you are measuring for voltage or current.

To illustrate how to use a multimeter, we will start out measuring the voltage in a 9-volt battery. Remember from Chapter 4 that there is no absolute zero voltage—voltages are merely measured with reference to each other. Therefore, a multimeter doesn’t tell you the exact voltage of something—there is no exact voltage. Instead, a multimeter allows you to choose two points on your circuit and measure the voltage difference (also known as the **voltage drop**) between them.

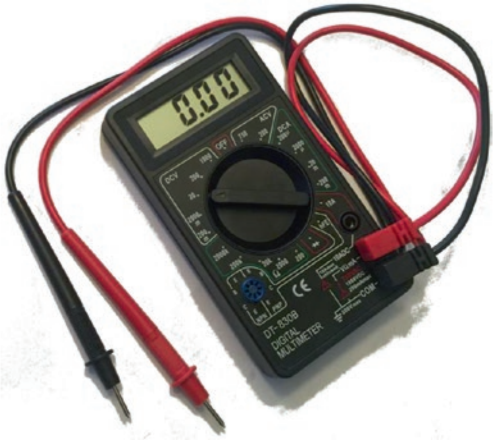

Figure 6-12. *A Low-Cost Multimeter*

Now, remember that a 9-volt battery means that the battery should have 9 volts between its positive and negative terminals. Don't try it yet, but when we measure voltage, we will expect that the multimeter will tell us that the voltage difference is near 9 volts.

When using your multimeter, you must set *what* you are going to test *before* you test it. Otherwise, you can easily damage your multimeter or your circuit. Therefore, since we are going to measure voltage, select the DC Voltage setting on your multimeter (*do not* select the DC Current or DC Resistance setting!). If you are using a high-quality **auto-ranging** multimeter, that is all you need to do. However, when starting out, most people buy the bottom-of-the-line multimeter. That's not a problem, but just know that you will probably accidentally break it at some point.

If you are using a lower-quality multimeter, you will need to select not only *what* you want to measure but the *estimated range* of values that you want to measure. On my multimeter, the DC Voltage has five different settings—1000, 200, 20, 2000 m, and 200 m. These are the upper boundaries (in volts) that these settings can read.

So, for a 9-volt battery, using the 1,000-volt setting is probably unwise. It may give a reading, but it probably won't be accurate. However, if I try it on too low of a setting (say, 2000 m), it either won't read, or it will blow out my multimeter. So the safe thing to do is to start with the highest reasonable setting (or just the highest setting if you don't know what's reasonable) and test it and then reduce the setting until it gives you a good reading.

So, for instance, for my 9-volt battery, let's say I didn't know the voltage. Therefore, I'm going to measure the battery using the 1,000-volt setting. After setting the multimeter to 1,000 volts, I will put the red lead on the positive terminal of the battery and the black lead on the negative terminal. Be sure that you *firmly* press the *tip* of your leads against the positive and negative terminals. If it is not firm or if you use the sides of your terminals, you will not get a good reading.

When I do this, my multimeter reads 9.

Now, notice that this reading is significantly less than our 1,000-volt setting. Therefore, it may not be entirely accurate. So I will reduce the setting to the 200-volt setting and measure again. This time, my multimeter reads 9.6. This is definitely a more accurate reading—it is giving me an extra digit of accuracy! However, this reading is still significantly below the setting.

Therefore, I will reduce the setting again to the 20-volt setting and remeasure. This time, the measurement is 9.66. Again, it is more accurate. Now, can I reduce the setting even more? Well, the next setting is 2000 m, which is basically 2 volts. Our reading is 9.66 volts, so it is above the cutoff point for the next setting. Therefore, I should not try it on a lower setting, both for the sake of accuracy and for the sake of my multimeter's lifespan.

However, I should note that if I did use a lower setting, since the setting is listed as being in millivolts (i.e., 2000 m), then the reading would also be in millivolts. That is, if we were to read the value of the battery on that setting, it would say 9660, because that is how many millivolts the battery has.

Now, you could be wondering, why is a 9-volt battery anything other than exactly 9 volts? Well, it turns out that in electronics, no value is exact, and no formula works perfectly. When we talk about a 9-volt battery, we are actually talking about a battery that runs anywhere from 7 volts to

9.7 volts. In fact, my battery that started out at 9.66 volts will slowly lose voltage as it discharges. This is one of the reasons why measurement is so important.

Also, this means that in our circuits, we will have to find ways to compensate for varying values. Our circuits should work across a wide range of possible values for our components. We will discuss strategies for this as we go forward.

The next thing we will measure is resistance. Pull out a resistor—any resistor. The resistor datasheet in Appendix E shows you how to find the resistor values based on the color bands on the resistor. I don't know about you, but my eyes are not that good at looking at those tiny lines on the resistor and figuring out which color is which. Many times, it is easier just to test it with the multimeter.

The process is the same as with measuring the voltage, except that you start at the lowest setting and work up. First, find the resistance settings on your multimeter (perhaps just marked with the symbol for ohms—Ω). Start with the smallest value (200 in my case). On this setting, the multimeter read 1, which means that it didn't pick up a signal. So I turned it up to the next setting, 2000. This time, it read 1002. Remember that if the value that the meter is set to includes a metric suffix (i.e., m, k, or M), that suffix gets applied to the value that is displayed on the screen.

Note that you should *never test for resistance in a live circuit*. The multimeter uses power to measure resistance, and if there is already power in the circuit, it can damage the multimeter and/or the circuit. However, to test for current and voltage the circuit must be powered.

6.5 Using a Multimeter with a Breadboard

We can use our multimeter with our breadboard too. Let's say that we wanted to measure the voltage between the positive and negative rails of the breadboard.

There are two ways to do this. The first, if the size of your multimeter probes and the size of your breadboard connection points allow it, is to simply shove the probes of your multimeter into connection points on the positive and negative rails. Since these will be connected to the power by a wire, these will be at the same voltage levels as the battery itself.

Second, if your breadboard/multimeter combination does not support this, you can do the same thing by simply connecting two jumper wires into the positive and negative rails and then testing the voltage on the other end of the wires.

Also, if you are testing components for voltage, you can also use your multimeter on the exposed legs of the component. This is often easier than either trying to push your probes into the breadboard or running extra wires to your multimeter.

To try out using your multimeter with your breadboard, configure your breadboard similar to Figure 6-8. Use this layout, and *not* one of the ones with fewer wires (you will see why in a minute). With the battery connected to the breadboard, set your multimeter to the highest voltage setting, and put the red lead in any empty hole in the positive rail. While that lead is there, put the black lead in any empty hole in the negative rail.

This should give you the same reading that you received for the battery terminals. Remember that the power rails are connected all the way across—that is why putting your probes in any hole on the line works! If you work your way down the ranges on your multimeter, you should find that you get the same value that you did when you measured directly on the battery's terminals. Again, if your probes do not fit inside the connection points, you can also use wires to connect out from your breadboard to your multimeter probes.

You can now do the same to any component on your board. Let's find the voltage difference between one side of the resistor and the other. To do this, find an empty hole on the same terminal strip as the left-hand side of the resistor, and put the red lead from your multimeter in that hole. Then, find an empty hole on the same terminal strip as the right-hand side of the resistor, and put the black lead from your multimeter in that hole. Now you can measure the voltage difference. Note that to measure voltage differences, the circuit *must* be active. If the power is gone, the voltage difference will likely drop to zero. Use the same ranging procedure to find the voltage drop between the left-hand and right-hand sides of the resistor.

Even though we have not discussed diodes, this doesn't prevent you from measuring the voltage difference between the legs of the diode in your circuit. Use the same procedure as before to measure the voltage drop.

6.6 Measuring Current with a Multimeter

Now we will learn to measure current using the same circuit layout from Figure 6-8. Like voltage, measuring current requires that the power to your circuit be on. To measure current, use the DC Amperage (sometimes called DC Current) settings on your multimeter.

Measuring current is a little different than measuring voltage in a circuit. Instead of just placing your probes in the breadboard as it is, you are going to use your probes to *replace a wire*. You will remove a wire and then place your probes in the holes (connection points) where the wire used to be. Alternatively, if your multimeter probes do not fit into the connection points, you can again run two wires, one from each hole, from the breadboard to your multimeter probes.

Using either of these approaches, the circuit will then use your multimeter *as the wire* that was removed, and the multimeter will then measure how much current is running through it and report it to you on the screen. You will need to use the same ranging technique as you used before with voltages to get an accurate report.

Let's say that you wanted to measure the current going through the wire that connects the resistor to the LED. To do this, we will start by *removing* that wire, and connecting the red lead to where the wire used to be on the left (since it is more positive) and the black lead to where the wire used to be on the right (since it is more negative). The multimeter should now report back how much current the circuit is using. This will vary for a number of reasons, but should be about 17 mA.

Now, put the wire back, and remove another wire and measure current there. No matter which wire you choose, they should all measure the same current. The reason is that, since all of these components are in series (one right after the other), they must all have the same amount of electricity flowing through them (otherwise, where would the electricity be going?).

6.7 Using a Power Regulator

So far, we have discussed several problems of using batteries in electronics projects. First, with batteries, we don't know exactly how much voltage they will deliver. A 9 V battery will deliver between 7 V and 10 V, and the actual amount will vary across its life. Additionally, the connectors available from batteries usually don't have the solid jumper wire ends, so it is hard to connect them to breadboards.

Both of these problems can be solved with a power regulator module. A power regulator module will take power from other sources (such as a battery) and reduce the voltage to a value which, while lower, will be constant. The power regulator we will use is the YwRobot breadboard power supply.

This low-cost device will take an input between 6.5 and 12 volts and deliver a constant voltage at the output of either 3.3 or 5 volts (we will use the 5 V setting). This device can be connected to a battery with an appropriate battery clip.[2] Figure 6-13 shows what this looks like.

---

[2] This can also be connected to a wall outlet using an appropriate adapter or connected to your laptop for a USB power supply. For the purposes of this book, we recommend against both of these options as it adds additional risk if something is wired incorrectly.

As you can see, the power module clips onto the power rails of the breadboard. The most important thing is to make sure that the power module is oriented correctly so that the positive and negative markings on the power module line up with the positive and negative power rails. Additionally, this power module has a shunt which, depending on where it is placed, sets whether it outputs 3.3 V or 5 V or is switched off. You need to be sure that the shunts on both sides are set to the 5 V position.

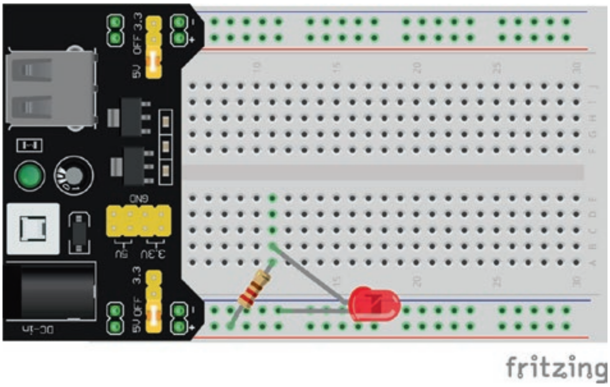

Figure 6-13. *Breadboard with a Power Module*

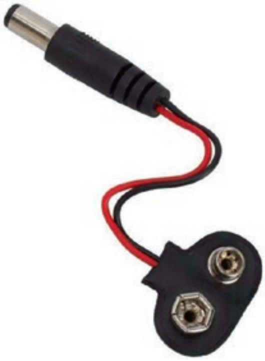

Figure 6-14. *9 V Battery Clip*

Finally, you need to plug the battery in. A 9 V battery can be plugged into the power module using a battery clip designed for CCTV cameras. They have a 9 V clip on one side and a barrel plug on the other side, which plugs nicely into the power module. You can see one in Figure 6-14.

After that is set up, don't forget to turn it on! The power module has an LED that lights up when the power module is turned on. This is really convenient because you don't have to include an on/off switch or an on light on your project, because the power module has one for you.

So how does the power module show up in the schematic? Well, actually, it doesn't directly. The combination of battery and power module basically just yields a 5 V battery in the schematic. So we will just represent it with the normal battery symbol, but set to 5 volts.

There are other power modules available as well, and they all basically work the same way. Just be sure that the voltage is set to 5 volts.

Review

In this chapter, we learned the following:

1. Solderless breadboards can be used to quickly create circuits.
2. Solderless breadboards allow circuits to be easily constructed and destructed in such a way that the components are reusable from one project to the next.
3. Both wires and the legs of a component are attached to connection points on the breadboard.
4. Connection points in the same terminal strip are connected by a wire behind the breadboard.

5. To connect two components together, all you have to do is put their legs on the same terminal strip of the breadboard.
6. The power rails on a breadboard extend either all the way down the board or sometimes split at the halfway point.
7. The bridge of a breadboard divides and separates different groups of terminal strips. This allows a chip to be placed over the bridge, allowing each of its pins a separate terminal strip.
8. The schematic drawing of a circuit can be assembled onto a breadboard, giving a definite implementation of the drawing.
9. There are multiple different ways to place a given circuit drawing onto a breadboard.
10. Components on a breadboard can be connected by wires, or they can be connected by placing their legs in the same terminal strip.
11. There are many different styles of placing components onto breadboards, which have tradeoffs between how easy it is to reconfigure and how clean the result is.
12. A multimeter allows you to measure several important values on a circuit, including resistance, voltage, and current.

13. If your multimeter is not auto-ranging, you must test your value several times, starting with the highest range setting for the value you are looking for and decreasing it through the settings until you find a precise value. For resistance values, this is reversed—we start with the lowest range setting and move upward.
14. Always be sure your multimeter is set to the right setting *before* measuring.
15. Always turn your circuit off before measuring resistance.
16. Your circuit must be on to measure voltage or current.
17. Voltage is measured by connecting your multimeter to empty connection points in the terminal strips that you want to measure. This can be done either by putting your multimeter leads directly into the relevant connection points or by running wires from those connection points to your multimeter leads.
18. Current is measured by using your multimeter to replace a wire that you want to measure current running through.
19. Many circuit values vary much more than what you might think, so it is good to design circuits in a way that will handle these variances.
20. Power modules can deliver consistent voltages even when the components feeding into them (such as batteries) may have a significant amount of variance.

Apply What You Have Learned

All measured values should be measured using the ranging technique discussed in this chapter:

1. Start with the circuit you built in Figure 6-8. Measure the voltage drop across the resistor, and then measure the voltage drop across the LED. Now, measure the voltage drop across both of them (put the red multimeter lead on the left side of the resistor and the black multimeter lead on the right side of the LED). Write down your values.
2. Using the same circuit, change the LED from red to blue. Measure the values again and write them down. Measure the current going through the circuit using any wire. Is it the same or different than before?
3. Add another LED in series with the one you have already. Measure the voltage drops on each side of each component in the circuit. Measure the current going through any given wire. Write down each value.
4. Take the new circuit you built in the previous problem and draw the schematic for the circuit.

CHAPTER 7

Analyzing Series and Parallel Circuits

In Chapter 5, we looked at our very first circuit and how to draw it using a circuit diagram. In this chapter, we are going to look at different ways components can be hooked together and what they mean for your circuit.

7.1 Series Circuits

The circuit built in Chapter 5 is considered a **series circuit** because all of the components are connected end to end, one after another. In a series circuit, there is only one pathway for the current to flow, making analyzing the circuit fairly simple.

It does not matter how *many* components are connected together—as long as all of the components are connected one after another, the circuit is considered a series circuit. Figure 7-1 shows a series circuit with several components included.

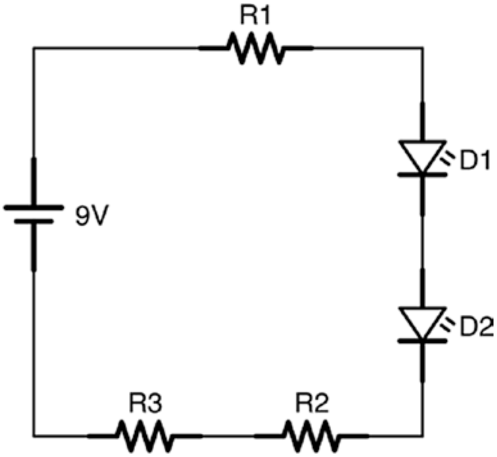

Figure 7-1. *A Series Circuit with Several Components*

If all of the components are in a series, then, even if there are multiple resistors scattered throughout the circuit, you can figure out the total resistance of the circuit just by adding together all of the resistances. This is known as the **equivalent resistance** of the series.

In this example (Figure 7-1), if R1 is 100 Ω, R2 is 350 Ω, and R3 is 225 Ω, then the total series resistance of the circuit will be 100 + 350 + 225 = 675 Ω.

That means that the current is easy to figure out as well. If we ignore the LEDs (since we have not yet learned to calculate using them), then we can use the total series resistance to calculate current the same way we did with the single resistor.

Since the voltage is 9 volts, then we can use Ohm's law to find out the current going through the system.

$$I = V / R = 9 / 675 = 0.013\text{A}$$

Note that A stands for ampere, and we will be using this in our calculations from here on out. However, we usually measure in milliamps (abbreviated as mA), so let us convert:

$$0.013 * 1000 = 13\text{mA}$$

So our circuit will draw about 13 milliamps of current. This amount of current is the same amount running through all of the components in the series.

7.2 Parallel Circuits

Circuits are wired into a **parallel circuit** if one or more of their components are arranged into multiple branches.

Figure 7-2 shows a simple circuit with two resistors in parallel. In this figure, the circuit has *two* branches. R1 is in the first branch, and R2 is in the second branch. The place where the branch occurs is called a **junction**, and is usually marked with a dot to show that all the wires there are connected.

In a parallel circuit, electricity will flow through both branches simultaneously. Some of the current will go through R1 and some of it will go through R2. This makes determining the total amount of current more difficult, as we have to take into account more than one branch.

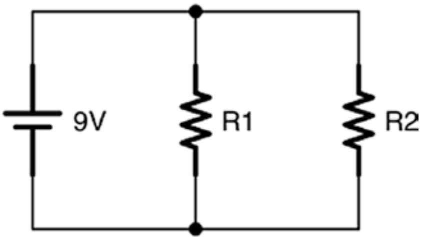

Figure 7-2. *Two Resistors Wired in Parallel*

However, there are two additional laws we can use to help us out, known as **Kirchhoff's circuit laws**. The guy's name is hard to spell, but his rules are actually fairly easy to understand.

7.2.1 Kirchhoff's Current Law

The first law is known as **Kirchhoff's current law**. Kirchhoff's current law states that, at any junction, the total amount of current going *into* a junction is exactly the same as the total amount of current going *out* of a junction. This should make sense to us. Think about traffic at a four-way intersection. The same number of cars that enter that intersection must be the same number of cars that leave the intersection. We can't create cars out of thin air; therefore, each car leaving must have come in. Cars don't magically disappear; therefore, each car entering must leave at some point. Therefore, Kirchhoff's circuit law says that if you add up all of the traffic going in, it will equal the amount going out.

ADVANCED: ANOTHER WAY OF LOOKING AT IT

Another way to say this is that the total amount of all of the currents at a junction is zero. That is, if we consider currents coming in to the junction to be positive and currents going out of the junction to be negative, then their total will be zero since the size of the currents coming in must equal the size of the currents going out.

So let's look at a junction. Figure 7-3 shows a junction where one wire is bringing current in and it branches with two wires bringing current out. The first wire going out has 0.75 A of current, and the second wire going out has 0.34 A of current. How much current is going into the junction from the left?

Since the total coming in must equal the total coming out, then that means the total coming in must be

$$0.75\text{ A} + 0.34\text{ A} = 1.09\text{ A}$$

Therefore, the total amount of current coming into the circuit is 1.09 A.

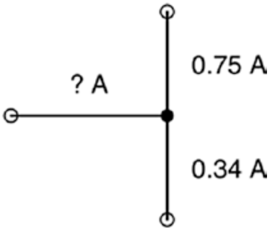

Figure 7-3. *A Simple Junction*

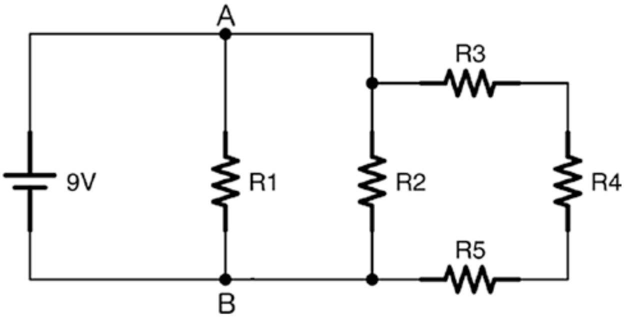

Figure 7-4. *A Circuit with Many Parallel Paths*

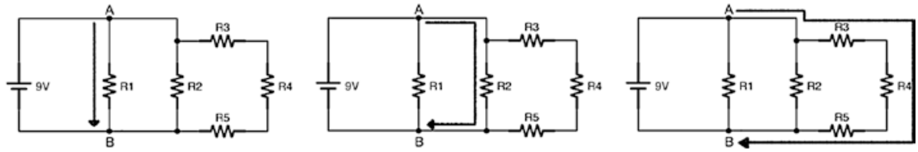

Figure 7-5. *All Paths Between Two Points Have the Same Voltage Drop*

Now, let's say we had a junction of four wires. On the first wire, we have 0.23 A of current coming in. On the second wire, we have 0.15 A of current going out. On the third wire, we have 0.20 A of current going out. What must be happening on the fourth wire? Is current coming in or going out on that wire?

To figure that out, we have to look at the totals so far. Coming in, we have the one wire at 0.23 A. Going out, we have the two wires for a total of 0.15 A + 0.20 A = 0.35 A. Since we only have 0.23 A coming in, but there is 0.35 A going out, that means that the fourth wire must be bringing current in. Therefore, the amount that this fourth wire must be bringing in is 0.35 A – 0.23 A = 0.12 A.

7.2.2 Kirchhoff's Voltage Law

Kirchhoff's current law makes a lot of sense, because the amount of "stuff" coming in is the same as the amount of "stuff" going out. This is similar to our everyday experience. Kirchhoff's voltage law, however, is a bit more tricky. **Kirchhoff's voltage law** states that, given any two specific points on a circuit at a particular time, the difference in voltage between the two points (known as the **voltage drop**) is the same *no matter what pathway you take to get there*.

Figures 7-4 and 7-5 illustrate this point. If we wanted to measure the voltage drop between the two points indicated (A and B), then that voltage drop, at least at a particular point in time, would be the same no matter what pathway electricity travels. The direct route between the two points has the same voltage drop as the more winding pathways, no matter what the values of the resistors are.

So how does that square with Ohm's law?

The way it works is that Ohm's law will cause all of the *currents* through each part of the circuit to adjust in order to make sure that the *voltage* stays the same.

As you can see, the voltage drop between A and B *must* be 9 volts because the battery is a 9-volt battery, and there are no components (only wires) between the battery terminals and A and B. Since batteries always have a constant voltage between their terminals, that means that A and B will have the same voltage—9 volts.

Therefore, that means that the voltage drop across R1 is 9 volts, because it is one of the pathways between A and B, and all pathways get the same voltage. Let's put in some real values for these resistors and see if we can figure out how much voltage and current is happening in each part of the circuit. Let's set R1 = 1,000 Ω, R2 = 500 Ω, R3 = 300 Ω, R4 = 400 Ω, and R5 = 800 Ω. Now, let's find out what our circuit looks like.

As we have noted, *every* path must have the same voltage drop—9 volts. So let's start with the easiest one, the current going across R1. Since we have a 9-volt drop and 1,000 Ω, we can just use Ohm's law for current:

$$I = V / R = 9\text{V} / 1{,}000\Omega = 0.009\text{A}$$

So we have 0.009 A running across R1.

Now, what about R2? R2 is connected to point A simply by a wire. As we mentioned in Chapter 5, wires can be considered to be zero length. Therefore, R2 is just as much directly connected to point A as R1 is. Therefore, the voltage drop across R2 is also going to be 9 volts. Again, using Ohm's law, we can see that

$$I = V / R = 9\text{V} / 500\Omega = 0.018\text{A}$$

So the current going across R2 is 0.018 A.

What about the current going across R3, R4, and R5? Well, if you notice, those resistors are all in series, so we can add them all up and just use the total resistance.

So the total resistance for this section of the circuit will be

$$R3 + R4 + R5 = 300\Omega + 400\Omega + 800\Omega = 1{,}500\Omega$$

So, using Ohm's law, the current running through this part of the circuit will be

$$I = V / R = 9\text{V} / 1{,}500\Omega = 0.006\text{A}$$

Now, remember that the total current flowing into any junction has to be equal to the current flowing out of it. So let's look at the junction between R2 and R3. We calculated that the current flowing to R2 is 0.018 A and the current flowing to the series starting with R3 is 0.006 A. Therefore, there has to be 0.018 + 0.006 = 0.024 A flowing into that junction.

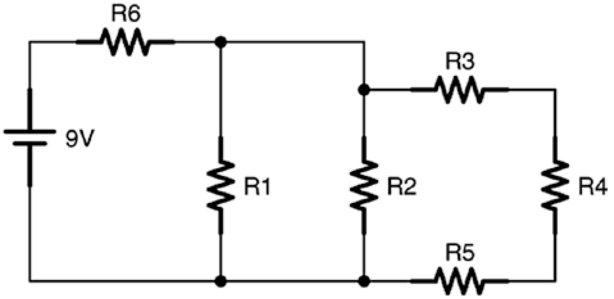

***Figure 7-6.** Kirchhoff's Voltage Law with Series and Parallel Components*

Now, how much current is flowing out of junction A? Well, earlier, we noted that the amount of current flowing across R1 was 0.009 A, and we just calculated that there is 0.024 A flowing out the junction between R2 and R3. That means that there must be 0.033 A total flowing into junction A.

While there were a lot of steps to determine this, each individual step was fairly straightforward. We simply combined Ohm's law, Kirchhoff's voltage law, and Kirchhoff's current law to figure out each step.

Now, one important thing to notice is that there is *less* current running through the pieces of the circuit with more resistance than there is with the pieces of the circuit with less resistance. The electric current is more likely to go down the path of least resistance. This is a very important point and should not be overlooked, as it will come in handy in later chapters.

7.3 Equivalent Parallel Resistance

The sort of calculation that we have done in the previous section gets trickier if there is a series resistance before or after the parallel resistance. Figure 7-6 gives an example of this. The setup is just like the previous circuit, except there is a single resistor (R6) in series with the battery *before* the parallel branches. This will prevent our simple calculations from working because the current flowing in each of the branches of the circuit will all add together to tell us the amount of current flowing through R6. However, the voltage drop across R6 will depend on the current flowing through it. If this voltage changes, then it will change our starting voltage for our calculations to figure out the parallel branches.

Thus, we have ourselves in a loop—in order to find out the current flowing through the parallel branches, we have to know their starting voltage. In order to find out their starting voltage, we have to know how much the voltage dropped across R6. In order to know how much the voltage dropped across R6, we have to know how much current was flowing through it!

This may seem like an impossible problem, but basic algebra allows us to work it out, though the details are kind of ugly. Instead, there is an equation that we can use for parallel resistors which will give us an **equivalent resistance** for a group of parallel resistors. That is, we can take a group of parallel resistors, and we can calculate the total resistance of those resistors, as if they were acting together as one resistor. In other words, we can find out what value we would need for a single resistor to replace all of the other resistances.

If you have resistors in parallel to each other (let's call them R_1, R_2, and R_3) and you want to know the resistance of their *combined* action (which we will call total RT), then you would use the following equation:

$$R_T = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3}} \qquad (7.1)$$

This equation works for any number of resistances that we have in parallel. We can just keep on adding them to the end of the list:

$$R_T = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \ldots + \frac{1}{R_N}} \qquad (7.2)$$

So let's look at our circuit and see how we can find out the current flowing through each resistor. For this example, we will again say that $R1 = 1{,}000\ \Omega$, $R2 = 500\ \Omega$, $R3 = 300\ \Omega$, $R4 = 400\ \Omega$, and $R5 = 800\ \Omega$. Additionally, $R6 = 250\ \Omega$.

In order to compute this, we first have to figure out *what* is in series and what is in parallel. Notice the loop made by R3, R4, and R5. Those are all connected end to end, so they are in series. Because they are in series, we can get their equivalent resistance just by adding them together—300 + 400 + 800 = 1,500 Ω. Therefore, we can actually *replace* these resistors with a single, 1, 500 Ω resistor. We will call this "combined" resistor R7. Now, if you look at the new picture, with R7 standing in for the loop, you will see that R1, R2, and R7 are in parallel with each other.

Therefore, we can find out their combined resistance by using Equation 7.2:

$$R_T = \frac{1}{\frac{1}{R1} + \frac{1}{R2} + \frac{1}{R7}}$$

$$R_T = \frac{1}{\frac{1}{1{,}000} + \frac{1}{500} + \frac{1}{1500}}$$

$$R_T = \frac{1}{0.001 + 0.002 + 0.00067}$$

$$R_T = \frac{1}{0.00367}$$

$$R_T = 272.5\Omega$$

Therefore, the equivalent resistance of all of the parallel resistances is about 272.5 Ω, which means that we could in theory replace *all* of these resistors (R1, R2, R3, R4, and R5) with a single resistor that is 272.5 Ω. Also notice that this resistance is actually *less* than each of the individual resistances.

Now, to get the total resistance of the circuit, we notice that this parallel resistance (272.5 Ω) is in series with R6, which is 250 Ω. Since they are in series with each other, we can simply add them together. The total resistance of this circuit is 250 + 272.5 = 522.5 Ω. We can now use Ohm's law to find the total amount of current running through this circuit:

$$I = \frac{V}{R}$$

$$I = \frac{9}{522.5}$$

$$I = 0.0172\text{A}$$

Thus, the whole circuit has 0.0172 ampere of current running through it. Using this, we can now go back through and identify how much current and voltage is flowing through each individual piece.

Because the entirety of the 0.0172 ampere is going through the first resistor (R6), that means that the voltage drop of the R6 resistor will be, using Ohm's law

$$V = I \cdot R$$

$$V = 0.0172 \cdot 250$$

$$V = 4.3\text{V}$$

That means that this resistor will chew up 4.3 V. This leaves us with 9 – 4.3 = 4.7 V after the series resistor.

We now know the starting and ending voltages of each branch of the parallel resistors—4.7 V at the beginning (what we just calculated the voltage to be after the series resistor) and 0 V at the end (because it connects to the negative terminal of the battery, which we have designated as the 0-volt reference).

Therefore, we can use Ohm's law to find the amount of current flowing through each of them. For R1:

$$I = \frac{V}{R}$$
$$I = \frac{4.7}{1{,}000}$$
$$I = 0.0047\,\text{A}$$

For R2:

$$I = \frac{V}{R}$$
$$I = \frac{4.7}{500}$$
$$I = 0.0094\,\text{A}$$

And finally, for the series that is in a loop at the right (R3, R4, and R5):

$$I = \frac{V}{R}$$
$$I = \frac{4.7}{1500}$$
$$I = 0.0031\,\text{A}$$

Since the loop is all in series, that means all of the resistors in that series will have 0.0031 A going through them.

If we add all of these currents, we will see that 0.0031 + 0.0094 + 0.0047 = 0.0172 A, which is the amount of current we originally figured out.

What we have learned is that we can replace the entire circuit with a single value for its resistance to figure out how the circuit will behave as a whole. For a simple circuit like this, having all of these parallel branches doesn't do much, so it may seem pointless. However, in a real circuit, each of these branches may be, instead of a resistor, a more complicated component that has some amount of resistance. If you know the resistance, you can calculate how much current is flowing through it the same way.

However, we start with only resistors in order to make the problems simpler.

7.4 Wires in a Circuit

In complicated circuits, sometimes we run out of room and must draw wires on top of each other even though the wires aren't connected. In this book, we try to make clear which wires are connected by placing a dot on the junction point. Another way to show this is to show the wires crossing if the wires are joined but showing one of the wires as being broken across the intersection point if the wires are not joined. Figure 7-7 demonstrates the difference. The wires on the left are joined together as indicated by the dot. The wires on the right are not joined in any way; they just had to be drawn across each other because of space reasons in the diagram. In this book, the convention we follow is to use dots to indicate joined wires, but we do not break lines for unjoined wires.

Also, the lengths of wires that we draw are irrelevant. Usually, in simple circuits, we should consider that wires are all zero length. If, after a resistor, the voltage in the circuit has dropped to 5 V, then we can consider that the *whole wire* until the next circuit is at 5 V. If a wire branches into multiple branches, even though each branch will have a different amount of *current* running on it, each branch of the wire will all have the *exact same voltage* until they reach another component.

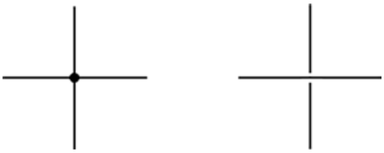

Figure 7-7. *Showin Joined Wires (Left) vs. Showing Unjoined Wires (Right)*

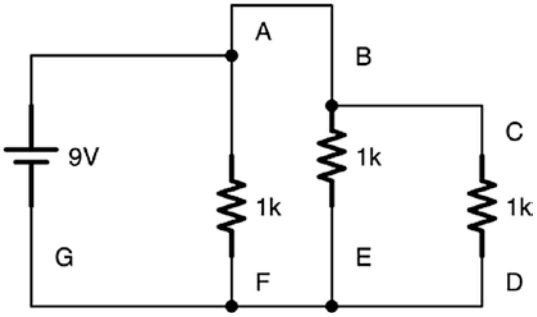

Figure 7-8. *Several Points on a Circuit*

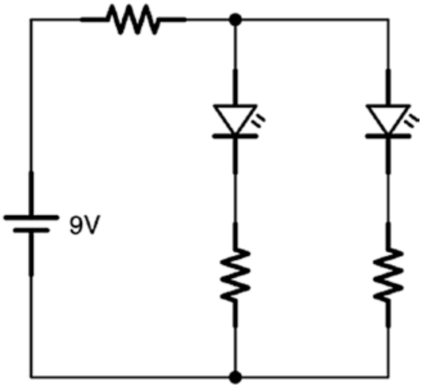

Figure 7-9. *A Circuit with Series and Parallel Components*

Therefore, in the circuit in Figure 7-8, you can see several points labeled A, B, C, D, E, F, and G. In this circuit, A, B, and C all have equivalent voltages (though not equivalent currents) since there are only wires (and not components) between them. Likewise, D, E, F, and G all have equivalent voltages since there are only wires between them. Also, since D, E, F, and G are all connected to the battery negative (i.e., ground) with no components between them, that means that they are all at 0 volt. Likewise, since A, B, and C are all directly connected to the battery positive with no intervening components, they are all at 9 volts.

7.5 Wiring Parallel Circuits onto a Breadboard

One other issue we need to look at is how to wire parallel circuits onto the breadboard. It is actually very simple to do. In this section, we are going to put the circuit in Figure 7-9 onto a breadboard.

Notice that, in this circuit, there is a series resistor at the beginning and then two parallel circuits that branch off from it. It doesn't matter much what the value of the resistors are, but we will put them at 1,000 Ω if you need a specific value (anything between 200 and 2,000 Ω should work fine).

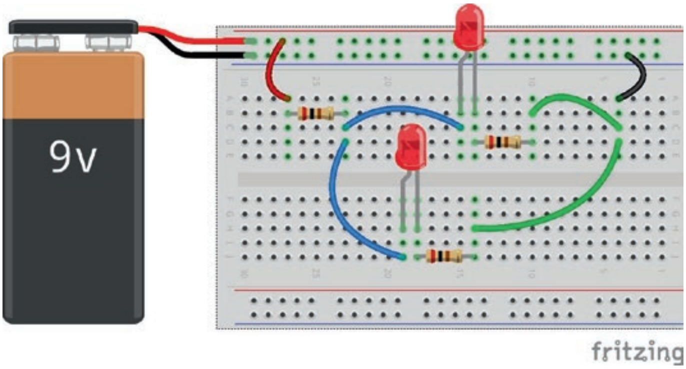

Figure 7-10. *A Circuit with Series and Parallel Components on the Breadboard*

To get the circuit onto the breadboard, remember that anything that is connected in the same terminal strip on a breadboard is connected together. This means that, when we have a parallel subcircuit, we connect all of the branches of the subcircuit into the same terminal strip. Figure 7-10 shows what this looks like.

Let's follow the path of electricity through the breadboard. First, the current flows from the positive terminal to the positive rail on the breadboard. A wire then pulls the positive +9 V power onto the board. This wire is connected to a resistor by putting one leg of the resistor in the same terminal strip as the wire. On the other leg of the resistor, there are *two* wires that are in the same terminal strip. Each of these goes to a different part of the circuit. We have one LED with a resistor on the top and one LED with a resistor on the bottom. These are just normally connected components.

However, after the resistor, the two subcircuits come back together to a terminal strip on the right. Then, a wire on the same terminal strip takes that back to the negative rail on the breadboard (which connects to the negative terminal on the battery).

Note that I could have used a lot fewer wires to accomplish the same circuit. However, I thought that using more wires would make it more clear what is happening at each junction, especially when the circuit gets divided into branches or comes back together.

Take a moment to look at both the schematic drawing and the breadboard picture, and be sure that you can trace the flow of the schematic on the actual breadboard.

Review

In this chapter, we learned the following:

1. In a series circuit, electricity flows in a single line through all of the components.
2. In a parallel circuit, electricity branches and flows in multiple branches.

3. Most real circuits are combinations of series and parallel circuits.
4. When you have resistors together in series, the total resistance of all of the resistors combined is simply the sum of their individual resistances. $R_T = R_1 + R_2 + \ldots + R_N$.
5. In a parallel circuit, Kirchhoff's current law says that the total amount of current entering a branch/junction is the same as the total amount of current leaving the branch.
6. In a parallel circuit, Kirchhoff's voltage law says that, between any two points on a circuit at a given point in time, the voltage difference between those two points will be identical no matter what pathway the electricity follows to get there.
7. When resistances are in parallel, the total resistance for the parallel circuit is given by the equation

$$R_T = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \ldots + \frac{1}{R_N}}$$

8. By using these laws in combination, we can predict how current will flow in each part of our circuit.
9. Series circuits are placed onto a breadboard by putting the connected legs of two connected components onto the same terminal strip.
10. Parallel circuits are placed onto a breadboard by connecting each subcircuit branch to the same terminal strip.

Apply What You Have Learned

1. There is a junction in a circuit that has one wire with current flowing in and two wires with current flowing out. There is 1.25 A of current coming in, and the first wire going out has 0.15 A of current. How much current is leaving through the second wire?
2. There is a junction in a circuit that has two wires with current flowing in and two wires with current flowing out. The first wire with current flowing in has 0.35 A of current, the first wire with current flowing out has 0.25 A of current, and the second wire with current flowing out has 0.42 A of current. How much current is flowing in on the second incoming wire?
3. At a junction of four wires, wire 1 has 0.1 A of current flowing in, wire 2 has 0.2 A of current flowing in, and wire 3 has 0.4 A of current flowing out. Is the current in wire 4 going in or out? How much current is flowing on it?
4. If I have three 100 Ω resistors in series, what is the total resistance of the series?
5. If I have a 10 Ω resistor, a 30 Ω resistor, and a 65 Ω resistor in series, what is the total resistance of the series?
6. If I have a 5 Ω resistor and a 7 Ω resistor in series, what is the total resistance of the series?

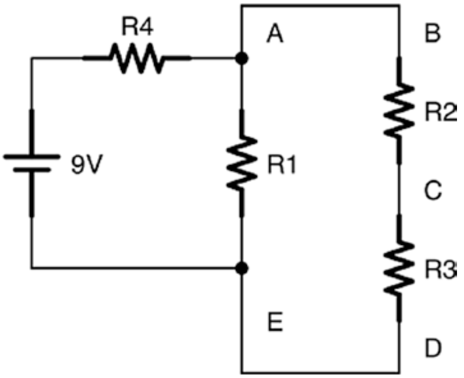
7. If I have two resistors in parallel, a 30 Ω resistor and a 40 Ω resistor, what is the total resistance of this circuit?

8. If I have three resistors in parallel—25 Ω, 40 Ω, and 75 Ω—what is the total resistance of this circuit?

9. If I have four resistors in parallel—1,000 Ω, 800 Ω, 2,000 Ω, and 5,000 Ω—what is the total resistance of this circuit?

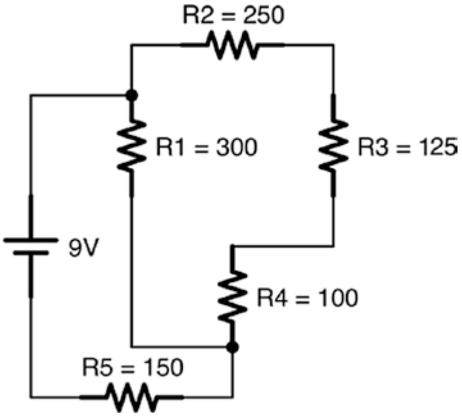
10. If I have three resistors in parallel—100 Ω, 5,000 Ω, and 10,000 Ω—what is the total resistance of this circuit? Which of the resistors is the total resistance most similar to?

11. Take a look at the following circuit diagram. If the voltage drop between B and C is 2 volts and the voltage drop between C and D is 3 volts, what is the voltage drop between A and E? What is the voltage at E? What is the voltage at A?



12. If the preceding circuit runs with 2 A total current, what is the value of the resistor R4?

13. The following circuit is a combination of series and parallel resistances. Each resistor is labeled with its resistance value, given in ohms. Find out how much current is flowing through each resistor and how much each resistor drops the voltage.



14. Build the circuit in Figure 7-10 on your own breadboard. Measure the voltage drops across every component, and measure the amount of current flowing into the first series resistor.

CHAPTER 8

Diodes and How to Use Them

This chapter introduces the **diode**. We have used light-emitting diodes (LEDs) in previous chapters, but have not really discussed their function except for emitting light. In this chapter, we are going to look at regular diodes, light-emitting diodes, and Zener diodes, to get a feel for what these devices are and how they might be used in circuits for more than just light.

8.1 Basic Diode Behavior

Unlike resistors, diodes have both a positive and negative side. For any component with both positive and negative legs, the positive leg of the component is termed the **anode** and the negative leg is termed the **cathode**. On LEDs, the anode is longer than the cathode. However, for other types of diodes, the cathode is marked with a line. You can remember this because in the schematic of a diode, the cathode has the blocking line.

The diode performs two fundamental "actions" with electric current. The first action of a diode is to drop voltage by an essentially fixed amount *without* affecting or limiting current. This amount of voltage is called the **forward voltage drop** and it is usually around 0.6 V for most non-LED diodes. Forward voltage is often abbreviated as V_F. For most LEDs, the

forward voltage drop depends on the color of the LED, with a red LED dropping about 1.8 V and a blue LED dropping about 3.3 V. The forward voltage drop can vary among the other colors as well.

To remind you, when we say “voltage drop,” we are referring to the difference in voltage between the positive and negative legs of the diode. Therefore, no matter what the voltage is coming into the diode, the voltage coming out of the diode will be that voltage minus the voltage drop.

The second action of a diode is to limit the direction of current to a single direction. With some exception, the diode only allows current to flow one way in the circuit. The “normal flow” of a current through the diode is to flow from the anode to the cathode. Looking at the schematic symbol, current flows in the direction that the arrow is pointing, and current is blocked from flowing the other way (you can think of the line as a “block” preventing reverse flow).

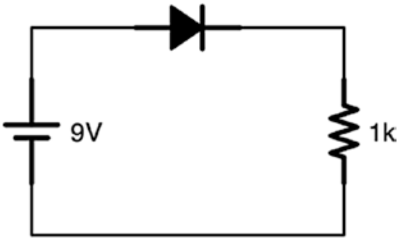

Figure 8-1. *A Diode and Single Resistor Circuit*

However, diodes are limited in the amount of reverse flow they can block. At a certain point, diodes reach their **breakdown voltage**. The breakdown voltage is the voltage at which they will stop blocking voltage. In regular diodes, this is a failure mode, and the precise value shouldn’t be relied upon (we will see an exception to this with Zener diodes). Usually, though, this value is high enough not to worry about (i.e., around 100 volts).

8.2 Circuit Calculations with Diodes in Series

Now let's talk about how to properly calculate the behavior of circuits with diodes. Remember, the key to a diode is that if current is flowing through the diode, the voltage drop across the diode will be essentially constant. For a normal non-LED diode, this voltage drop is almost always 0.6 V. This is so common it is usually assumed, and never listed in the circuit itself.

Therefore, take a look at the circuit in Figure 8-1. Since the voltage source is 9 volts, that means that the total voltage drop between the positive and negative is 9 volts. The diode will eat 0.6 V of the voltage, but will not limit the current in any way. The resistor, then, since it is the only component left, will use up the rest of the voltage—8.4 V. Therefore, we can calculate the current in the circuit using Ohm's law:

$$I = V / R = 8.4 / 1000 = 0.0084\text{A} = 8.4\text{mA}$$

Therefore, our circuit will use 8.4 mA of current. So, as you can see, when doing calculations, the diodes simply provide a drop in voltage, they do not limit (or even affect) current.

This is true no matter how many diodes or resistors I have in my circuit. Figure 8-2 shows a circuit like that. To figure out the behavior of this circuit, remember that *every* diode has a 0.6 V voltage drop. Since the circuit has three diodes, that means that the diodes will drop a total of $0.6 * 3 = 1.8$ V.

Therefore, we will have 1.8 V taken up by diodes, which drop voltage without limiting current. Since we have a 9 V source, there will be $9 - 1.8 = 7.2$ V that is not eaten by diodes. This voltage will go to our two resistors. These resistors, even though they are separated by diodes, are essentially in series with each other. Therefore, we can treat them as a single resistor in series. So the total resistance on the circuit will be $1k + 2k = 3k\ \Omega$.

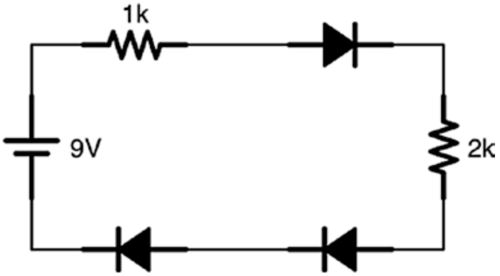

***Figure 8-2.** A Circuit with Multiple Diodes and Resistors*

We can then find the total current running through the circuit using Ohm's law:

$$I = V / R = 7.2\text{V} / 3{,}000\Omega = 0.0024\text{A} = 2.4\text{mA}$$

However, it is possible to put too many diodes in your circuit. Since they each eat 0.6 V in their forward voltage drop, that puts a limit on how many you can string together in series from a given battery. For a 9 V battery, if I try to put 20 diodes together in series, I will have used *more* than the total 9 volts that I have available. Therefore, current will not flow. With 20 diodes, the voltage drop will be 20 $*$ 0.6 = 12 V. Since this is more voltage than the battery can put out, no current will flow.

So we have seen two conditions for which current will not flow through a diode—the first is that the diode will block current from flowing in the wrong direction, and the second is that the diode will not conduct if the voltage source cannot provide enough voltage to bridge the forward voltage drop of the diode.

8.3 Circuit Calculations with Diodes in Parallel

The real magic of diodes comes when using them in parallel circuits. Remember the rules that we learned in Chapter 7. Kirchhoff's voltage law says that between any two points, the voltage drop between those two points will be the same *no matter what path the current follows*. Therefore, since the voltage drop across a diode is *fixed*, that means that we can guarantee a maximum voltage drop between two points on a circuit by putting diodes between them.

Figure 8-3 shows what this looks like. The voltage drop from one side of the diode to the other is 0.6 V. Period. End of story (actually, it could be less, which would keep the diode from conducting altogether, but we won't consider that at the moment).

Kirchhoff's voltage law tells us that *no matter what path is traveled*, the voltage difference between those two points will be the same. Since the 2k resistor is attached to the same two points that the diodes are attached to, Kirchhoff's voltage law tells us that the voltage across the resistor *must* be the same as the voltage across the diode. Thus, the voltage across the resistor *must* be 0.6 V.

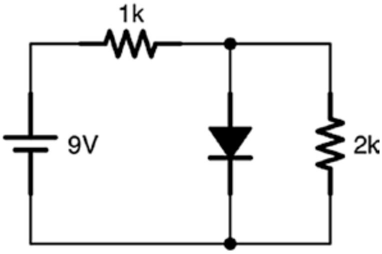

Figure 8-3. *A Single Diode in Parallel with a Resistor*

Using Ohm’s law, we can deduce the amount of current flowing through that resistor:

$$I = V / R = 0.6 / 2{,}000 = 0.0003\text{A} = 0.3\text{mA}$$

So how much current is flowing through the diode? To find this out, we need to use Kirchhoff’s current law. The amount entering the junction where the diode and the 2k resistor split off is the same as the amount leaving it. We know that 0.3 mA leaves the junction to go to the resistor. Therefore, if we could figure out how much current was coming *into* the junction, we could figure out how much is going through the diode.

To discover that value, we need to know how much current is going through the 1k resistor. To figure that out, we need to know the voltage drop across the resistor. However, we can figure this out easily. Since the tail end of the diode is connected to ground (the negative terminal), that means that after the diode, we are at 0 V. Therefore, since the diode voltage drop is 0.6 V, then the voltage before the diode must be 0.6 V. That means that the rest of the voltage must have been consumed by the 1k resistor.

Since the voltage source is 9 V, that means that the voltage for the entire circuit from positive to negative is 9 V, and therefore, the voltage drop across the resistor must have been 9 – 0.6 = 8.4 V. Using this value, we can determine the current going through the resistor using Ohm’s law:

$$I = V / R = 8.4 / 1{,}000 = 0.0084\text{A} = 8.4\text{mA}$$

In this circuit, there is 8.4 mA going through the first resistor. That means that there is 8.4 mA coming into the junction. We know that 0.3 mA is going out of the junction through the 2k resistor. That means that the rest of the current is going through the diode. Therefore, we can calculate that the current going through the diode is 8.4 – 0.3 = 8.1 mA.

Diodes don’t make the math harder, but they do force you to *think* a little harder about how you apply the rules.

Let's take a look at a slightly harder example, using Figure 8-4. In this circuit, we have two diodes in parallel with two resistors in parallel. This parallel circuit is in series with a resistor on the front and another diode at the end.

It is almost always easiest to analyze circuits starting with the diodes because their voltage drops are fixed. If we look at this circuit, the diode at the end gives the circuit a voltage drop of 0.6 V.

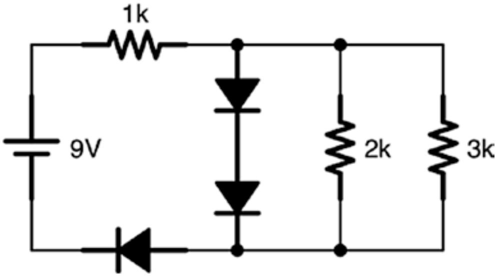

Figure 8-4. *A Circuit with Multiple Diodes*

Now let's look at the parallel part of the circuit. Here, we have three pathways—one through two diodes and two other pathways through resistors. However, one of the pathways contains all diodes. We know that diodes give a constant voltage drop, and we know that Kirchhoff's voltage law says that all pathways between two points have the same voltage drop. Since we have two diodes, the voltage drop of this parallel pathway is 0.6 ∗ 2 = 1.2 V.

Now we have the parallel resistors to worry about. However, we can use the formula for parallel resistance (Equation 7.2) to figure out the total resistance of the parallel resistors.

$$R_T = \frac{1}{\frac{1}{R1} + \frac{1}{R2}} = \frac{1}{\frac{1}{2,000} + \frac{1}{3,000}} \approx \frac{1}{0.0005 + 0.0003333} = \frac{1}{0.0008333} \approx 1200\Omega$$

However, we technically don't even need that number, because, since we already know the voltage drop across each resistor (it *must* be 1.2 V because of Kirchhoff's voltage law), we can just apply Ohm's law to each resistor.

Now, using Ohm's law, we can calculate the current flowing through the resistors. So, for the 2k resistor, we have

$$I = V / R = 1.2\text{V} / 2{,}000\Omega = 0.0006\text{A} = 0.6\text{mA}$$

For the 3k resistor, we have

$$I = V / R = 1.2\text{V} / 3{,}000\Omega = 0.0004\text{A} = 0.4\text{mA}$$

The total current going into both resistors is simply the sum of each of the currents, 0.4 + 0.6 = 1.0 mA. So there is 1 mA total flowing through the two resistors. To find out how much current is flowing through the diode, we will need to know how much current is coming into the circuit itself out of the first resistor.

So how much current is flowing through the first resistor? Well, the voltage drops we have calculated so far include a 0.6 V drop at the end and a 1.2 V drop in the middle. That is a total of 1.2 + 0.6 = 1.8 V. Since the battery is 9 V, that means that there is 9 − 1.8 = 7.2 V left to be consumed by the circuit. Therefore, that must be the voltage drop of the first resistor. Using Ohm's law, we find that

$$I = V / R = 7.2\text{V} / 1{,}000\Omega = 0.0072\text{A} = 7.2\text{mA}$$

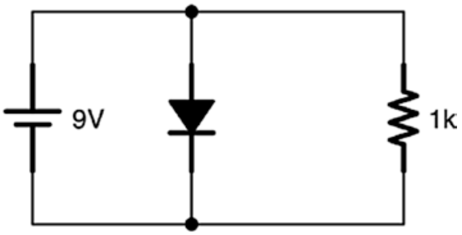

Figure 8-5. *A Bad Diode Circuit*

Therefore, we have 7.2 mA flowing through that first resistor. So, if we have 7.2 mA coming into the parallel circuit in the middle and 1 mA flowing to the resistors, the amount of current flowing through the diodes down the middle is 7.2 – 1 = 6.2 mA. The amount of current going through the final diode is the full 7.2 mA of current in the circuit.

Again, there are a lot of steps, but none of the steps are individually very hard. You simply start with the easiest-to-find values (in this case, the voltage drops from the diodes) and work out from there.

8.4 Diode Short Circuits

Next, let's look at a very bad design with a diode. Let's say that someone wanted to use a diode to regulate the amount of voltage across a resistor to 0.6 V. Therefore, they built the circuit shown in Figure 8-5. Can you figure out what the problem is here?

Well, the voltage drop across the diode will be 0.6 V. However, the battery operates at 9 V. This means that there is 8.4 V left in the circuit with *zero* resistance. Using Ohm's law, that gives us

$$I = V / R = 8.4 / 0 = \infty$$

Thus, having a diode going direct from the positive to the negative of your voltage source is essentially the same as a short circuit. That is why the circuit is bad! To use a diode, there must *always* be resistance somewhere in series with the diode in order to dissipate the current from the excess voltage. The resistor can be before the diode or after it, but it must be there to absorb the extra voltage.

Additionally, it is important to make sure the amount of current flowing through your diode is within the specifications of the diode you are using. Most LEDs, for instance, are only rated for small currents up to about 30 mA.

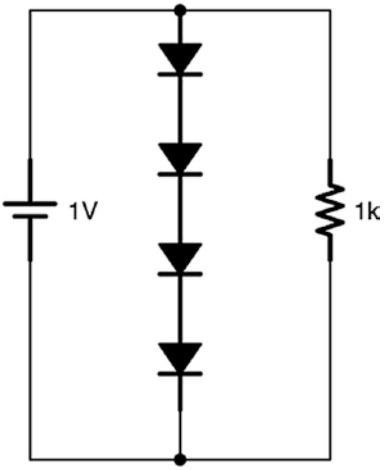

Figure 8-6. *Nonconducting Diodes*

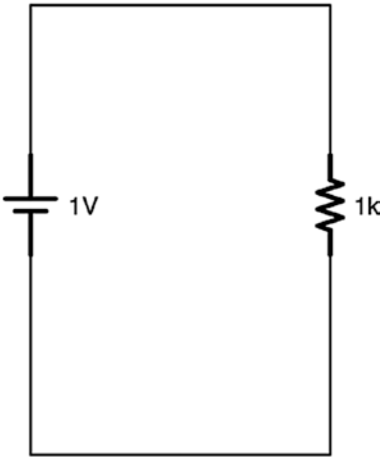

Figure 8-7. *A Circuit Equivalent to Figure 8-6 Because of Nonconducting Diodes*

8.5 Nonconducting Diodes

There is one case where diodes do not maintain a constant voltage drop, and that is where there is not enough voltage to go across them. Figure 8-6 shows an example of this.

In this figure, the voltage drop across the center diode bridge is 0.6 + 0.6 + 0.6 + 0.6 = 2.4 V. However, the battery source is only 1 V. Since the voltage drop of the diodes is larger than the available voltage, this part of the circuit is basically turned off. In reality, there is a small but ignorable leakage current (about 0.00000022 mA in this case if you were really curious), but we can think of this circuit as effectively switched off.

So keep that in mind—if you ever wind up with more forward voltage drop from a diode than you have available voltage, you may treat the diode as if it were an open (i.e., unconnected) circuit, as if it were not even there.

Therefore, we would analyze Figure 8-6 as if it were just like Figure 8-7.

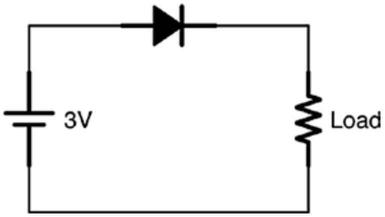

Figure 8-8. *A Simple Diode Protection Circuit*

8.6 Usage of Diodes

Diodes can be thought of as circuit traffic cops—they regulate the flow of electricity. They make sure that everything within a circuit is happening in a controlled manner. They regulate the circuit in two different ways—by limiting the direction of current and, in parallel circuits, by establishing fixed voltages between two points.

The simplest usage of a diode is to use it as a device that makes sure that your battery is plugged in the right orientation. If you have a device that will be damaged if someone puts the battery in backward, a simple diode will make sure that the current can only flow in one direction.

The circuit in Figure 8-8 shows what this looks like. Note that we have a resistor labeled "Load." Many times in circuits, a load resistor is shown to represent whatever else is happening in another part of a circuit. Thus, this circuit shows that the diode is protecting the rest of the circuit (whatever it is) from the user putting the battery in backward. However, this has a cost—the diode will eat 0.6 V in order to provide this protection.

Another problem often solved by diodes is voltage regulation. Because diodes provide a fixed voltage drop between two points, you can use diodes to ensure a fixed voltage for devices that require it.

For instance, when we looked at batteries in Chapter 6, we noted that their voltage actually varied quite a bit. A 9 V battery might give you anywhere from 7 V to 9.7 V. This is true of any battery, not just the 9 V variety. In that chapter, we showed how we could use a voltage regulator to accomplish this, but a similar effect can be accomplished with diodes. If you need a fixed amount of voltage, you can use diodes to provide that at the cost of some extra current.

This isn't recommended for a whole project (the excess current can generate a lot of heat), but sometimes makes sense in limited circumstances. However, for demonstrating the concept, let's look at what it would take to provide voltage regulation using diodes.

Figure 8-9 shows a simple voltage regulator using diodes. Given a 5 V battery (actually, a battery of any size significantly over 3 V will work), this circuit will provide a regulated 3 V of electricity to whatever is connected to it as a load (remember a "load" resistor is just a stand-in for whatever we want to attach to this).

Because the diodes provide a fixed voltage drop of 0.6 V each, then that pathway has a total voltage drop for five diodes of $5 * 0.6 = 3.0$ V. Kirchhoff's voltage law says that between two points, *every* pathway between them will have the same voltage drop. This means that the load, since it is connected to those two points, will have the same voltage drop, thus regulating the amount of voltage used by the load.

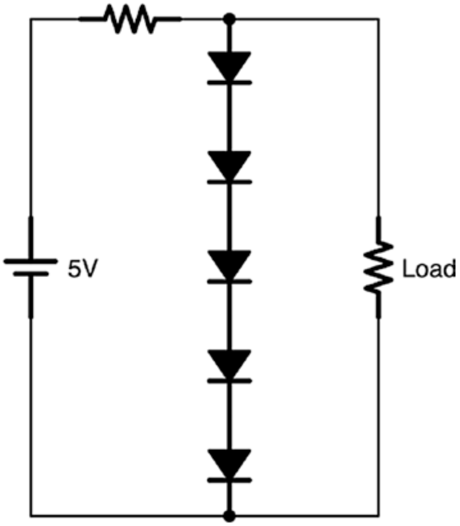

Figure 8-9. *A Simple 3 V Voltage Regulator*

But what about that first resistor at the beginning of the circuit? Remember, if we provide a pathway through diodes only, we create a short circuit in the system. There has to be some element (usually a resistor) that eats up whatever voltage is left over. Therefore, putting a small resistor before our diode pathway will give the circuit a place to use the excess voltage and limit the amount of current that flows.

The size of the resistor will depend on how much current the load requires and how much current you are willing to waste. A small resistor wastes more current, but allows for a higher maximum current used by the load. A larger resistor wastes less current, but if the load needs a lot of current, it could interfere with the voltage regulation.

To see how this could happen, let's say that our load is equivalent to 1,000 Ω. This means that the amount of current that the load will draw can be calculated using Ohm's law:

$$I = V / R = 3\mathrm{V} / 1{,}000\Omega = 0.003\mathrm{A} = 3\mathrm{mA}$$

So the load will use up 3 mA of current. That means that, however much current goes through our first resistor, however much that is over 3 mA will be drained off through the diodes. So let's calculate what that looks like on a tiny, 20 Ω resistor. The voltage will be 5 – 3 = 2 V.

$$I = V / R = 2\mathrm{V} / 20\Omega = 0.1\mathrm{A} = 100\mathrm{mA}$$

So, if we just used a 20 Ω resistor, that means that even though the load only used 3 mA, the whole circuit will be using 100 mA to operate! Therefore, we need a bigger resistor to limit the amount of current we use. Let's try a 500 Ω resistor:

$$I = V / R = 2\mathrm{V} / 500\Omega = 0.004\mathrm{A} = 4\mathrm{mA}$$

This is much better—we are only using 4 mA in this circuit, so we are only wasting 1 mA. There has to be *some* amount of waste to do the voltage regulation.

Let's say that, after a while, our battery sags down to only providing 4 V of power. What happens now? Well, using the 500 Ω initial resistor, that means that there is only 1 V extra to drain off, so the current will be

$$I = V / R = 1\mathrm{V} / 500\Omega = 0.002\mathrm{A} = 2\mathrm{mA}$$

Here, the current is only 2 mA, but we need 3 mA to power the circuit! Thus, if we use a 500 Ω resistor, we can't handle our power supply dropping down to 4 V.

What about using the 20 Ω resistor? In this case, Ohm's law would give us

$$I = V / R = 1\text{V} / 20\Omega = 0.05\text{A} = 50\text{mA}$$

So, here, the 20 Ω resistor will still provide plenty of excess current to allow our regulator to keep working. However, it is still eating up an extraordinary amount of current compared to our load.

So how do you choose the right resistor? The way to work situations like this is to think about what are the maximum cases you are designing for and then calculate appropriately. So, if I want this circuit to work when the battery sags down to 4 V, I need to decide how much excess current I'm willing to have at that level. Let's say I decide that I always want at least half a milliamp to run through the diode (somewhat of an arbitrary number, but if the diode has no power, it is not providing any regulation—this is a low number that is still "noticeable" on the circuit). That means that, since my load will be using 3 mA, the total amount of current running through the initial resistor will be 3.5 mA, or 0.0035 A. Therefore, I calculate what the resistor will need to be at 4 V using Ohm's law:

$$R = V / I = 1\text{V} / 0.0035\text{A} \approx 286\Omega$$

Therefore, for this situation, the initial resistor should be 286 Ω. Now, let's figure out how much current this wastes when the battery is at full charge—5 V (which means that there will be a 2 V drop across this resistor).

$$I = V / R = 2\text{V} / 286\Omega \approx 0.007\text{A} = 7\text{mA}$$

So, at full charge, there is 7 mA going through this resistor, which means we will waste 4 mA. Whether or not that is acceptable to your circuit depends on what you are going to do with it!

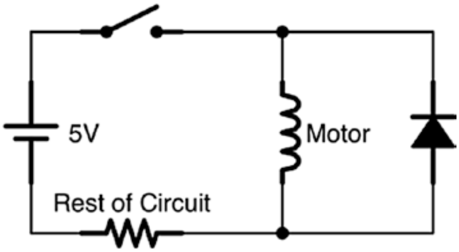

Figure 8-10. *A Diode Protection Circuit*

Note that there are better means of regulating battery voltage for a whole circuit than using diodes. However, many times you need a regulated voltage somewhere *within* a more complex circuit. Diodes are great for that, and the same calculations and considerations apply.

One final note: As mentioned earlier, although we think of diodes as providing a fixed voltage, they actually do vary a little bit with the amount of current flowing through them. In any circuit, you should allow for ±10% variance in the voltage drop of a diode.

8.7 Other Types of Diode Protection

Diodes can provide other types of protection for circuits as well. As single-direction control valves, they can be used to prevent a variety of overvoltage conditions. Oftentimes they are wired in such a way that they will not normally conduct, but will conduct under certain conditions to redirect extra voltage in a safe manner.

Figure 8-10 shows an example circuit. In this circuit, a DC motor is connected to a switch. Notice the diode that is wired backward. Normally, this diode does absolutely nothing because the current is flowing in the other direction, so it just goes through the motor. DC motors, however, tend to generate very large voltages for a short time when switched off (see Chapters 20 and 23 for more information about DC motors and inductive loads). Therefore, when the motor is switched off, the motor can produce a very large voltage—up to 50 V in this circuit!

To protect the rest of the circuit from this sudden influx of voltage, the diode provides an alternative path back through the motor. Thus, when the voltage starts to build up after the switch closes, the diode provides a safe pathway back through the motor for it to flow, allowing the voltage buildup to slowly dissipate through the motor, rather than overloading a circuit expecting 5 V with 50 V.

Oftentimes when looking at circuit diagrams, you may find diodes in funny places and oriented in funny ways. These are oftentimes providing some sort of protection to the circuit from potential failure conditions or exceptional circumstances. Many microchips, for instance, use diodes to shunt off excess voltage from static electricity shocks.

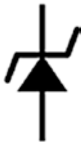

Figure 8-11. *The Zener Diode Schematic Symbol*

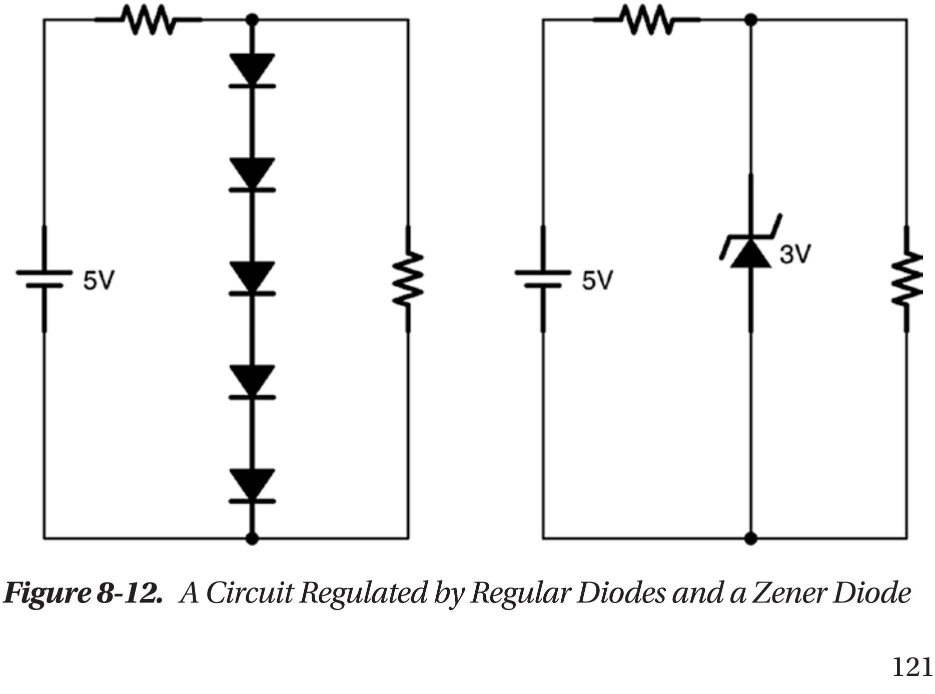

Figure 8-12. *A Circuit Regulated by Regular Diodes and a Zener Diode*

8.8 Zener Diodes

One problem with using diodes for voltage regulation is that their forward voltage drop is pretty small, so you have to have quite a few of them to regulate larger voltages. Zener diodes can help out in these situations. Figure 8-11 shows the symbol for a Zener diode.

Remember that most diodes have a breakdown voltage if you try to pass voltage the wrong way. However, in most diodes, this is a failure mode—doing this can, at best, be unpredictable, and, at worst, damage your diode. A Zener diode, however, is built so that it has a very predictable operation at its breakdown voltage. In fact, at its breakdown voltage, it acts like a normal diode with a larger voltage drop.

However, since you are using the breakdown voltage rather than the forward voltage, Zener diodes are wired into your circuit *backward*. Figure 8-12 shows what this looks like. In this figure, on the left you have the same 3 V regulated circuit as Figure 8-9. On the right, you have an equivalent circuit regulated by a Zener diode instead. Since we are using the Zener diode's breakdown voltage rather than its forward voltage, it has to be wired backward for it to work.

Not only that, the breakdown voltage drop for a Zener diode is much more constant over a larger range of current than the forward voltage drop of most regular diodes. Because of this, Zener diodes are used much more often for voltage regulation than a series of regular diodes.

Zener diodes come in a variety of breakdown voltages. In any exercise in this book which involves drawing a circuit with a Zener diode, you may presume that the Zener diode with the voltage drop you are looking for exists. When drawing a circuit, be sure to label the Zener diode with the breakdown voltage you are needing.

8.9 Schottky Diode

A Schottky diode is very similar to a normal diode, but it is made using a different process, meaning that its voltage drop is significantly reduced. While a “normal” diode’s forward voltage drop is about 0.6 V, a Schottky diode’s voltage drop can be as low as 0.15 V. This can be very useful in cases where a diode is needed to regulate the direction of electrical flow, but the voltage requirements are sensitive enough that you can’t afford the 0.6 V of a regular diode.

8.10 Diode-Like Behavior in Other Components

Another important reason for being familiar with diode operation is that other types of components have parts which contain diodes or behave in diode-like ways. When we discuss bipolar junction transistors (BJTs) (see Chapter 24), we will see that these components partially consist of diode-like behavior.

Review

In this chapter, we learned the following:

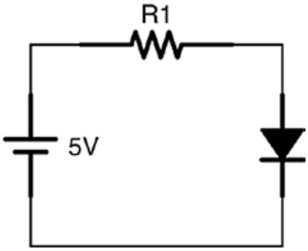
1. Diodes only allow current to flow in one direction.
2. Diodes have a fixed forward voltage drop across the diode—0.6 V for normal diodes and a range of about 1.8 to –3.3 V for LEDs.
3. Different color LEDs have different voltage drops.

4. Diodes also have a breakdown voltage—the amount of voltage for which, if applied in the reverse direction, the diode will no longer block current.
5. When analyzing circuits with diodes, it is often easier to analyze the diodes first, since the voltage drop is fixed.
6. Because of Kirchhoff's voltage law, anything wired in parallel with diodes will have the same voltage drop as the diodes (or possibly less).
7. If the forward voltage drop on a diode is greater than the available voltage in the circuit, the diode will not conduct, and it can be treated as an open circuit.
8. If diodes are connected to the positive and negative terminals of a voltage source (such as a battery) with no resistance in series, this will create a short circuit, causing extremely large amounts of current to flow through the diodes.
9. Diodes are often used as control valves to regulate the direction of current flow on a circuit.
10. Diodes are often used to regulate the amount of voltage between two points on a circuit.
11. The series resistor used with voltage-regulating diodes determines both how much current is wasted and how much current the load can draw—lower-value resistors waste more current but allow the load to draw more current, and higher-value resistors waste less current but don't allow as much potential current to your load.

12. When designing circuits, it is often useful to account for the most extreme variations possible. This will allow your circuit to be more flexible.
13. Diodes can also provide protection to circuits against strange failure conditions, such as voltage spikes and static electricity. Diodes in strange places in circuit diagrams are often there to protect the circuit against certain types of failures or events.
14. Zener diodes are built so that they have very reliable operation on their breakdown voltage.
15. Wiring a Zener diode backward gives you the equivalent of several forward diodes in series and can be used for simple voltage regulation.
16. The breakdown voltage of a Zener diode is much more constant than the forward voltage of a regular diode and therefore works even better for voltage regulation.
17. Zener diodes come in a wide variety of breakdown voltages and are usually labeled on the circuit with the necessary breakdown voltage.
18. Schottky diodes are like ordinary diodes except they have a much smaller forward voltage.
19. Understanding diode behavior is important because a number of components contain diodes or exhibit diode-like behavior.

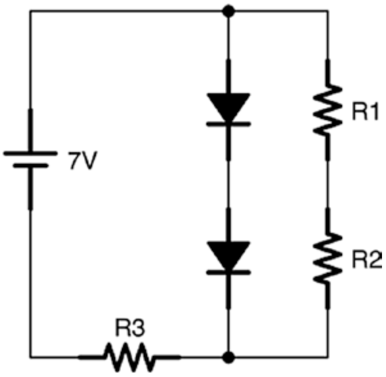
Apply What You Have Learned

1. If you have a 9 V voltage source, a blue LED, and a 500 Ω resistor all in series, how much current is running through the LED?
2. If you have a 3 V voltage source and a red LED, what size resistor do you need to put in series with the LED to have it use 3 mA of current?
3. If you have a 10 V voltage source, a blue LED, a red LED, and a 200 Ω resistor all in series, how much current is running through the LEDs?
4. If I have a 12 V voltage source, a blue LED, and a red LED and the LEDs have a maximum current of 30 mA before they break and a minimum current of 1 mA before they turn on, what range of resistors can I put in series with the LEDs to get them to light up without breaking?
5. In the following circuit, calculate how much current is flowing through each component and each component's voltage drop if R1 is 500 Ω (note that the diode is just a regular diode, not an LED).



6. Let's say instead of an ordinary diode, the diode is a blue LED. Recalculate the current going through each component and the voltage drops for each component.

7. In the following circuit, calculate how much current is flowing through each component and each component's voltage drop if R1 is 300 Ω, R2 is 400 Ω, and R3 is 500 Ω.



8. Draw a circuit that provides a 6-volt regulated power supply to the circuit load from a 9-volt battery using regular diodes. Choose a resistor that works efficiently for a circuit load of 500 Ω and operates with a battery voltage from 7 V to 9.6 V. What is the current at the lowest and highest ranges of the battery? How much is used by the circuit load, and how much is wasted through the diodes in each configuration?

9. Draw an equivalent circuit to the previous question using a Zener diode instead of normal diodes.

CHAPTER 9

Basic Resistor Circuit Patterns

When most people look at a schematic drawing, all they see is a sea of interconnected components with no rhyme or reason combining them. However, most circuits are actually a collection of **circuit patterns**. A circuit pattern is a common way of arranging components to accomplish an electronic task. Experienced circuit designers can look at a circuit and see the patterns that are being used. Instead of a mass of unrelated components, a circuit designer will look at a schematic and perceive a few basic patterns being implemented in a coherent way.

In this chapter, we are going to learn three basic resistor patterns and learn to work with switches as well.

9.1 Switches and Buttons

Switches and buttons are very simple devices, but nonetheless we probably need to take a moment to explain them. A switch works by connecting or disconnecting a circuit. A switch in the "off" position basically disconnects the wires so that the circuit can't complete. A switch in the "on" position connects the wires.

There are different types of switches depending on their operation. The ones we are concerned with are called "single pole single throw" (SPST) switches, which means that they control only one circuit (single pole) and the only thing they do is turn it on or off (single throw).

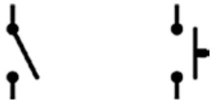

Figure 9-1. *Schematic Symbols for an SPST Switch (Left) and an SPST Button (Right)*

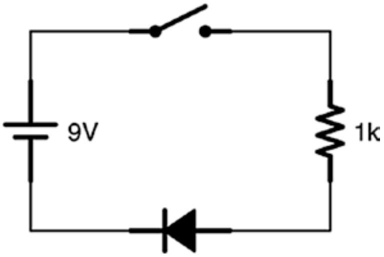

Figure 9-2. *A Simple Switch Circuit*

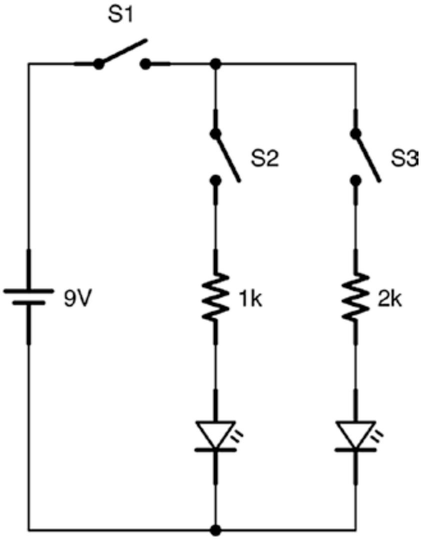

Figure 9-3. *A Circuit with Multiple Switches*

Figure 9-1 shows what the schematic symbols for an SPST switch and an SPST momentary switch (i.e., a button) look like. As the drawing indicates, when the switch is open, the circuit disconnects. When the switch closes, it connects the circuit. While the switch holds its position stable (someone has to manually switch it back and forth), the button only connects the circuit *while it is being pushed*. While the button is being pushed, the circuit is connected, but as soon as someone stops pushing the button, the circuit opens back up.

Figure 9-2 shows what a simple circuit with a switch looks like. It is just like a normal LED circuit, but with a switch controlling whether or not electricity can flow. Note that the switch is just as effective on the other side of the circuit. If the switch was the last part of the circuit, it would be equally as effective. Remember, in order for current to flow, there must be a full circuit from positive back to negative.

Switches can also be used to turn on or off individual parts of a circuit—basically reconfiguring the circuit while it is running. In the circuit given in Figure 9-3, a master switch (S1) turns the whole circuit on or off, and two individual switches (S2 and S3) turn parallel branches of the circuit on and off.

To analyze a circuit with switches, you need to analyze the way the circuit behaves with each configuration of switches. In this case, obviously when S1 is open, no current at all flows. However, this circuit will use different amounts of current when S2 is closed, S3 is closed, and both S2 and S3 are both closed. Therefore, to truly know the behavior of the circuit, you need to calculate the current usage in each of these situations.

9.2 Current-Limiting Resistor Pattern

The first resistor pattern we are going to learn is one that we already know—the current-limiting resistor pattern. The idea behind this pattern is that a resistor is added to limit the amount of current that can flow through a device. The size of the resistor needed depends on the size of the voltage source, the action of the device itself, and the maximum amount of current to allow. Then, the resistor size needed can be calculated using Ohm's law.

Many resistors are added to circuits to limit current flow. At the beginning, we used resistors to make sure we didn't destroy our LEDs. In Chapter 8, we used a resistor to limit the amount of current flowing through our voltage regulation circuit.

In many different circuits, we will need resistors to limit current for two different reasons—to avoid breaking equipment and to save battery life. Oftentimes, we are actually choosing resistor values to accomplish both of these tasks.

If an LED breaks with 20 mA, then we need a resistor big enough to keep the current that low. However, if the LED light is sufficiently visible with 1 mA, then, to save battery life, we might want a bigger resistor. Battery capacity is often measured in milliamp-hours (mAh), with a typical 9 V battery holding 400 mAh. So, with such a battery, an LED circuit at 10 mA will drain the battery in 40 hours (400 mAh/10 mA = 40 h), but the same LED circuit with a bigger resistor, limiting the current to 1 mA, will take a full 400 hours (400 mAh/1 mA = 400 h) to drain the same battery! That will save you a lot of money in the long run.

9.3 Voltage Divider Pattern

A **voltage divider** occurs anytime there are two resistors together with a subcircuit coming out from in between them. They usually are connected to a fixed positive voltage on one side of the first resistor and the ground on the other side of the second resistor, but this isn't strictly necessary. A simple schematic of a voltage divider is shown in Figure 9-4. Notice that there are two resistors between the voltage source and the ground (a 1k on top and a 2k on the bottom) and a subcircuit (indicated by the load resistance) branching off from between them. Under certain circumstances (which will be covered in a moment), we can basically ignore the parallel resistance of the subcircuit and just look at the voltages at each point in the main voltage divider circuit.

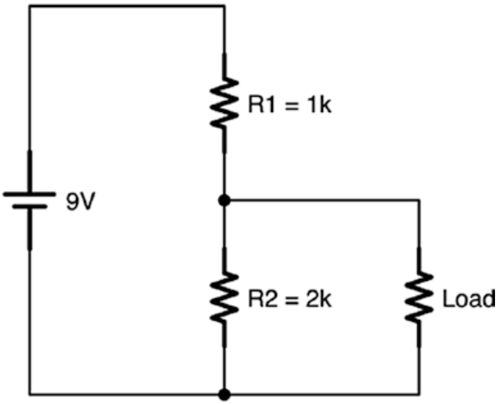

Figure 9-4. *A Simple Voltage Divider Circuit*

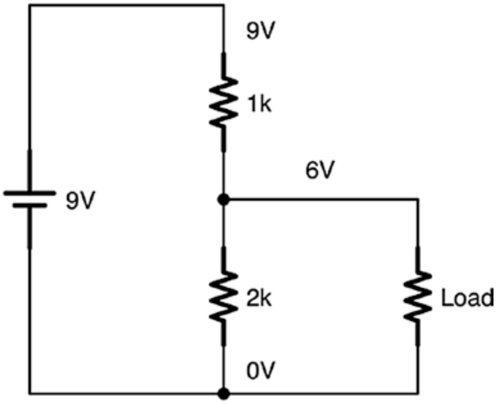

Figure 9-5. *Voltage Divider with Voltages Labeled*

9.3.1 Calculating the Voltages

We can see that the voltage at the top of the voltage divider is 9 V (because it connects to the positive terminal) and at the bottom of the voltage divider it is 0 V (because it connects to the negative terminal). Therefore, the total voltage drop across both resistors must be 9 V. Since the resistors are in series (remember, we are ignoring the load for now), we can find the total resistance in the circuit by just adding their resistances. So 1,000 Ω + 2,000 Ω = 3,000 Ω. Since the current in a series is the same for the whole series, we can now use Ohm's law to calculate the current flow:

$$I = \frac{V}{R} = \frac{9\text{V}}{3{,}000\Omega} = 0.003\text{A} = 3\text{mA}$$

So there is 0.003 A (3 mA) in this circuit. That means that *each* resistor in the series will have this amount of current flowing through them. Therefore, we can calculate the voltage drop across each resistor. Let's look at the 1k resistor:

$$V = I * R = 0.003\text{A} * 1{,}000\Omega = 3\text{V}$$

So the voltage drop across the first resistor is 3 V. That means that, since the battery started at 9 V, at the end of the resistor the voltage compared to ground is 6 V. We can calculate the voltage drop across the second resistor either by Ohm's law again or just by noting the fact that since the other end of the resistor is connected to ground, the voltage *must* go from 6 V to 0 V.

Figure 9-5 shows the voltages at each point (relative to ground). As you can see, the wire from the middle of the voltage divider has a new voltage that can be used by the load. This is what voltage dividers are normally for—they have a simple way of providing a scaled-down voltage to a different part of the circuit.

9.3.2 Finding Resistor Ratios

But how do we choose the values of the resistors?

One thing to note is that the second resistor consumed exactly twice as much voltage as the first resistor. Additionally, the second resistor was exactly twice as large as the first resistor. Thus, as a general principle, the relative sizes of the resistors will determine the relative amounts of voltage they eat up. So, if we needed a 4.5 V output—that is half of our input voltage—we would need both resistors to be the same.

A more explicit way of stating this is with an equation. Given a starting voltage V_{IN} connected to the first resistor, R_1, and the second resistor (R_2) connected to ground, the output voltage (V_{OUT}) coming out between the resistors will be given by the equation

$$V_{OUT} = V_{IN} * \frac{R_2}{R_1 + R_2} \tag{9.1}$$

Note that the specific resistance values don't matter yet—it is the *ratio* we are concerned about so far. To get 4.5 V, we can use two 1 kΩ resistors, two 200 Ω resistors, or two 100 kΩ resistors. As long as the values are the same, we will divide the voltage in half.

If we wanted an 8 V output, we would do a similar calculation. Since we start at 9 V, we need to use up $\frac{1}{9}$ of the voltage in the first resistor, and $\frac{8}{9}$ of the voltage in the second resistor. Therefore, our resistors need to be in similar ratio. We could use a 100 Ω resistor for the first resistor and an 800 Ω resistor for the second resistor. Alternatively, we could use a 10 Ω resistor for the first resistor and an 80 Ω resistor for the second resistor. It is the ratio that matters most.

9.3.3 Finding Resistor Values

So how do you determine exactly what value to use? Here is where we start thinking about the load again. While we have been treating the voltage divider as a series circuit, in truth we have one resistor in series and then a parallel circuit with the other voltage divider resistor in parallel with the load. Our simplified model (where we ignore the parallel resistance) will work, *as long as the load resistance does not impact the total parallel resistance by a significant amount*. Therefore, let's look at how the load resistance affects the parallel resistance.

So, using Equation 7.2, we can write a formula for the total resistance of these two, with R_2 being our second voltage divider resistor and R_L being our load resistance:

$$R_T = \frac{1}{\frac{1}{R_2} + \frac{1}{R_L}}$$

Now, let's look back at the circuit in Figure 9-5. Let's say that the resistance of the load (R_L) is 400 Ω, which is much less than the resistance of the voltage divider resistor (R_2, which is 2,000 Ω). So what is the total resistance?

$$R_T = \frac{1}{\frac{1}{R_2} + \frac{1}{R_L}} = \frac{1}{\frac{1}{2{,}000} + \frac{1}{400}} = \frac{1}{0.0005 + 0.0025} = \frac{1}{0.003} \approx 333\Omega$$

This is significantly different from our simplified model which ignored the load resistance, which gave 2,000 Ω. That means that our simplified model won't work with this value.

Now, let's imagine a bigger load resistance so that it is equal to the R_2 resistance (2,000 Ω) and recalculate:

$$R_T = \frac{1}{\frac{1}{R_2}+\frac{1}{R_L}} = \frac{1}{\frac{1}{2{,}000}+\frac{1}{2{,}000}} = \frac{1}{0.0005+0.0005} = \frac{1}{0.001} \approx 1{,}000\Omega$$

This is still significantly off, but it is much closer. So, now, let's look at what happens if the load resistance is double of R_2, or 4,000 Ω:

$$R_T = \frac{1}{\frac{1}{R_2}+\frac{1}{R_L}} = \frac{1}{\frac{1}{2{,}000}+\frac{1}{4{,}000}} = \frac{1}{0.0005+0.00025} = \frac{1}{0.00075} \approx 1{,}333\Omega$$

Here, we are getting much closer to our original value. Now, let's say that the load is ten times the resistance of our R_2 resistor, or 20,000 Ω. That gives us this:

$$R_T = \frac{1}{\frac{1}{R_2}+\frac{1}{R_L}} = \frac{1}{\frac{1}{2{,}000}+\frac{1}{20{,}000}} = \frac{1}{0.0005+0.00005} = \frac{1}{0.00055} \approx 1{,}818\Omega$$

This is very close to the resistance of $R2$ by itself. So what we can say is that our voltage divider circuit can ignore the resistance of the load *if the resistance of the load is significantly more than the resistance of the voltage divider resistor*. A way of writing this down is that $R\text{L} \gg R2$. What "significantly" means depends on how sensitive your circuit is to voltage changes, but, generally (and for the purposes of the exercises), I will say that "significantly more" should mean at least ten times as much.

9.3.4 General Considerations

So, for low-resistance loads, a voltage divider does not work well, because it puts too little resistance between the voltage source and ground. However, in Chapter 11, we will see that many circuits have loads of approximately infinite resistance, so voltage dividers work really well in those cases.

In general terms, a voltage divider with smaller resistors is "stiffer" because it varies less in response to variations in a load, but it also eats up more current. A voltage divider with larger resistors doesn't work with low-resistance loads, but it also uses up much less current.

If you need to know full equations for figuring out voltage divider resistors, I have them listed in Equations 9.2 and 9.3. In these equations, V_{IN} is the voltage coming into the voltage divider, V_{OUT} is the voltage going out of the divider into your load, and R_{L} is the load resistance. R_1 is the resistor connected to the positive power supply, and R_2 is the resistor connected to the ground. If you are good at algebra, you might see if you can deduce these formulas yourself from the information given in this section:

$$R_2 = \frac{R_L}{10} \tag{9.2}$$

$$R_1 = \frac{R_2 * \left(V_{IN} - V_{OUT}\right)}{V_{OUT}} \tag{9.3}$$

9.4 The Pull-Up Resistor

The pull-up resistor is a strange circuit, but we will find very good applications for it once we start dealing with ICs in Chapter 11. It is probably easiest to describe by simply showing you a circuit and then describing how it works.

Figure 9-6 shows the circuit diagram for a basic pull-up resistor circuit. Normally, we think of lighting up an LED by pushing the button. However, in this case, pushing the button causes the current to bypass the LED, which turns it off.

If you look at the path from where the circuit branches, when the button is not pressed, the current can only go one way—through the LED. However, when the button is pressed, the electricity has two options—either through the LED or directly to ground through the button. The electricity would always rather go directly to ground rather than through an intermediary, so *all* of the current goes through the closed button, and none of it goes through the LED.

Since the branch point is directly connected to ground when the button is pushed, that means that the voltage *at the branch point* is also zero. Kirchhoff's voltage law says that no matter what path is taken, the voltage drop will always be the same. However, an LED induces a voltage drop, but the voltages on both sides of the LED are zero. Therefore, electricity cannot flow through the LED.

So what is the function of the resistor? The resistor connects the switch and the LED to the positive voltage source and provides a limitation on the current that runs through it. The resistor must be *before* the branch point for it to work.

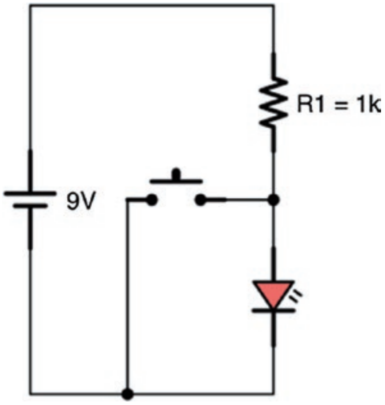

Figure 9-6. *Basic Pull-Up Resistor*

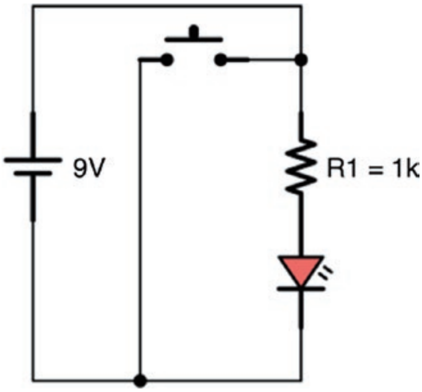

Figure 9-7. *Incorrect Way to Wire the Circuit*

Think about what happens without the resistor or if the resistor is after the branch point. The electricity will have a path directly from the positive voltage source to ground with no resistance—in other words, a short circuit. This will draw an enormous amount of electricity. Figure 9-7 shows what this would look like. Notice that when the button is pushed, you can trace a path from the positive voltage source to ground with no intervening resistance.

The resistor is called a pull-up resistor because it is connected to the positive voltage source and is used to "pull up" the voltage on the circuit to a positive value when the switch is open while still providing safety (by limiting the current) when the switch is closed.

In short, a pull-up resistor is usually used to supply positive voltage to a circuit which might be turned off by redirecting the voltage to ground. The resistor provides both the electrical connection to the positive source and a limit to the amount of current that will flow if the current flow is then routed to ground (usually through some kind of switching mechanism).

9.5 Pull-Down Resistors

One more basic resistor circuit that is often used is the pull-down resistor. While the pull-up resistor is connected to the positive power rail, the pull-down resistor is instead connected to ground. So, in a pull-up resistor, if part of the circuit is disconnected, the voltage goes high. In a pull-down resistor, if part of the circuit is disconnected, the voltage goes low. However, we don't yet have enough background really to understand how they are used here. They are covered more fully in Chapter 12. They are merely mentioned here because they are one of the basic resistor circuit patterns that are seen throughout electronics.

Review

In this chapter, we learned the following:

1. Buttons and switches allow circuits to be altered while they are running by connecting circuits (allowing pathways for electric current) and disconnecting circuits (blocking pathways for electric current).
2. Most circuits are a combination of common, well-understood circuit patterns.
3. The more experienced you are with the basic circuit patterns, the easier it is to see these circuit patterns when you look at a schematic drawing.
4. A current-limiting resistor is a resistor that is used to limit the maximum current flow within a circuit, either to protect other components or to limit overall current usage.

5. A voltage divider is a pair of two resistors connected in series with one another (usually connected to a positive voltage on one side and the ground on the other), but with another wire coming out in between them to provide voltage to another circuit (called the *load*).
6. In a voltage divider, it is assumed that the resistance of the load is significantly more than (i.e., greater than ten times) the resistance of the second half of the voltage divider because then the load can be basically ignored for calculating voltage drops.
7. For a voltage divider, the ratio of the voltages consumed by each resistor is the same as the ratio of their resistances. The output voltage coming out of the first resistor is the level of the voltage that will be supplied to the load.
8. Another way of stating the output voltage is $V_{OUT} = V_{IN} * \frac{R_2}{R_1 + R_2}$, where R_1 is the resistor connected to the positive voltage and R_2 is the resistor connected to ground.
9. Voltage dividers with smaller resistances are “stiffer”—they are impacted less by the resistance of the load. Voltage dividers with larger resistances are not as stiff but waste much less current.
10. A pull-up resistor circuit is a circuit in which a positive voltage which may be switched to ground at some point is provided through a resistor.

11. The pull-up resistor both (a) connects the circuit to the positive voltage to supply a positive current when the circuit is not switched to ground and (b) limits the current going to ground (i.e., prevents a short circuit) when the output is switched to ground.
12. It is called a pull-up resistor because it pulls the voltage up when the circuit is not switched to ground.

Apply What You Have Learned

1. In Figure 9-3, calculate the amount of current used by the whole circuit for each configuration of the switches S2 and S3 when S1 is closed. You can assume that the LEDs are red LEDs.
2. Build the circuit given in Figure 9-3 (you may swap out resistors with different but similar values—anything from 300 Ω to about 5 kΩ should work).
3. Given a 15 V voltage supply, what size of a resistor would be needed to make sure that a circuit never went over 18 mA?
4. Given a 9 V battery source, design a voltage divider that will output 7 V to a load that has a resistance of 10 kΩ.
5. Given a 3 V battery source, design a voltage divider that will output 1.5 V to a load that has a resistance of 1 kΩ.

6. In Figure 9-6, how much current is going through the circuit when the switch is open? How much when it is closed? You can assume that the LED is a red LED.
7. How would you modify the circuit in Figure 9-6 to keep the maximum current in the circuit under 2 mA? Draw the full circuit out yourself.
8. Build the circuit you designed in the previous question. If you do not have the right resistor values, use the closest ones you have.

CHAPTER 10

Understanding Power

So far we have covered the basic ideas of voltage, current, and resistance. This is good for lighting up LEDs, but for doing work in the real world, what is really needed is **power**. This chapter on its own adds very little to your capabilities as a circuit designer, but it is absolutely critical background information for the chapters that follow. Additionally, this chapter contains information critical to the safe usage of electronics. Knowing about power, power conversions, and power dissipation will be critical to taking your electronics abilities into the real world.

10.1 Important Terms Related to Power

To understand what power is, we need to go through a few terms from physics (don't worry—they are all easy terms):

1. **Work** happens when you move stuff.
2. Work is measured in **joules**. A joule is the amount of work performed when a 1-kilogram object is moved 1 meter.
3. The capacity to perform work is called **energy**. Energy is also measured in joules.
4. **Power** is the sustained delivery of energy to a process.

© Jonathan Bartlett 2020
J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_10

5. Power is measured in **watts** (abbreviated W). Watts are the number of joules consumed or produced per second.
6. Another measurement of power is horsepower (abbreviated hp). One horsepower is equivalent to 746 watts. Horsepower is not important for electronics, but I wanted to mention this because horsepower is a term you have probably heard, and I wanted you to be able to connect its importance to the ideas in this chapter.

One of the interesting things about work, energy, and power is that they can take on a number of forms that are all basically equivalent. For instance, we can have mechanical energy, chemical energy, and electrical energy (as well as others). We can also perform mechanical work, chemical work, and electrical work. All these types of energy and work can be converted to each other. They are all also measured in joules. Therefore, we have a common unit of energy for any sort of task we want to accomplish.

Now, when we actually apply energy to perform work, we do not get a 100% conversion rate. In other words, if we want to do 100 joules of work, we will probably need more than 100 joules of energy to perform the task. That's because the process of converting energy into work (as well as converting between different types of energy and work) is **inefficient**—not all of the energy gets directed to the task we want to perform. There is no perfectly efficient process of converting energy to work. Additionally, there is no way to create energy from nothing—any time you need additional energy, you will need a source for it.

When energy is converted to work, *all* of the energy does something, even if it isn't work on the task you want. Usually, the inefficiencies get converted to **heat**. So, if I have a process that is only 10% efficient and I give that process 80 joules of energy, then that process will do only 8 joules of work, leaving 72 joules of energy that is converted to heat.

Work and energy are usually the quantities we care about for systems that do a fixed task (i.e., require a fixed amount of energy). In electronics, however, we are usually building systems that stay on for sustained periods of time. Therefore, instead of measuring energy, we measure power, which is the continuous delivery of energy (or the continuous usage of energy in doing work).

As we mentioned, power is measured in watts, where a watt is 1 joule per second. So, if you have a 100 W light bulb, that bulb uses 100 joules of energy each second. True, 100 W incandescent light bulbs are very inefficient, which is why they get so hot—the energy that is not converted to light gets converted to heat instead. Today, incandescent bulbs are rarely used for that very reason. For instance, the LED bulbs that are labeled as "100 W" equivalent generally use about 11 W, but they are as bright as the old 100 W incandescents. What this means is that in an incandescent light, less than 11 W of energy was being put toward actually giving off light, and the rest was wasted as heat, which is why they got quite so hot.[1]

10.2 Power in Electronics

So we have a basic idea about what power is in general. In electronics, there are a few equivalent ways of calculating power.

The first is to multiply the number of volts being consumed by the number of amps of current going through a device:

$$P = V * I \tag{10.1}$$

---

[1] It is actually much less than 11 W, since LEDs are not perfectly efficient either. The point is that since they are both emitting the same amount of light (i.e., producing the same light energy), we can see that the difference in watts used is probably lost in heat.

Here, P indicates power measured in watts, V indicates volts, and I indicates current measured in amps. So, if my circuit is on a 9-volt battery and I measure that the battery is delivering 20 mA to the circuit, then that means I can calculate the amount of power that my circuit is using (don't forget to convert milliamps to amps first!):

$$\begin{aligned} P &= V * I \\ &= 9\text{V} * 20\text{mA} \\ &= 9\text{V} * 0.02\text{A} \\ &= 0.18\text{W} \end{aligned}$$

So our circuit uses 0.18 watt of power.

You can also measure the amount of power that individual components use. For instance, let's say that a resistor has a 3 V voltage drop and has 12 mA of current running through it. Therefore, the resistor uses up $3 * 0.012 = 0.036$ watt of power.

The second way of calculating power comes from applying Ohm's law. Ohm's law say

$$V = I * R \tag{10.2}$$

So, if we have the equation $P = V * I$, Ohm's law allows us to *replace* V with $I * R$. Therefore, our new equation becomes

$$P = (I * R) * I \tag{10.3}$$

Or we can simplify it further and say that

$$P = I^2 * R \tag{10.4}$$

We can also substitute $I = V/R$ and wind up with a third equation for power:

$$P = \frac{V^2}{R} \tag{10.5}$$

So, if we have 15 mA running through a 200 Ω resistor, then we can calculate the amount of power being used using Equation 10.4:

$$\begin{aligned} P &= I^2 * R \\ &= (15\text{mA})^2 * 200\Omega \\ &= (0.015\text{A})^2 * 200\Omega \\ &= 0.000225 * 200 \\ &= 0.045\text{W} \end{aligned}$$

10.3 Component Power Limitations

Now, if you think about it, the resistor in the previous example isn't actually *doing* anything. It is just sitting there. Therefore, since we are not accomplishing any *work* by going through the resistor, the energy gets converted to heat. Electronic components are usually rated for how much power they can **dissipate**, or easily get rid of. Most common resistors, for instance, are rated between 1/16 W and 1/2W (most that I've seen for sale are 1/4 W). This means that they will continue to work as long as their power consumption stays under their limit. If the power consumption goes too high, they will not be able to handle the increased heat and will break (and possibly catch fire!).

So far, our projects have dealt with low enough power that this isn't a concern. In fact, using 9 V batteries, it is hard to generate more than 1/4W of power—you would have to have less than 350 Ω of resistance on the *whole* circuit and have the entire voltage drop occur on the resistor.

In any case, whenever you are building circuits, you should keep in mind how much power the component is rated to handle and how much power it is actually consuming. You can use any of the equations given here to calculate power consumption. The component itself should have information on its maximum ability to handle power consumption and dissipation.

10.4 Handling Power Dissipation with Heatsinks

As we mentioned earlier, when power dissipates without doing any work, it is converted to heat. Some devices need to dissipate large quantities of heat under regular workloads. One common device that often needs to dissipate heat is the voltage regulator, like the 7805 regulator we will encounter in Chapter 12.

The way that this regulator performs its job is essentially by dissipating power until the voltage is at the right level. When used with any serious amount of current, this can actually get very, very hot. As such, the back side of these contains a metal plate which is used to dissipate heat. Additionally, it has a metal tab with a hole that can be used to attach a **heatsink**.

A heatsink is a metal structure with a large surface area that helps an electronic component dissipate heat. By being made of metal, it quickly moves the heat into itself. By having a large surface area, it can transfer the heat to the air, where it will then disperse into the environment.

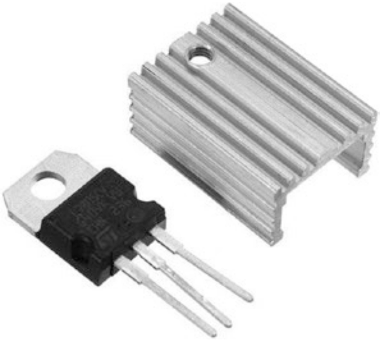

Figure 10-1. *A 7805 voltage regulator and its heatsink*

Figure 10-1 shows a 7805 chip next to its heatsink. To attach the heatsink, just screw it into the 7805. On the 7800 series of regulators, the tab is electrically connected to ground, so it should not produce a voltage. However, other types of chips in the same TO-220 package may actually have a voltage on the tab. In such a case, it would be wise to buy an isolation kit to electrically isolate the chip from the heatsink; otherwise, incidental contact with the heatsink could cause a short circuit. The isolation kit will only allow heat, not electricity, flow into the heatsink.

10.5 Transforming Power

As we have discussed, energy (and therefore power) can be transformed among a variety of forms—mechanical, electrical, chemical, and so on. In any case, always remember that energy is only reduced or lost, never gained.

The essence of energy transformation is at the heart of what makes batteries work. A battery contains energy stored in a chemical form. Chemical reactions in the battery allow electrons to move. By drawing the electrons through a specific path (drawing them to the positive from the negative), this reaction generates electrical energy. So we have a conversion from chemical energy (the reaction of the chemicals in the battery) into electrical energy (the pull of the electrons through the circuit).

This can also go the other way. Electrical energy can be used to stimulate chemical reactions. A common one is the separation of water into hydrogen and oxygen.

The same conversion can happen with mechanical energy. In an electric motor, electrical energy is converted into mechanical energy in the motor. But the reverse also can occur. A power generator is made by converting mechanical energy into electrical energy.

We won't go into details on how each of these transformations works (you would need to take courses in chemistry, mechanics, etc. to know more), but the essential ideas are that

1. Energy and power can be transformed between a variety of forms.
2. These forms of energy can all be measured with the same measuring stick (joules).
3. Every energy transformation will lose (never gain) some amount of energy through inefficiencies.

Power and energy are known as **conserved quantities**, because, although they are transformed, they are never created or lost. Note that when we talk about power lost through inefficiencies, the power actually isn't lost in total; it is merely converted to heat. You can think of heat as power that is applied in a nonspecific direction. Energy is lost when it is transformed not because it disappears but rather because all processes which channel one form of energy into another are imperfect.

In Section 10.2, "Power in Electronics," we noted that, in electronics, the power (measured in watts) is determined by *both* the voltage and the current—by multiplying them together. Therefore, what will be conserved in electronics will not be the voltage or the current individually, but their product. What this means is that we can, at least in theory, increase the voltage without needing a power gain, but at the cost of current. Likewise, we can, at least in theory, increase the current without needing a power gain, at the cost of voltage. In both of these cases, rather than transforming electrical power to another form of power altogether, we are transforming it into a different configuration of electrical power.

Devices that convert electrical power between different voltage/current configurations are known as **transformers**. A step-up transformer is one that converts a low voltage to a higher voltage (at the cost of current), and a step-down transformer is one that converts a high voltage to a lower voltage (but can supply additional current).

Technically, for DC circuits, these are usually known as **DC-DC power converters** or **boost converters** instead of being called transformers, but the same rules apply—the total number of watts delivered can never increase, but the voltage can be converted up and down at the expense or gain of the current.[2]

So, if I had a source of 12 V and 2 A, then I would have $12 * 2 = 24$ W. Therefore, it may be possible to convert that to 24 V, but I would only be able to get 1 A of current ($24 * 1 = 24$). However, I could drop the voltage to get more current. If I needed 4 A, I could reduce the voltage to 6 V.

Also remember that in doing these transformations, there is always some amount of power loss as well, but these calculations will give you what the maximum possibilities are. The actual mechanisms that these devices employ for doing power conversions are outside the scope of this book.

10.6 Amplifying Low-Power Signals

Many devices, especially integrated circuits, are only capable of processing and generating low-power signals. Microcontrollers (like the ATmega328/P) have limits to how much power they can send or receive. The ATmega328/P can only source up to 40 mA per pin and only about 200 mA total across all pins simultaneously. At 5 V, 40 mA would yield a maximum of 0.2 W. Therefore, if you want to turn on a device that requires more power than that, you will need to **amplify** your signal.

Now, as we discussed previously, you can't actually create more power out of nothing. What you can do is, instead of trying to *create* power, you can instead *control* power. We will discuss several specific techniques on how to do this starting in Chapter 24, but the essential idea is that you can amplify a signal by using a small signal to control a larger one.

---

[2] As a sidenote, if you tried to wire a regular AC transformer to a DC power supply, it would not deliver any power at all—DC-DC converters work on very different principles than AC transformers.

Think about your car. The way that you control your car is by taking a low-power signal, such as the gas pedal, and using it to control a high-power signal, such as the engine. My foot is not directly powering the car. My foot is merely using the pedals to tell another power source—the engine—how much of its energy it should move. My foot doesn't actually interact directly with the engine at all, except as a valve to unleash or not unleash the power available in the gas tank and engine.

In the same way, since the output signals from the microcontrollers are low power, instead of using these signals directly, we will use the signals to control larger sources of power. Devices which can do this include relays, optocouplers, transistors, op-amps, and darlington arrays. We will cover more about amplification starting in Chapter 24.

Review

In this chapter, we learned the following:

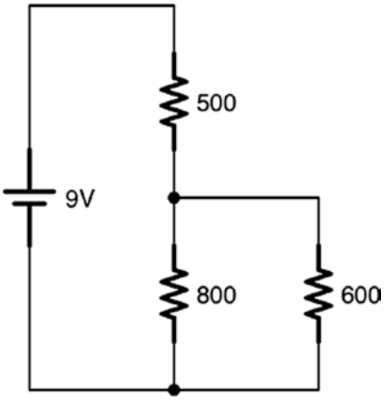
1. Work is what happens when you move stuff and is measured in joules.
2. Energy is the capacity to do work and is also measured in joules.
3. Power is the sustained delivery of energy and is measured in joules per second, also called watts.
4. Power can be converted to a number of different forms.
5. Converting power to another form or using it to do work always has inefficiencies, and these inefficiencies result in energy lost to heat.

6. In electronics, power (in watts) is calculated by multiplying the voltage by the current ($P = V * I$). It can also be calculated as $P = I^2 * R$ or $P = V^2/R$.
7. To calculate the power consumption of an individual component, use the voltage drop *of that component* and multiply it by the current flowing through it (measured in amps, not milliamps).
8. Most components have a maximum rating for the amount of power they can safely consume or dissipate. Be sure you design your circuits so that your components stay under that limit.
9. Some components can handle additional power dissipation by adding a heatsink, which will more effectively dissipate the excess heat into the air.
10. Power can be transformed into other types of power (mechanical, chemical, etc.), but can never go beyond the original amount of power.
11. Electrical power can also be transformed into different combinations of voltage and current, as long as the total power remains the same.
12. Components that do this transformation are called transformers for AC power and DC-DC converters for DC power.
13. Because power cannot be created, the way that signals are amplified is by using a small power signal to control a larger power source.

Apply What You Have Learned

1. If I have 50 joules of energy, what is the maximum amount of work I could possibly do with that amount of energy?
2. If I am using up 10 joules of energy each second, how many watts am I using up?
3. If I convert 30 watts of mechanical power into electrical power with 50% efficiency, how many watts of electrical power are delivered?
4. If I have a circuit powered by a 9 V battery that uses 0.125 A, how many watts does that circuit use?
5. If a resistor has a 2 V drop with a 0.03 A current, how much power is the resistor dissipating?
6. If a resistor has a 3 V drop with a 12 mA current, how much power is the resistor dissipating?
7. If a 700 Ω resistor has a 5 V drop, how much power is the resistor dissipating?
8. If a 500 Ω resistor has 20 mA flowing through it, how much power is the resistor dissipating? If the resistor was rated for 1/8 of a watt, are we within the rated usage for the resistor?

9. In the following circuit, calculate the voltage drop, current, and power dissipation of every component (except the battery). If the resistors are all rated for 1/8 of a watt, are any of the resistors out of spec?



CHAPTER 11

Integrated Circuits and Resistive Sensors

So far, the components we have studied are simple, basic components—batteries, resistors, diodes, and so on. In this chapter, we are going to start to look at **integrated circuits**, also called **chips**, **microchips**, or **IC**s. An IC is a miniaturized circuit placed on silicon. It is a whole collection of parts geared around a specific function. These functions may be small, such as comparing voltages or amplifying voltages, or they may be complex, such as processing video or even complete computers. A single chip may hold just a few components, or it may hold billions.

Miniaturized circuits have several advantages—they are cheaper to produce in mass, they use less power, and they take up less space in your overall circuit—all because they have a reduced area and use fewer materials. These miniaturized circuits are what allowed for the computer revolution over the last century.

11.1 The Parts of an Integrated Circuit

Integrated circuits, as we have noted, are basically miniaturized circuits placed on a silicon plate, called the die. This die is where all of the action of the integrated circuit takes place.

© Jonathan Bartlett 2020

J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_11

The die is then placed into a **package**, which then provides connection points for circuit designers to interface with the IC. These connection points are often called **pins** or **pads**. Each pin on an IC is numbered, starting with pin 1 (we will show you how to find pin 1 shortly). Knowing which pin is which is important, because most of the pins on a chip each have their own purpose, so if you attach a wire to the wrong pin, your circuit won't work or you will destroy the chip. Most packages are marked with the chip's manufacturer and part number. If they weren't, it would be nearly impossible to tell one chip from another.

There are many different types of packaging available, but there are two general types that are often encountered:

Through-Hole: In this packaging type, the connection points are long pins which can be used on a breadboard. This type of packaging is easiest for amateur usage.

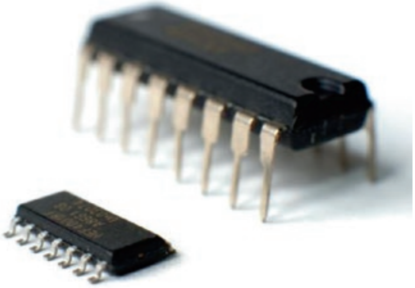


Figure 11-1. *Comparison of the Same IC in SMD (Left) and DIP (Right) Packages (Image Credit: Shutterstock/Youra Pechkin)*

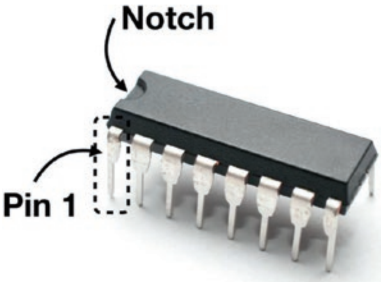

Figure 11-2. *Pin 1 is Immediately Counterclockwise of the Notch (Image Credit: Shutterstock/Cristian Storto)*

Surface Mount: In this packaging type, the connection points are small pads which are meant to be soldered to a circuit board. These packages are much smaller (and therefore less expensive) and can be more easily managed by automated systems to build completed circuits. These are also referred to as SMDs (surface mount devices) or SMT (surface mount technology).

Since we are only using breadboards in this book and not doing any soldering, we will only concern ourselves with through-hole packaging. However, through-hole packaging itself comes in a variety of styles. The main one we will concern ourselves with is called a **dual in-line package**, or **DIP**. Figure 11-2 shows the same chip in SMD and DIP configurations.

An integrated circuit in a DIP package has two rows of pins coming out of the package. Most chips either mark the top of the chip with a notch or indentation (where pin 1 is immediately counterclockwise of the notch) or mark pin 1 with an indentation or both. See Figure 11-2 to see how to use the notch to find pin 1. The rest of the pins are numbered counterclockwise around the chip.

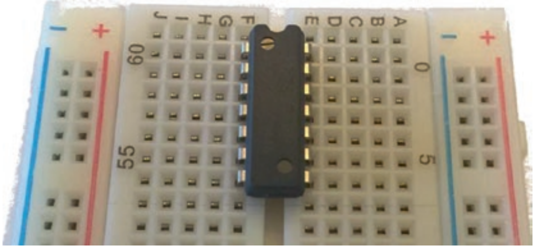

Figure 11-3. *A DIP IC Inserted Into a Breadboard*

The beauty of a DIP-packaged IC is that it fits perfectly onto most breadboards. Figure 11-3 shows how you can place your IC across the breadboard's bridge and each pin on the chip will have its own terminal strip to connect to.

Be careful, though, when inserting ICs into breadboards. The spacing of the pins on an IC is often slightly wider or shorter than the breadboard's bridge, and pins have to be inserted carefully. If you just jam the IC into the breadboard, you will likely accidentally crush one or more of the pins that aren't exactly aligned on the hole. Instead, compare the spacing of the pins to the bridge spacing on your breadboard. If it doesn't match up, *very gently* bend the pins with your fingers or with pliers to get them to match up. It's usually just a very small amount, but if you don't take care, you can easily damage your IC.

Usually, the ICs that I purchase are just a little wide, and I will squeeze the pins on each side slightly between my thumb and finger until they move close enough together. However you adjust the pins, make sure they line up before pushing them into their connection points on the breadboard. Also, with larger ICs, you may also need to slightly wiggle the IC back and forth as you gently insert it into place on the breadboard.

11.2 The LM393 Voltage Comparator

There are thousands and thousands of available chips which do a dizzying array of functions. In this chapter, we are going to focus on a very simple chip—the LM393 voltage comparator. This chip does one simple task. The LM393 compares two input voltages and then outputs either a high-voltage signal or a low-voltage signal depending on which input voltage is greater. The LM393 is actually a *dual* voltage comparator, which means that it will do two separate comparisons on the same chip. Like most chips, the LM393 is an *active* device, which means that it additionally requires a voltage source and a ground connection to provide power to the device.

Figure 11-4 shows the pin configuration (also called the **pinout**) of the LM393. The first thing to note on any pinout is where the voltage and ground connections are. In this case, the voltage is marked as `VCC`, and the ground is marked as `GND`. Even though the LM393 has *two* voltage comparators on the chip, they both share the power (`VCC`) and ground (`GND`) pins. The left side of the chip diagram shows the inputs and output for the first voltage comparator (`1IN+`, `1IN-`, and `1OUT`), and the inputs and output for the second voltage comparator are on the right (`2IN+`, `2IN-`, and `2OUT`). In your projects, you can use whichever one is more convenient for you, or even both at the same time if you have more than one voltage comparison task.

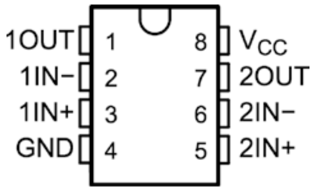

Figure 11-4. *The Pin Configuration of an LM393*

So the `1IN+` pin (pin 3) and the `1IN-` pin are where the two voltages are being fed that are being compared by the first comparator. The `1OUT` is the pin which will contain the output. If the voltage at `1IN+` is less than the voltage on `1IN-`, the output pin will be at a low (i.e., near-zero/ground) voltage. If the voltage at `1IN+` is greater than the voltage on `1IN-`, the output pin *will not conduct at all*, but this will be considered a "high" (positive voltage) state. This sounds counterintuitive, but, as we will see, this lets us set our own output voltage to whatever we want without causing too much complexity. This configuration where high-voltage outputs don't conduct is called an **open collector** configuration. Don't worry if this is a little confusing, we will discuss it more in depth later in the chapter.

VOLTAGE SOURCES ON INTEGRATED CIRCUITS

Note that the voltage pins on integrated circuits can be marked in a number of different ways. The positive voltage source is often labeled as V_{CC} , V_{DD}, or *V*+. The ground connect is often labeled as *GND*, V_{EE}, V_{SS}, or *V*–. There are additional ways that these are labeled as well. Finding the positive and ground connections for an IC should always be the first thing you do with it.

11.3 The Importance and Problems of Datasheets

Every IC (and, usually, any other part as well) has a **datasheet** supplied by the manufacturer which tells you important details about how you should use their chip in your circuit. Reading datasheets is one of the worst parts of electronics, in my opinion. For me, datasheets rarely have the information I am actually looking for in a way that is easy to find.

In fact, most datasheets assume that you already know how to use the device, and the datasheets are just there to supply additional details about the limitations of the device. For instance, looking through the LM393 datasheet from Texas Instruments, the actual operation of the device isn't even listed until page 11, and there it is buried within a sub-subsection, almost as a sidenote.

These datasheets are written *by* people who have spent a lot of time being electrical engineers, and they are written *for* people who have spent a lot of time being electrical engineers, so when mere mortals read the datasheets, the important pieces are often shrouded in unintelligible gibberish. For instance, the fact that the "high" output state of the device doesn't conduct isn't mentioned explicitly anywhere at all in the datasheet. Instead, it is implied by the configuration.

The reason for this is that the datasheets are usually read by professionals familiar with the type of device and who just need to know the electrical details so they don't accidentally bend the device beyond the breaking point. Thus, the datasheets oftentimes spend more time just showing and describing the layout of the circuit on the chip and graphs of different chip properties, and then you are left to interpret what that means for your circuit. For advanced circuit designers, this is great. For students and hobbyists, however, this is oftentimes more frustrating than helpful.

However, datasheets do often provide a few basic details that are helpful to everyone. They will often tell you

- What each pin does
- What the power requirements are
- What the outer limits of the chip's operation are
- An example circuit that you can build with the device

For all of these reasons, Appendix E contains simplified datasheets for a number of common devices that are easier to read than the standard ones.

For the LM393, the important points are as follows:

1. The input voltage on V_{CC} can be anywhere between 2 V and 36 V.
2. When sensing voltage, the LM393 doesn't really draw any (or at least much) current, so there are no parallel resistances we need to worry about.
3. The output is high when `IN+` is greater than `IN-` and low (i.e., near-ground) when `IN+` is less than `IN-`, with an error range of about 2 millivolts.
4. When the output is low, this means the output pin will conduct current into itself (since it is at ground, positive charge will naturally flow into it), but if it sinks more than 6 mA into it, you will destroy it, so you have to be sure that you know the maximum amount of current that could flow through the pin when it is at ground.
5. When the output is high, this means the output will not conduct any current, but instead act as if it were disconnected. As we will see, this will allow us to supply our own "high" voltage level.

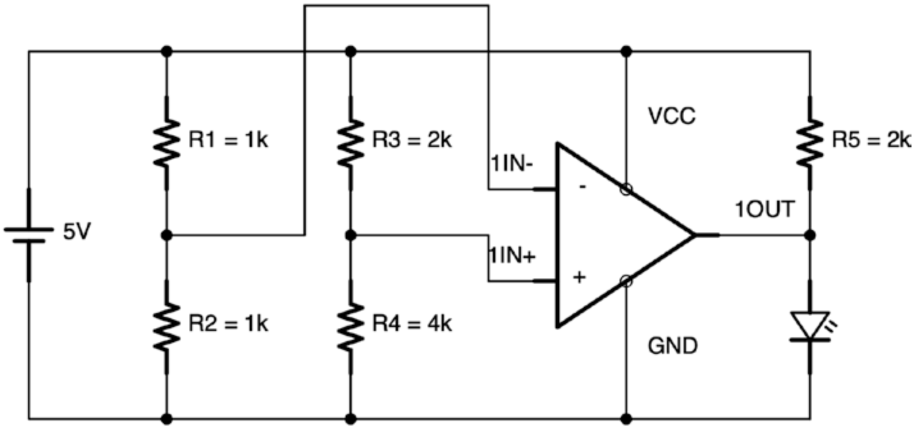

Figure 11-5. *A Simple Comparator Circuit*

That isn't to say that the datasheets aren't important, but for a beginner, the datasheets usually aren't what you need to get started.

11.4 A Simple Circuit with the LM393

In this section, I am going to show a simple circuit using the LM393 chip. In doing so, we are going to be using several of the resistor circuit patterns that we learned in Chapter 9.

The circuit we are discussing is shown in Figure 11-5. Can you identify the resistor circuit patterns? Take a minute and see if you can find some. Note that the wire coming out of `1IN-` crosses two wires that it is *not* joined with.

The first thing to notice is that we have *two* voltage dividers. The first voltage divider is between R1 and R2. Since R1 and R2 are the same resistance and are connected to both 5 V and 0 V, that means that they divide the voltage in half, giving a 2.5 V output. The second voltage divider is between R3 and R4. Since R3 is half of the resistance of R4, that means that it only uses up half as much voltage as R4. Thus, since R3 eats up 1.7 V and R4 eats up 3.3 V, the wire coming out from the middle is at 3.3 V.

Then, to the right of the circuit, you can see that we have a current-limiting resistor in front of the LED. That is not its only function, though. It also functions, as we will see shortly, as a pull-up resistor.

So what is the big triangle? Comparators (and several other circuits commonly placed on ICs) are represented as triangles in the schematic (we could have also placed the chip itself there). Each of the connections is labeled the same as they are labeled in the pinout diagram in Figure 11-4 so they would be easy to locate.

The way that the circuit works is very simple. The voltage coming in to `1IN+` is 3.3 V, and the voltage coming in to `1IN-` is 2.5 V. Since `1IN+` is greater than `1IN-`, then that will turn `1OUT` to high (positive voltage). However, remember that we said that `1OUT` *does not conduct* when it is high. It acts like an open switch. Therefore, R5 acts like a pull-up resistor and supplies the positive voltage for us to our LED to turn it on.

Now let's say that the input voltages were reversed. What would happen? If `1IN-` is greater than `1IN+`, then `1OUT` will go low (0 volt) and also conduct. It will act like a closed switch going to ground.

Therefore, current will go the easy route—it will go through `1OUT` (directly to ground) instead of through the LED (1.8 V or more), effectively denying power to the LED and switching it off. This works just like the switch in the circuit in Chapter 9, Section 9.4, "The Pull-Up Resistor." When `1OUT` is low, it acts like a closed switch to ground and acts as a sink for all current at that point in the circuit. When `1OUT` is high, it acts like an open switch, and whatever voltage/current you provided at that point is allowed to continue on.

The resistor R5 does several jobs. The first job is to act as a pull-up resistor, as we just described. Remember that a pull-up resistor prevents the load to ground from going too high when the switch is closed. Without the pull-up resistor, when the switch is closed (`1OUT` goes low), we would have a short circuit from the voltage source to ground. This would not only waste a large amount of electricity; it would break the LM393, because it can only sink a maximum of 6 mA of current. Having a 2 kΩ resistor, we limit the current for the closed switch to $I = V/R = 5/2{,}000 = 0.0025\ A = 2.5$ mA.

When the switch is open, the current flows through the resistor to the LED, and then the resistor acts as a current-limiting resistor for the LED. The amount of current to the LED will be calculated as $I = V/R = (5 - 1.8)/2{,}000 = 3.2/2{,}000 = 0.0016$ A = 1.6 mA.

11.5 Resistive Sensors and Voltages

One of the more practical uses of the voltage comparator circuit is to measure the values of sensors which act as variable resistors. Many different materials in the world act as resistors. What's really interesting is that many of these materials *change their resistance* depending on external factors. Some of them change their resistance based on temperature, pressure, light, humidity, and any number of other environmental factors.

Now, changing resistance doesn't tell us much by itself. If we put a resistor between a voltage source and ground, it will always eat up that voltage source. However, if you use it in concert with a fixed resistor to make a voltage divider, you can then get the output voltage to vary based on the changes in resistance.

Figure 11-6 illustrates this principle. It is a simple voltage divider, where the top resistor is actually a photoresistor (a resistor that varies based on light) and the bottom resistor has a fixed resistance. Thus, as the light varies, the top resistance will vary. This will change the ratio between the top and bottom resistors, which will affect the output voltage.

To use this circuit, you will need to know the resistances of your photoresistor on the different conditions you are interested in. I usually use the GL5528, which ranges from 10 kΩ in bright light to 1 MΩ in complete darkness. However, depending on your specific photoresistor as well as the light conditions that you think of as "light" and "dark," the resistance values that are relevant for light and dark will be different for you. So, whatever photoresistor you use, it is worthwhile to measure the resistance using your multimeter in the different conditions you think of as light and dark.

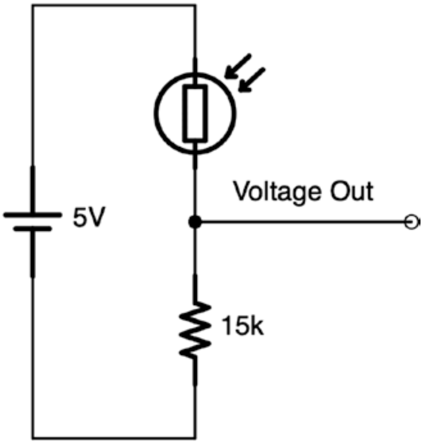

Figure 11-6. *A Simple Resistor Sensor Circuit*

11.6 Sensing and Reacting to Darkness

So far in the book, we have focused entirely on example circuits that didn't really do anything. They lit up, they had voltage and current, but there wasn't much interesting that they were doing. However, now, we finally have enough knowledge to start building circuits that *do* something.

We have

1. A way to generate a fixed voltage (using a voltage divider)
2. A way to generate resistances from real-world events (photoresistors and other resistance sensors)

3. A way to convert changes in resistance to changes in voltage (using a voltage divider with one fixed resistor)
4. A way to compare our varying voltage to our fixed voltage (using the LM393 comparator)
5. A way to utilize the output signal from the LM393 to do work (using the pull-up resistor and the LED)

There are a lot of pieces to put together this simple circuit, which is why it has taken so long to do anything worthwhile. However, if you have followed along carefully, now that you are here, you should be able to see how all of this fits together.

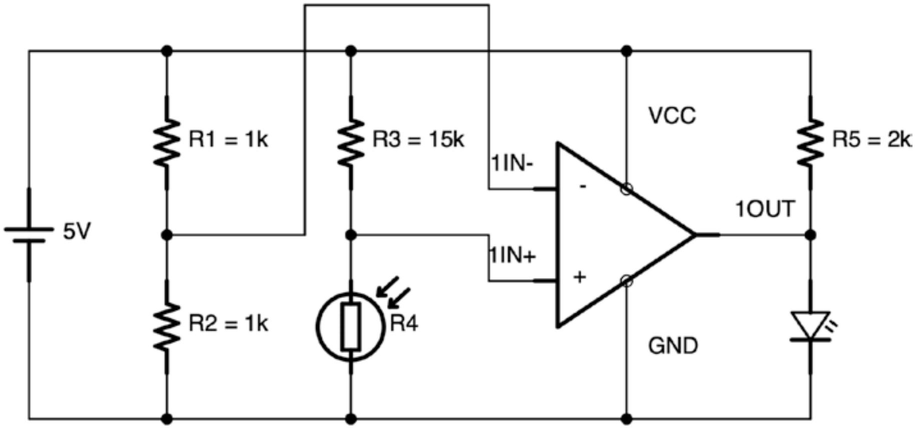

Figure 11-7. *Darkness Sensor Schematic*

What we will do is to take the circuit given in Figure 11-5 and modify R4 to be our photoresistor and R3 to be a fixed resistor. In my own testing, I discovered that the light/dark switchover point for my photoresistor was about 15 kΩ. Therefore, I am going to use a 15 kΩ resistor as the fixed resistor for R3. Yours may need to vary based on your experimentation with your photoresistor.

When there is light in the room, the photoresistor will have a lower resistance than 15 kΩ, which will make the fixed resistor R3 use up more of the voltage. Thus, the voltage at the divider will be less than 2.5 V, which will turn `1OUT` to low (which closes the switch and makes a path to ground on the output before it gets to the LED, which turns the LED off).

In low-light conditions, the resistance will jump way up above the resistance of the fixed resistor. If the upper, fixed resistor has less resistance than the bottom resistor, then the voltage at the divider will be larger than 2.5 V, activating the comparator and turning `1OUT` to high (i.e., opening the switch and allowing power to flow through the LED).

The final circuit is given in Figure 11-7. You can see a way to lay it out on the breadboard in Figure 11-8.

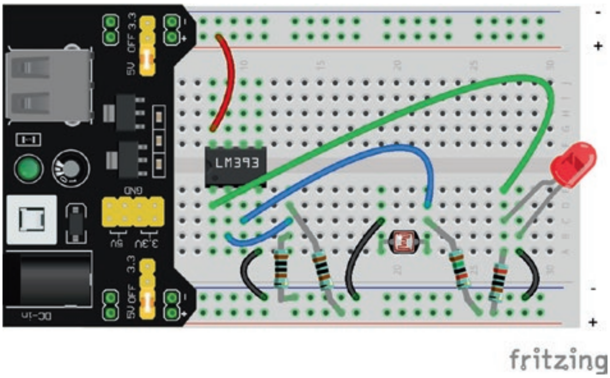

Figure 11-8. *Darkness Sensor Breadboard Layout*

Sources and Sinks

Two terms that often come up when dealing with circuits are the concepts of a current **source** and a current **sink**. A source is a component whose pins might provide current to other parts of the circuit. A sink is a component whose pins might pull current from other parts of the circuit.

For the LM393, its input pins neither source nor sink current (at least not any significant amount). The input pins more or less just sense the voltage without pulling any measurable current. Therefore, they are neither sources nor sinks of current. Technically, they probably sink a few nanoamps (billionths of an amp), but not nearly enough to affect our circuit analysis.

The output pin, even though it is called an *output*, doesn't source any current. Instead, it acts either as a sink (when low) or as a disconnected circuit (when high). This is known as an **open collector** output.

Anytime an IC sources or sinks current, be sure to read the datasheets on the maximum amount of current it can source or sink. These are usually quantities that *you* have to limit—they are merely telling you at what point their circuit will physically break. Therefore, you must use resistors to limit the currents to make sure that they are within limits.

However, be aware that many (but certainly not all) ICs do not source current, using open collectors for their output operations. This has the disadvantage that you have to supply your own voltage and pull-up resistor to the output pin, but it also has the advantage that the output is set to *whatever voltage level you choose*. In other words, you don't need to pick a new comparator IC to get a different output voltage.

Review

In this chapter, we learned the following:

1. Integrated circuits (called ICs or chips) are miniaturized circuits packaged up into a single chip that can be added to other circuits.
2. ICs can have a few or several billion components on them, depending on the function.

3. ICs have different types of packages, including through-hole (optimized for breadboards) and surface mount (optimized for soldering and machine placement).
4. Dual in-line packages (DIPs) are the most common through-hole packaging type used for students, hobbyists, and prototype builders.
5. DIP chips should be placed in the breadboard saddling the bridge, so that each IC pin is attached to its own terminal strip.
6. On most chips, pin 1 is located immediately counterclockwise of the notch in the chip, and remaining pins are numbered counterclockwise.
7. Most ICs are active devices, meaning that they have a direct connection to a power supply and ground in addition to their normal input and output pins.
8. An IC datasheet is a document that tells about the electrical characteristics of an IC. However, most of them are difficult to read and assume you are already familiar with the part. However, they are very useful for getting a pinout for the chip as well as telling the maximum ratings for voltages and currents.
9. The LM393 is a dual voltage comparator IC—it compares two voltages and alters its output based on which is larger.
10. The LM393's inputs do not consume any significant current when sensing the input voltages.

11. The LM393's outputs are open collectors—which means that they act as a switch to ground. When the output is "low," the pin acts as a closed switch to ground. When the output is "high," the pin acts as a disconnected circuit.
12. Because the LM393 acts as a disconnected circuit when high, a pull-up resistor circuit is required to get an output voltage.
13. Many sensors are based on the fact that the resistance of many materials will change with environmental factors. Therefore, the sensor acts as a variable resistor, with the resistance telling you about the environment.
14. A resistive sensor can be used with a fixed resistor to make a variable voltage divider, essentially converting the resistance to a voltage, which then can be detected.
15. By putting the sensor-based resistive voltage divider in comparison with a fixed reference, we can use the LM393 comparator to trigger an output when the sensor crosses some threshold of resistance.

Apply What You Have Learned

1. Calculate the amount of current flowing through each element of the circuit in Figure 11-5. You can presume that the LM393 uses about 1 mA for its own (internal) operation and that the LED is a red, 1.8 V LED. What is the total amount of current used by the circuit?

2. Take the circuit in Figure 11-5 and swap which voltage divider is attached to `1IN+` and `1IN-`. Now calculate the total amount of current used by this circuit.

3. The Spectra flex sensor is a resistive sensor that changes its resistance when bent. When it is straight, it has a resistance of 10 kΩ. When it is bent, it has resistances of 60 kΩ and above. Draw a circuit that turns on an LED when the resistor is bent. Use a resistor symbol for the flex sensor, but label it as `FLEX`.

4. Build the circuit in Figures 11-7 and 11-8.

5. If you wanted to wait until the room was even darker before the LED went on, how would you change the circuit?

Digital Electronics and Microcontrollers

CHAPTER 12

Using Logic ICs

In Chapter 11, we worked with our first integrated circuit, the LM393 voltage comparator. In this chapter, we are going to look at other ICs and talk more about how they are named and used in electronics.

12.1 Logic ICs

One of the easiest class of ICs to use are the *logic* ICs. A logic IC is a chip that implements a basic function of **digital logic**. In digital logic, electric voltages are given meanings of either “true” or “false,” usually with “false” being a voltage near zero and “true” being a positive voltage (often between 3 and 5 volts). These values are also referred to by a number of other designations—a 1 (for true) and 0 (for false) or HIGH (for true) and LOW (for false).[1] Then, the digital logic ICs implement logic functions that combine different signals (usually designated as A and B) and give an output signal (usually designated as Y or Q).

---

[1] Very rarely, some ICs will reverse the meaning of the positive and zero voltages.

For instance, the **AND** function will output a “true” (positive voltage) value if both of its inputs are true and will output a “false” (near-zero voltage) value otherwise. In other words, if A *and* B are true, Y is true. As another example, the **OR** function will output a “true” value if either of its inputs is true. In other words, if A *or* B is true, Y is true. Figure 12-1 shows the most common types of logic operations and how they work.

As we have seen, AND yields a true result when both A and B are true, and OR yields a true result when either A or B is true. So what are the others? **XOR** is *exclusive OR*, which means that it is just like OR, but is also false when both inputs are true. **NOR** is *not OR*, which means that it is the exact opposite of OR. Likewise, **NAND** is *not AND*, which means that it is the exact opposite of AND. Finally, **NOT** only has one input and simply reverses its value.

Each digital logic function, when implemented in electronics, is called a **gate**. The nice thing about building circuits with logic gates is that, rather than using math, you can build circuits based on ordinary language.

Operation	**A**	**B**	**Y** (output)
AND	false	false	false
AND	false	true	false
AND	true	false	false

Figure 12-1. *Common Logic Operations*

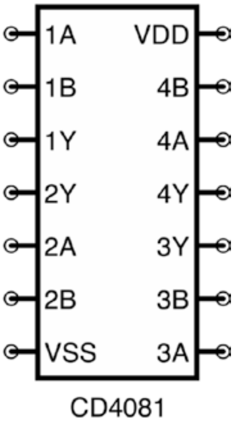

Figure 12-2. *The Pinout of a CD4081 Chip*

If you were to say, "I want my circuit to output a signal if both button 1 *and* button 2 are pressed," then it is obvious that you would use an AND gate to accomplish this.

INVERTED INPUTS AND OUTPUTS

Sometimes an input or an output on a chip will be labeled with a line on top of the input or output name. This means that the result (or requirement) will be the *opposite* of what you would otherwise expect. For instance, if the output is Y, then $\overline{\text{Y}}$ refers to the opposite value of Y. So, if Y is true, then $\overline{\text{Y}}$ will be false.

The same can occur on inputs as well. For instance, some chips have a reset on the chip which will reset the chip. However, we would normally consider "signaling" a pin to be sending it a voltage. Sometimes the chips would prefer that you signal the reset by bringing the voltage low instead of high. In these cases, they usually designate this by putting a bar over the name of the input pin, so the reset pin would be labeled $\overline{\text{RESET}}$ in order to indicate this behavior.

These are known as **inverted** inputs and outputs.

Most logic gates are implemented in chips that contain multiple (often four) implementations of the same gate. For instance, the CD4081 chip is a quad–NAND gate chip. The pinout for this chip is shown in Figure 12-2. Note that it has a supply voltage pin (pin 14) as well as a ground pin (pin 7) to supply power to all the gates on the chip. Each logic gate is numbered 1–4, and the inputs are labeled A and B with the output of Y.

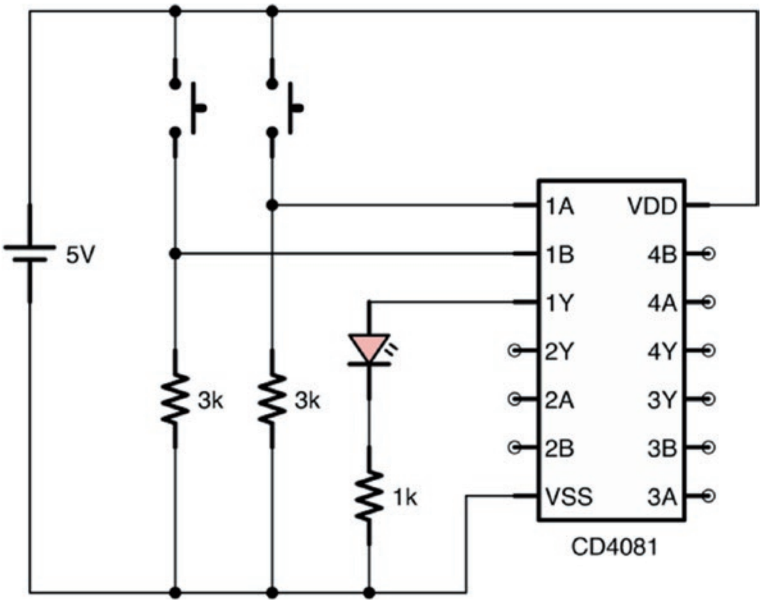

Figure 12-3. *Example Circuit Using an AND Gate*

To use the chip, you pick which one of the four gates you are going to use (it doesn't really matter which). If we want to use Gate 1, then we put our inputs on 1A and 1B, and then our output signal goes to 1Y. Note that, unlike the IC from the last chapter, this logic gate has a powered output—it actually supplies voltage and current to drive a (small) output signal.

Logic gates are wired to expect relatively fixed, predefined voltages on their inputs and output the same voltage levels. They do not need current-limiting resistors for their inputs because the inputs themselves are usually high resistance (i.e., 1,000,000–10,000,000 Ω). Because of the high resistance on the inputs, it also means that even if there is a resistor on the input, it will not affect the input voltage significantly. It also means that the current going into the gate is essentially ignorable: $I = \frac{V}{R} = \frac{5}{10{,}000{,}000} = 0.0005\text{mA}$.

For some logic chips, the input voltage is expected to be around 3.3 V or 5 V, while for others, it is based on the supply voltage. However, nearly all ICs are limited in how much current they can put out before they fry. This is usually somewhere in the range of 8–20 mA, depending on the chip. Because of this, if you use a logic gate to directly power a device (such as an LED), you probably will need a current-limiting resistor to keep the output current down below these limits.

There are logic chips that have open collector outputs (like the LM393 from Chapter 11), but they are more rare because they are harder to use.

Let’s say that we want to build a circuit which will turn on an LED if *both* of two buttons are pushed at the same time. Figure 12-3 shows a circuit to accomplish this. It has two buttons, one wired to 1A (pin 1) and one wired to 1B (pin 2). The output 1Y (pin 3) then goes to an LED with a current-limiting resistor. You may wonder what the resistors attached to the buttons are doing. Those will be explained in Section 12.3, “Pull-Down Resistors.”

For most logic chips, the manufacturers recommend that unused inputs (but not outputs!) be connected to ground. This makes the chip more efficient in power consumption, but for simple projects like these, it isn’t really necessary. If you wish to connect the unused inputs to ground, then it is a better circuit design.

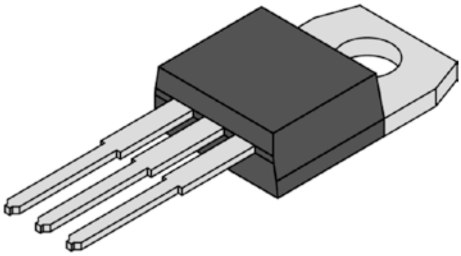

Figure 12-4. *A 7805 Voltage Regulator in a To-220 Package*

Note that the circuit shows a 5 V source. While the CD4081 is tolerant of a wide range of input voltages and would operate just fine at 9 V, many digital logic chips are not. Many digital logic chips operate at pre-specified voltages, usually either 5 V or 3.3 V. Therefore, we will take a moment and look at how we can get an input source for a specific voltage.

12.2 Getting a 5 V Source

So far in this book, we have used a custom power regulator to regulate the voltage on the board. Thankfully, this voltage is actually selectable—jumpers on the board allow you to select 5 V or 3.3 V, which are precisely the voltages usually required.

However, if we didn't have such fancy regulators, how would we achieve a 5 V source? There are several options for doing this, all depending on your requirements and/or the supplies you have available to you.

One option is to build a simple 5 V power supply using the knowledge you already have. In Chapter 9, we showed how to build a voltage divider to step down the voltage from a higher voltage source to a lower one. Although not ideal, this could work fine for simple test circuits. A better option would be to build the Zener diode voltage regulator that was shown in Chapter 8 if you have a 5 V Zener diode handy (however, you would need to be careful to calculate the output wattage, as these can dissipate a lot of power).

A better option is to use a voltage regulator IC. The LM7805 is a simple voltage regulator circuit you can use to convert a 7–24 V voltage source into a 5 V voltage source with somewhat minimal current loss. It is itself an IC, though with a different kind of packaging than we've seen, known as a **TO-220 package**. You can see what this looks like in Figure 12-4. On these packages, if you are reading the writing on the package, pin 1 (input voltage) is on the left, pin 2 (ground) is in the middle, and pin 3 (output voltage) is on the right. Figure 12-5 shows what this looks like in a circuit diagram.

Figure 12-6 shows how to attach the LM7805 regulator to your breadboard. First, plug the regulator into your breadboard so that each pin is on its own terminal strip. Next, plug the positive wire from the battery into the terminal strip with the voltage regulator's pin 1 and the negative wire from the battery to the negative/ground power rail on the breadboard. Then, connect the voltage regulator's pin 2 (ground) to the negative/ground power rail. Finally, connect the voltage regulator's pin 3 (output voltage) to the positive power rail.

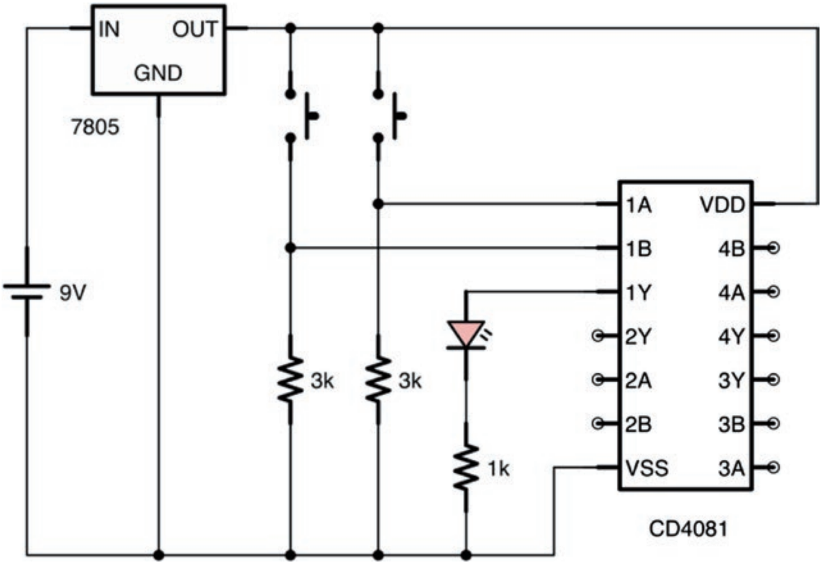

***Figure 12-5.** Logic Gate Circuit with a Voltage Regulator*

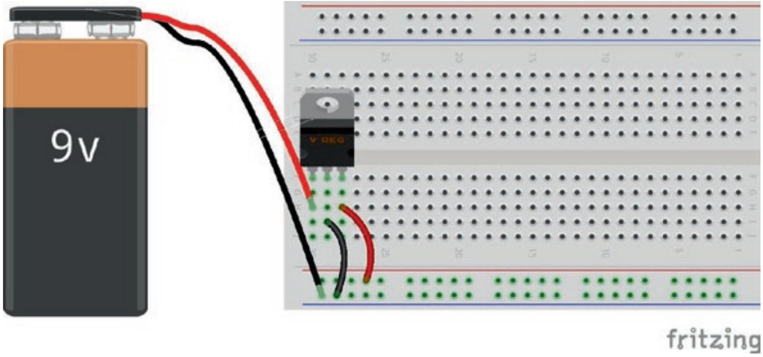

Figure 12-6. *Simple Way to Attach the LM7805 to Your Breadboard*

This will give you a 5 V supply without all of the circuitry of our previous power regulator. This is especially helpful if you have strange power needs or need to use a minimum of space for your power regulation.

Note that some LM7805s have pins that are too big for breadboards. That's unfortunate, but they are pretty rare. As long as you buy from companies that target hobbyists, you are likely to get a component that will work well with breadboards.

In any case, we will continue to use our power regulators, but I wanted to note that there are other ways to supply the correct amount of power to chips that require fewer components.

12.3 Pull-Down Resistors

In Figure 12-3, we looked at the circuit diagram for a simple AND gate. We noted that each button had a resistor connecting it to ground, but we did not mention why. In digital logic circuits, buttons and single-pole switches, when they are open, essentially disconnect the circuit. Because the inputs are high-resistance inputs (i.e., they use very little current), simply disconnecting the input circuits is not always enough to turn them off! Think of it this way—when you connect the circuit by pushing the button, the whole wire becomes positive. When you let go of the button, the state of the wire has not changed. Eventually the positive charge will drain out through the gate, but, since the input uses so little current, it may take a while for that to happen. Therefore, we have to provide another path for the electricity to go when the button is not pressed. These resistors are called pull-down resistors because, when the button circuit is not connected, they pull the voltage level down close to zero.

The resistor is very important because, when the button is connected, it keeps the voltage high and limits the amount of current that leaks out across the resistor. If you directly connected the button to ground without the resistor, then pushing the button would not raise the voltage because it is still directly connected to ground and would therefore remain at 0 volt. Having the resistor there makes sure that the voltage on the inputs remains high while the button is pressed and bleeds off when the button is released.

In short, without a path to ground, when you let go of the button, the input could remain high. Moreover, without the resistor, pushing the button would cause a short circuit. Therefore, a pull-down resistor allows voltage to drain off quickly when the button is not pressed, but also prevents disasters and wasted current when the button is pressed.

Additionally, static electricity in the air can cause the actual voltage on the gate to fluctuate when it is not connected. Physically connecting the gate to the ground through a resistor will make sure there is always *some* complete circuit which provides a deterministic value for the voltage at the gate.

The value of a pull-down resistor is usually somewhere between 1 kΩ and 10 kΩ. Beyond 10 kΩ, the actual function of pulling the voltage down to zero can be slowed down. Additionally, even above 4 kΩ, it is possible to interfere with the actual logic operation of the chip. Having a resistor below 1 kΩ, however, means that you are just wasting current.

Figure 12-7. *Multiple Logic Gates Combined in a Circuit*

So, for any button-type input to a digital logic circuit (where the circuit is *phyiscally disconnected* when the input is off), a pull-down resistor is needed to make sure that the input *actually* goes low when the button stops being pushed or the switch turns off.

12.4 Combining Logic Circuits

Logic chips that operate at the same voltage are very easy to combine together. Let's say that you had three buttons that you wanted to monitor and you wanted the light to come on if someone pushed either buttons 1 *and* 2 together *or* button 3 (or all of them). To do that, you would need an AND gate and an OR gate. Buttons 1 and 2 would be wired with the AND gate, and button 3 would be combined with the output of the AND gate through an OR gate.

Figure 12-7 shows what this looks like. Since there are so many voltage/ground connections, the figure does not have an explicit battery drawn; instead, it simply shows +5 V wherever it should connect to the voltage source and a ground symbol wherever it should connect to the battery negative. As you can see here, there are two logic ICs—the CD4081 having the AND gate and the CD4071 having the OR gate. The output of the first AND gate is wired into one of the inputs of the OR gate.

Figure 12-8. *Logic Gates Represented as Shapes Instead of IC Pins*

This works because, unlike the LM393 (discussed in Chapter 11), these logic gates actually supply output voltage and current as well. Because the inputs to the logic gates are high resistance (they act like there is an extremely large resistor connected to the input), there is no need for a current-limiting resistor when combining gates in this way.

Now, it is fine to draw logic circuits the way we have in Figure 12-7. However, as the logic becomes more complex, actually drawing all of the connections to voltage and ground becomes tiring, and trying to get all of the wires to the right spot on the chip can get messy as well. Because of this, engineers have devised a simpler way of describing logic gates and logic circuits in schematics.

Instead of representing the entire chip on a schematic, engineers will represent only the logic gates themselves.

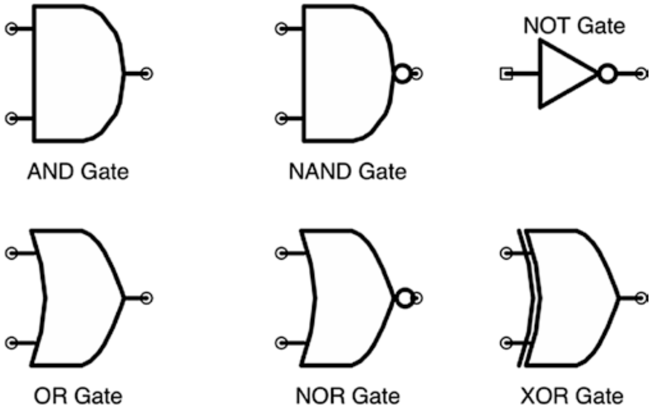

Figure 12-9. *Common Gates Used in Schematic Drawings*

Additionally, since the power goes to the whole chip (and not the individual gates), in such a drawing, the power connections for the gates are not shown. The standard that was developed represents each type of gate with a shape. Figure 12-8 shows what this circuit drawing looks like if it is drawn using shaped gates instead of IC pins. The actual physical circuit is the same; this is only to simplify the schematics to make them easier to understand and follow.

Figure 12-9 shows what these gate drawings look like. The AND gate has a flat back panel and a simple, rounded front. The OR gate looks a bit like a space shuttle, with both the back and the front angled. The NOT gate is a triangle with a circle at the tip. This circle can also be added to other gates to show that the gate is the opposite one. For instance, a NAND gate is drawn by first drawing an AND gate and then adding a circle to the front, indicating that the gate behaves like an AND gate with a NOT gate in front of it. Similarly, the NOR gate is an OR gate with a circle in front of it. The XOR gate is similar to the OR gate, but with an extra line going across its inputs.

Many times, the internal schematics of a chip are shown using gate symbols, in order to help you understand the operation of the chip and how the pins work. For instance, Figure 12-10 shows how the CD4081 chip is wired up internally. You can see the inputs going through the logic gate and out toward the output. While this isn't any new information you didn't already know, if may help you understand why the pins are laid out the way that they are.

As an interesting sidenote, every logic function can actually be built from NAND gates, though you have to wire them up in strange ways. You can actually build a computer almost entirely from NAND gates if you wanted to. It is not incredibly important, but Figure 12-11 shows how to build each type of logic gate from NAND gates. As an activity, go through the truth tables in Figure 12-1 and see if you can follow how each set of values becomes the result.

12.5 Understanding Chip Names

One of the biggest problems in learning to build electronic devices is the bewildering array of chips, each with some weird name. "Oh, for that you want an NE555P," or "You could use a SN74HC00P or a CD4011BE for that task." What language are such people speaking?

There is a huge selection of chips available, and learning their names is a daunting task. Appendix C attempts to offer some method to the madness, but, at the end of the day, chip names are like people's names—you get to know them by using them. Nobody knows everybody's name, but, for the types of projects you like to work on (whatever that happens to be), there will be standard chips whose names you will eventually come to know.

Once you make it through this book, you should have a solid enough background to search for the chips you need, have some understanding of the part names, and be able to find the chips you need for your projects. If you buy the chips from a seller geared toward amateurs and hobbyists, they will likely also include tutorials and additional information available in an easier-to-understand format than just datasheets.

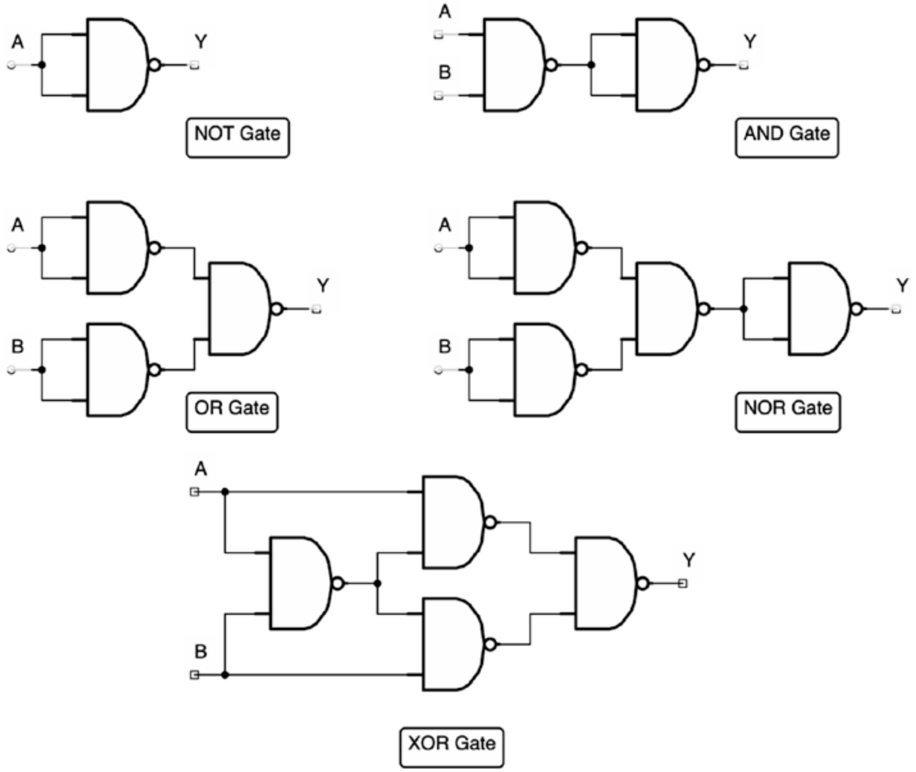

Figure 12-11. *How Each Gate Can Be Built from NAND Gates*

Review

In this chapter, we learned the following:

1. A logic IC implements basic digital logic functions such as AND, OR, NOT, and so on.
2. These logic functions refer to essentially the same ideas that they mean in ordinary language and exactly what they mean in formal logic.
3. Logic ICs use different voltage levels for true and false—usually with true being near the supply voltage and false being near zero voltage.
4. True is sometimes referred to as HIGH or 1. False is sometimes referred to as LOW or 0.
5. The inputs of a logic function are usually designated as A and B, and the output is usually designated as Y or Q.
6. If an input or output name has a line/bar printed on top of it, that means that the value is the logical *opposite* of what would be expected. So, if Y is the output value, then $\overline{Y}$ would be the opposite of the output value.
7. A single digital logic function is called a gate. Most logic ICs have more than one gate on a single chip.
8. Logic ICs require a supply voltage and a ground connection to power the logic.
9. Most logic ICs provide powered logic outputs, so that a “true” value supplies both voltage and a small amount of current on its output. However, a current-limiting resistor is usually required.

10. If an input to a logic IC may be disconnected for its “false” state (as is common with button inputs), then it needs a pull-down resistor to connect it to ground when the button is not being pushed.
11. Logic ICs can usually be combined by wiring the output of one to the input of another to create more complex logical conditions.
12. Logic gates are often drawn in schematics using basic shapes to indicate their operation, rather than as connections to chips. In these cases, the power connections are not shown by schematics.
13. Every logic gate can actually be built from NAND gates wired together.
14. IC names are very confusing and take time and experience to get to know them well.
15. Many ICs require specific voltage levels to operate, often at 5 V or 3.3 V.
16. Many solutions are available for generating specific voltages, including voltage dividers, Zener diodes, voltage regulators, and add-on breadboard power units.
17. The LM7805 is a very common 5 V voltage regulator.

Apply What You Have Learned

1. Draw the circuit in Figure 12-3 yourself. Identify the function of each resistor.

2. Build the circuit in Figure 12-3 (don't forget that the power source should be 5 V).
3. If you assume that a negligible amount of current flows through the inputs of the AND gate and that the output functions as a 5 V voltage source (and the LED is red), how much current flows through each resistor when all of the buttons are pressed? What, then, is the total current used by the circuit if you ignore the logic gate?
4. Measure the actual current that flows through each resistor. If you are having trouble pushing the buttons while you measure the current, just replace the buttons with wires for this test.
5. Measure the current that is used by the AND gate itself. You can do this by measuring the supply current of the AND gate. Measure it both when its output is true and false.
6. Draw a schematic of a circuit that has two buttons (B1 and B2) which light up an LED if either button is pressed. Use the logic gate shapes for the schematic.
7. Draw a schematic of a circuit that has two buttons (B1 and B2) which light up an LED if neither button is pressed. Use the logic gate shapes for the schematic.
8. Draw a schematic of a circuit that has four buttons (B1–B4) which light up an LED either if B1 and B2 are pressed or if B3 and B4 are pressed. Use the logic gate shapes for the schematic.

9. Look at the construction of the different gates from NAND gates in Figure 12-11. Copy down the OR gate construction four times, and trace how the output is generated for each possible set of inputs (true/true, true/false, false/true, false/false). Show the inputs and outputs on each NAND gate. Compare the outputs to the truth table for the OR function in Figure 12-1.
10. Take the circuit in Figure 12-3 and draw a schematic to use pull-up resistors on the inputs rather than pull-down resistors. How will this change the behavior of the circuit?
11. Let's say that we want to create a door buzzer so that someone outside a door can push a button to be let in. However, the person inside also wants a switch to be able to disable the buzzer. The buzzer can be thought of as a simple device that buzzes when any positive voltage is applied. Draw a circuit diagram of this setup using logic gates. The buzzer can be drawn as a resistor labeled "buzzer" (don't forget to connect the other side to ground!).

CHAPTER 13

Introduction to Microcontrollers

In Chapter 12, we learned the basics of digital logic. However, I think we can all agree that those chips wound up taking up a lot of space on our breadboards. If we wanted to do a lot of complicated tasks, we would wind up needing a lot of chips, we would need more and more breadboards to put them on, and our project would get unwieldy very quickly. Additionally, as the number of chips increased, it would get very expensive to build such projects.

Additionally, when all of the logic of a circuit is hardwired into the circuit through logic chips, it is very difficult to change. If you need to change the logic (convert an `AND` gate to an `OR` gate or do anything else), you wind up needing to wade through masses of circuitry to make the change you want. Then, if you are mass-producing the circuit, you have to set up for mass production all over again.

To solve all of these problems (and more), the microcontroller was introduced. A microcontroller is essentially a low-power, single-chip computer. A "real" computer chip usually relies on a whole slew of other chips (memory chips, input/output chips, etc.) to operate. A microcontroller contains all of these (though usually on a smaller scale) in a single chip that can be added to an electronics project.

Unlike your typical computer, most microcontrollers can't be connected to a mouse, keyboard, or other typical inputs and can't be connected to a monitor, disk drive, or other typical outputs. Instead, microcontrollers usually communicate entirely through digital (true/false) electrical signals on their pins.

So, instead of wiring complex logic onto their boards, many people opt to have microcontrollers provide the bulk of their digital logic. One complication that this adds, however, is that since the microcontroller is essentially a computer, then just, like a computer, it has to be programmed. This means that not only must circuit designers be familiar with electronics, they must also be familiar with computer programming.

13.1 The ATmega328/P Chip

The microcontroller we will be focusing on is the ATmega328/P. Actually, we will focus less on this specific chip than the overall environment surrounding it, known as Arduino (we will cover more of what this means in Section 13.2, "The Arduino Environment").

Even though the Arduino environment tries to minimize how much you have to know about the hardware itself, it is good to have a quick introduction to this chip and how it works.

The ATmega328/P is part of a family of microcontrollers developed by Atmel known as the AVR family. The AVR became popular because it was one of the first chips to use flash memory to store its programs, which allowed the onboard programs to be more easily changed.

Figure 13-1 shows a simplified pin configuration of the chip, focused on how it is used in the Arduino environment. The VCC pin and the GND pins are the primary power pins. The chip can run on a range of voltages, but 5 V is a very common and safe setting. AVCC and AGND power the chip's analog-to-digital converter unit.

All of the pins labeled "D" are digital input/output pins. They can be configured as inputs for buttons or other signals or as outputs for driving LEDs or other output devices. The pins labeled "A" are analog input pins (we will cover how to use these in Chapter 15). While the digital input pins can only read that a value is true/false, the analog pins can read voltages and convert them to numbers. AREF is a "reference voltage" used for setting the maximum voltage for analog inputs, but is usually unconnected (it should also not be a higher voltage than AVCC).

Microcontrollers, like most processors, control their operation by using a "clock." This is not a clock as you normally think of—it doesn't tell time. Instead of thinking of it as a clock, a better way to think of the "clock" is as a heartbeat. Basically, there is a continuous signal of pulses that are provided through the clock, and the pulses allow the chip to synchronize all of its activities. The ATmega328/P has an internal clock, but it can also be more efficiently operated by connecting an external clock (quartz crystals, for instance, provide a *very* steady pulse for this purpose).

As we have noted, the chip has a number of input and output pins. You might wonder, what does the chip *do* with its input and output pins? That is entirely up to you. It does *whatever you program it to do*. The ATmega328/P has **flash memory** on the chip which can store a computer program (flash memory means that it will remember the program even after the power turns off). You have to upload your program to the chip, and then after that, it will do whatever you like with its inputs and outputs. The D0 and D1 pins, in addition to providing input and output, can also be used to reprogram the chip. We will learn how to program the chip in Section 13.4, "Programming the Arduino."

13.2 The Arduino Environment

The chip itself is just one piece of the puzzle. In order to use the chip, you have to be able to program it. Programming requires the use of programming tools on your main computer. In addition, you also need some way to take the program that you built on your computer and load it onto the chip. That takes both software and hardware.

Then, once the program is on the chip, you have to build a circuit to properly power the chip. This requires voltage regulation for the VCC pin and several other recommendations from the manufacturer about how to set up the other pins. To make it run optimally, it would also be good to supply an external clock. All of this can be quite a lot of work, and a lot of pieces that need to be brought together.

Thankfully, most chips have what is called a **development board** that can be purchased. A development board is a prebuilt circuit that has a microcontroller chip pre-connected in its recommended manner. It is made to simplify the work of developing circuits. Likewise, most chips have a recommended **programming environment** as well. A programming environment is a set of tools for your computer that allow you to create programs for your microcontroller. Additionally, a device called an **in-system programmer** (ISP) connects your computer to your chip or development board and will transmit the program from your computer to the chip.

In 2005, a complete, simplified system for doing all of these tasks called **Arduino** was created, based off of an earlier system called Wiring. Arduino consists of (a) a simplified development environment for your computer to write software for microcontrollers, (b) a simplified development board to make it very easy to build electronics projects, and (c) integrating the in-system programmer into the development board so that all that is required to transfer the program to the microcontroller is a USB cable.

The Arduino environment supports a number of different microcontroller chips. Because it is a simplified environment, many of the special features of individual chips are not directly supported. However, for getting started and doing basic projects, the Arduino environment is excellent.

Even though there is a company behind Arduino, there are many Arduino-compatible boards made by other manufacturers. These boards use the same ATmega328/P microcontroller and often have very similar development boards and functions. Most importantly, they are compatible with the programming tools on the Arduino environment.[1]

---

[1] One important difference between "official" Arduino boards and most Arduino-compatible boards is the USB controller chip. Official Arduino boards use a chip from FTDI to do this, because the drivers for it are preinstalled on every operating system. To save on costs, many Arduino-compatible boards use a lower-cost chip to perform this function (often the CH340). Usually, the only disadvantage of this is that, on some operating systems, an additional driver is needed to communicate with these chips.

13.3 The Arduino Uno

This book focuses on the Arduino Uno development board. Figure 13-2 shows what the board looks like, as well as a general idea of what the different areas of the board accomplish. The Uno is very nice because the USB port allows a whole slew of functions—not only can it be used to receive programs for the chip but you can also power the board through the USB, as well as send data back and forth to the computer through it. If you are not connected to a USB, there is a separate power plug that can be plugged into the wall or to a 9 V battery.

The Arduino Uno provides chips for power regulation, USB communication, as well as the ATmega328/P microcontroller itself. It also supplies an external clock for the microcontroller. Finally, it provides **headers** (places on the board to plug in wires) for the major pins on the microcontroller. Thus, everything you need to make use of the chip is provided for you in this development board. You simply connect the input and output pins to your own breadboard, and you can have a working project that you can program.

13.4 Programming the Arduino

Now that we have seen the pieces of the Arduino environment, let's tackle programming the Arduino. This book is not a book about programming, so we will only cover the absolute basics.

The programming tool for the Arduino is called the **Arduino IDE**. IDE stands for "Integrated Development Environment"—in other words, the thing that you develop with. The Arduino IDE is available for pretty much any computer—Mac, Windows, or Linux. You can download the IDE from `http://arduino.cc/`.

Depending on whether you purchased an "official" Arduino or a clone, you may also have to download an additional driver for the USB interface. If you have an Arduino-compatible clone, you can download the driver from `http://bplearning.net/drivers`. Once you have installed the Arduino IDE and the USB driver, you are ready to start!

We will begin by using an example program (called a "sketch" in Arduino terminology) that ships with the Arduino. First, connect your Arduino to your computer with a USB cable. Open up the Arduino IDE; then click "File," then "Examples," and then "01.Basics"; and finally click "Blink." This loads up a ready-made program for your Arduino. This program simply turns the D13 pin on and off. On an Arduino, the D13 pin already has an LED attached to it, so you don't even need to add any components!

Now that you have the program loaded up, click the button with the checkmark icon. This verifies that the program is written in a way that the computer can understand. If it has any errors, it will show them in the black panel on the bottom.

Now you need to make sure that the IDE is targetted at your board. Go to "Tools" and then "Board" and make sure that "Arduino/Genuino Uno" is selected. Then, click "Tools" and then "Port" and make sure your Arduino was detected and that it is selected. If you don't see your Arduino listed here, you may need to check the USB driver installation.[2]

Once your configuration is verified, click the button with the arrow icon to upload it to the Arduino. It should take about 2–5 seconds, and then the LED on your Arduino should start blinking. If there are any errors, they will display in the black status area below. Note that some Arduinos come with this program preinstalled. If this is the case, your Arduino may not have changed what it is doing much. You can verify that it is all working by changing the program slightly. If you change all of the numbers that say `1000` to `500`, it should blink twice as fast. Remember, though, that you must verify it (click the checkmark button) and upload it (click the arrow button) to get your new code onto the board.

Now, let's take a look at the code and how it functions. The first part of the code should be grayed out. That's because it is a **comment**, or a note telling you about the program. This isn't read by the computer at all. Comments start with the characters /*, and they continue until they reach the characters */ (this can even span multiple lines). Shorter comments are sometimes made with the characters //. Those comments only continue until the end of the line.

After the comments, there are two **functions** defined—`setup()` and `loop()`. A function is simply a piece of code that is named. In the Arduino environment, the `setup` and `loop` functions are special. The `setup` function runs exactly once when the chip first turns on or resets or when a new program is loaded. It is used for things such as telling the chip which pins will be used for input and which ones will be used for output and doing other setup-related tasks. After the `setup` function completes, the `loop` function runs continually over and over again for as long as the chip is on.

---

[2] You might try the following instructions with a device listed there even if you don't recognize it as your Arduino in case your computer had difficulty detecting the device type.

If you look at the code, the `setup` function contains one command:

```
pinMode(13, OUTPUT);
```

This tells the microcontroller that digital output 13 (D13) will be used for output. Note that this refers to the D13 pin in Figure 13-1 (usually just labeled `13` on the Arduino Uno), not to pin 13 of the chip itself (which would be D7). With the Arduino Uno, we don't actually need to worry about the pinout of the ATmega328/P, we just need to read the names of the pins next to the pin headers.

The `loop` function is the main part of the code. It looks like this:

```
digitalWrite(13, HIGH);
delay(1000);
digitalWrite(13, LOW);
delay(1000);
```

The first line, `digitalWrite(13, HIGH);`, says to turn D13 to HIGH, which is about 5 V. This provides the power for the LED attached to D13. This pin will remain high until we tell it to do something else.

The next line, `delay(1000);`, tells the chip to wait for 1,000 milliseconds (which is 1 second). During this time, nothing happens—the chip just waits. Changing this number changes the amount of time that the chip will wait for. Changing it to `500` will cause it to wait for half a second, and increasing it to `2000` (note that there are no commas in the number!) will cause it to wait for 2 seconds.

The next line turns D13 to LOW/false/off/0 V. This turns off the LED, because there is no longer any voltage supplied to it. D13 will stay in this state until told otherwise. The next line then waits for 1 second. Once this function finishes, the chip will simply run the `loop` function again from the start.

In Chapter 14, we will look at how to build projects with the Arduino that use additional components.

Review

In this chapter, we learned the following:

1. A microcontroller is a small computer in a single microchip that provides customizable logic for handling digital signals.
2. A development board is a circuit board that simplifies the process of building circuits with a microchip by providing most of the standard connections for you, allowing you to focus your efforts on the things that make your project distinctive.
3. In order to use a microcontroller, it has to be programmed from a computer.
4. The Arduino environment is a combination of software and hardware meant to make building microcontroller projects easier.
5. The Arduino Uno is a development board for the Arduino environment that includes a microcontroller, USB connection, power regulation, and headers for connecting the microcontroller's input/output pins to other circuits.

6. The ATmega328/P is the microcontroller used in the Arduino Uno.
7. An Arduino program (called a sketch) has two standard functions—`setup` (which is run once when the chip powers on) and `loop` (which runs over and over again as long as the chip is on).
8. Once a program is uploaded to the Arduino Uno, it will be saved on the device until another program is loaded.

Apply What You Have Learned

1. Practice modifying and uploading the Blink program to the Arduino Uno. Change the numbers given to `delay` to different values, and see how that affects the operation of the program.
2. The ATmega328/P is only one of many different microcontrollers available in the AVR family. Research online to find one or two other AVR chips and what different features they have.
3. The AVR family is only one of many microcontroller families. Research one or two other microcontroller families and look at what features are claimed for each. Examples of other microcontroller families include PIC, STM32, MSP432, and the Intel Quark.
4. Go to the `arduino.cc` website and look at the different types of Arduinos that are available. What makes them different? Why might you choose one for a project over another?

CHAPTER 14

Building Projects with Arduino

Chapter 13 covered the basics of what microcontrollers are, what the Arduino environment is, and how to load a program onto an Arduino board. In this chapter, we will go into more depth on how to include an Arduino Uno into a project.

14.1 Powering Your Breadboard from an Arduino Uno

The first thing to understand about the Arduino Uno is that one of its main jobs is power regulation. As we saw in Chapter 13, the Arduino can use a variety of power sources—USB, battery, or a wall plug. Additionally, there is a connection on the Uno's headers that allows for you to supply power from some other source.

If you have a power source that just has wires coming out of it—like a 9 V battery with a simple wire connector—the Uno has a place that you can plug it in. The pin labeled V_{IN} is used for supplying an unregulated voltage supply (7–12 volts) to the Uno (*do not* use the one labeled 5 V—it is for *outputting* power). Therefore, if you plug the positive wire into V_{IN} and the negative wire into any of the *GND* pins (it doesn't matter which one), then the Uno will spring to life.

J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_14

On the flip side, you can actually power the rest of your project from the Uno and take advantage of its voltage regulation, as well as its numerous methods for getting power. To do this, simply take a wire from the 5 V connection on the Uno and connect it to the positive rail on your breadboard. Then, take another wire from one of the GND connections on the Uno and connect it to the ground rail on the breadboard. Voilà! A very flexible 5 V power supply for your breadboard. Figure 14-1 shows how to use this to light a simple LED circuit.

Also note that there is also a 3.3 V connection if you need it, as many small devices are powered at that level.

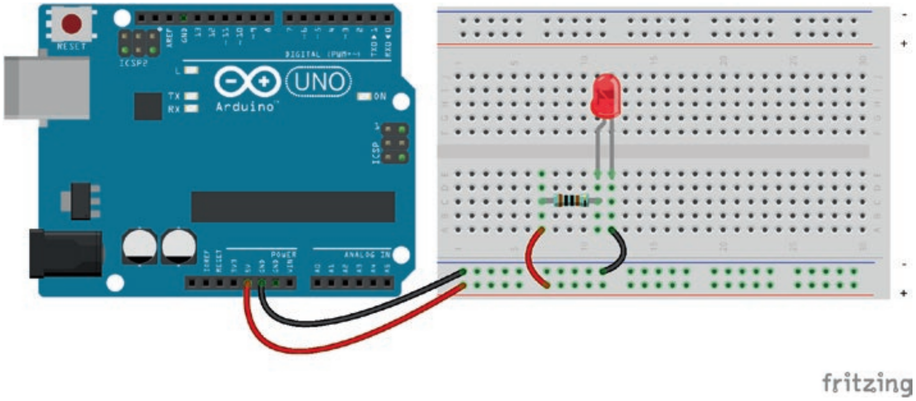

Figure 14-1. *Powering a Simple Project from an Arduino Uno*

14.2 Wiring Inputs and Outputs to an Arduino Uno

Now that we know how to power a breadboard from an Arduino Uno, we can now see how to connect inputs and outputs to the Uno.

Wiring inputs and outputs to an Uno is actually very easy. Outputs of the Uno can be viewed as simple voltage sources, like a battery, which operate at either 5 V (if set to HIGH) or 0 V (if set to LOW). Remember that any of the digital I/O pins can be set to be input or output pins in your Arduino program with the `pinMode` command.

However, even though an output pin can act as a voltage source, the current needs to be limited to prevent damage to the Arduino. Each output pin should only be sourcing up to 20 mA of current, and the total amount of output of all pins combined should never exceed 100 mA. So, for instance, if you have an LED output, be sure to add a resistor to limit the amount of current. Microcontrollers generally cannot drive high-power devices such as motors directly and must rely on some method of amplifying the signal after it leaves them (we will cover amplification in Part 4 of the book).

Inputs to an Arduino are essentially voltage sensors. They will detect a HIGH (around 5 V) or LOW (near 0 V) signal on the pin. You can think of them as having a very large resistor attached to them (about 100 MΩ—100 million ohms), so they don't actually use up any serious amount of current (in other words, you don't have to supply a current-limiting resistor because it is already built in). However, because they use so little current, that means that, just like our inputs in Chapter 12, they cannot be left disconnected, or the results may be randomized from static electricity in the air. Thus, for inputs, you should always attach a pull-up or a pull-down resistor (usually a pull-down) to the input to make sure that the input is *always* wired into the circuit in a known-valid state.

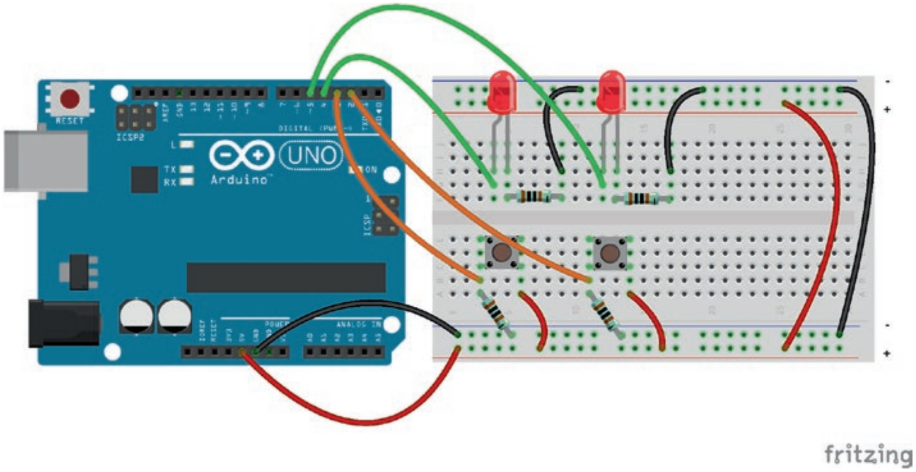

Figure 14-2. *Wiring a Simple Button-Based Arduino Project*

14.3 A Simple Arduino Project with LEDs

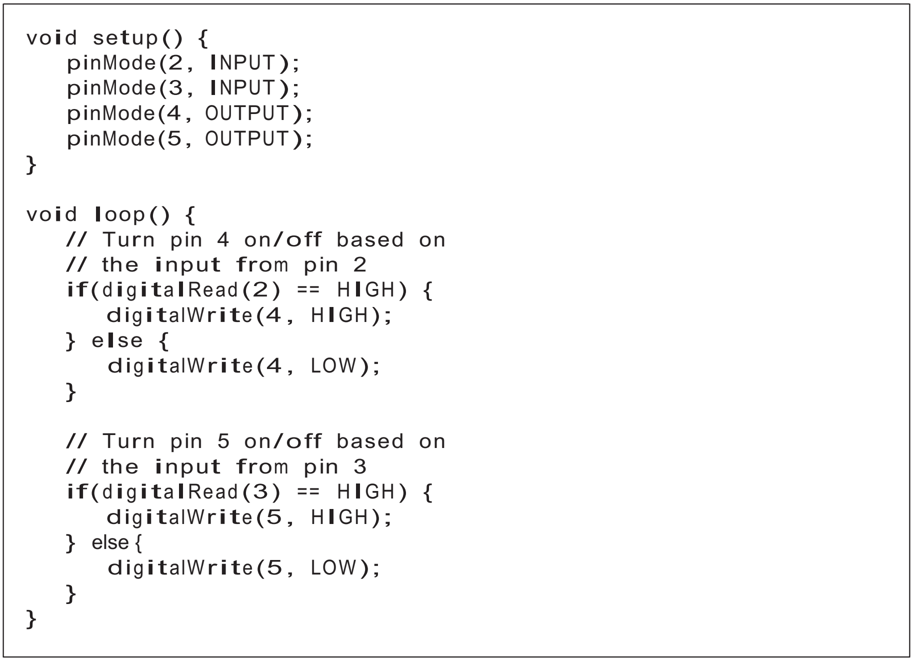
In this section, we are going to look at making a simple Arduino project with two buttons, each controlling one of two LEDs. This would actually be simpler to wire without the Arduino, but the goal is to make a baby step to understanding how Arduino projects work. Later we can do more complicated things, but, for right now, we will just see how we get an input signal to the Arduino and send an output signal back out.

This project is going to have buttons wired into Digital Pin 2 and Digital Pin 3 of the Arduino and LEDs wired into Digital Pin 4 and Digital Pin 5. Let's think about what these need to look like. The LEDs will each need a current-limiting resistor, and the buttons will each need a pull-down resistor.

Figure 14-2 shows how this should be wired up. The breadboard is being powered from the 5 V and GND terminals on the Arduino. The wires on the right side make sure power is connected to both sides of the breadboard. On the bottom, buttons are wired up with pull-down resistors and connected to Digital Pins 2 and 3 on the Arduino. On the top, the LEDs are connected to Digital Pins 4 and 5, with current-limiting resistors making sure they don't draw too much current.

Now, of course, for an Arduino, this is not enough. The Arduino also needs a program to control it! Figure 14-3 shows the program you will need to type in to control the LEDs.

Note that, as usual, the project is divided into two pieces—`setup()`, which only occurs once when the chip starts up, and `loop()`, which continuously runs over and over again until the chip is turned off or reset:



```
void setup() {
   pinMode(2, INPUT);
   pinMode(3, INPUT);
   pinMode(4, OUTPUT);
   pinMode(5, OUTPUT);
}

void loop() {
   // Turn pin 4 on/off based on
   // the input from pin 2
   if(digitalRead(2) == HIGH) {
      digitalWrite(4, HIGH);
   } else {
      digitalWrite(4, LOW);
   }

   // Turn pin 5 on/off based on
   // the input from pin 3
   if(digitalRead(3) == HIGH) {
      digitalWrite(5, HIGH);
   } else {
      digitalWrite(5, LOW);
   }
}
```

Figure 14-3. *An Arduino Program to Control Two Buttons and Two LEDs*

`setup()` simply tells which pins should be in which mode. Note that, unless it includes the calls to the `delay()` function, the `loop()` function will literally run thousands of times per second (or more). The Arduino Uno can execute approximately 16 million instructions per second. Each line of code translates to many instructions, but nonetheless, it goes *really fast*. Just keep this in mind when you are writing programs.

Inside the `loop()` function, we have a new Arduino function—`digitalRead()`. The `digitalRead` function takes a pin number and returns whether that pin is HIGH or LOW. We have put this into a conditional—*if* the read from the button pin is HIGH, then the corresponding LED pin is turned HIGH. Alternatively (i.e., *else*), if the read from the button pin is not HIGH (i.e., it is LOW), then the corresponding LED pin is turned LOW. Note that there are *two* equal signs used in the comparison. In many programming languages, you use two equal signs to tell the computer to compare values. A single equal sign often means that you are *setting* a value (not comparing them).

This book is not a book on computer programming, so we are not going to cover all of the details. Because of this, most of the programs will be given to you, and you will only need to make minor modifications. However, if you are interested in learning more, the programming language being used in the Arduino environment is C++, and the Arduino focuses on the easier-to-understand portions of it. The book *Beginning Arduino Programming* by Brian Evans is a good place to start. If you want to learn more about programming in general (not related to Arduino), you can check out my own book, *New Programmers Start Here*. If you want to understand better how programming works from the perspective of the computer, you can check out my book *Programming from the Ground Up*.

14.4 Changing Functionality Without Rewiring

Now, you might reasonably be thinking, *Wouldn't this be a lot easier if we just directly attached the buttons to the LEDs to turn them off and on?* Indeed, it would. However, by having the inputs and outputs all wired to the Arduino, we can actually *change* the functionality of the project *without* having to do a single bit of rewiring! For instance, if we wanted to have the left button control the right LED and the right button control the left LED, then all we would have to do is swap all of the 2s for 3s in the program and vice versa.

Now imagine if we had spent time developing such a device and even had it sent off to manufacturing, but later decided that we wanted to change the functionality. If all of the logic of the device is implemented by hardware, then that means that you have to throw away all of your old inventory to modify your functionality. If, instead, you use software to connect your components, then oftentimes you can update your device merely by updating your software.

Other modifications we can think of to this simple device might include the following:

1. Making the LEDs turn off rather than on when the buttons are pressed
2. Making the LEDs blink when the buttons are pressed
3. Changing the buttons to be simple toggles, so that you don't have to keep on holding the buttons down to keep the LED on

4. Requiring that the buttons be pushed in a particular order in order to turn on the LED
5. Requiring that both buttons be pushed to turn on the LEDs

This list could go on and on. By routing all control processing through your microcontroller, you make your devices much more flexible. Additionally, at some point, they also become cheaper. When mass-producing, microcontroller chips like the ATmega328/P can be had for just over a dollar. Some chips, when purchased in bulk, cost less than 50 cents! So, if a microcontroller is replacing a complex sequence of logic gates and other control functionality, moving all of your control logic to a microcontroller can actually be much less expensive than hardwiring it, and you get added flexibility as a side bonus.

Review

In this chapter, we learned the following:

1. You can power your breadboards using the 5 V and `GND` pins on the Arduino to simplify power regulation in your projects.
2. Input pins on the Arduino are high-impedance inputs (they act like they have a very large resistor attached, so they don't eat a lot of current).
3. Because input pins use so little current, buttons need to be sure they have a pull-up or pull-down resistor attached to make sure the input is always detecting real voltage values and not static electricity in the air.

4. Care has to be taken when using output pins to make sure the current is never too much for the chip.
5. Using a microcontroller allows you to rewrite the logic of the project without changing the wiring.

Apply What You Have Learned

1. Which Arduino pin do you use when supplying an unregulated voltage (i.e., a voltage above the 5 V that the Arduino runs at)?
2. What Arduino pins would you use to extract power out from an Arduino connected to a power supply?
3. What is the voltage of an output pin set to HIGH?
4. What is the maximum current that should be sourced by any particular Arduino pin?
5. If you have a red LED attached to an Arduino output pin, what is the minimum size of a resistor that you need?
6. If an Arduino input pin is completely disconnected from a circuit, what state does the Arduino read it as?
7. How much current does an Arduino input use?
8. What is the best way to wire a button to an Arduino?
9. What is an advantage of storing a program in a microcontroller even if the logic could be built directly in hardware?

CHAPTER 15

Analog Input and Output on an Arduino

In Chapter 14, we learned how to do basic digital input and output with an Arduino using its I/O pins. In this chapter, we will cover how to do analog input and output as well.

15.1 Reading Analog Inputs

So far we have been focusing on digital input and output—HIGH and LOW states. The Arduino Uno also supports some amount of analog input (through its analog pins) and a sort of "faked" analog output (through its pulse-width modulation (PWM) pins, which will be covered in the next section).

On the Arduino Uno, the analog input pins are grouped together in a section labeled "Analog In." These pins are voltage sensors similar to the digital I/O pins, but they can detect a range of values between 0 V and 5 V (you should never exceed 5 V on any Arduino pin). The `analogRead()` function is similar to the `digitalRead()` function in that it takes a pin number and returns an output value. The difference is that the pin number given to `analogRead()` corresponds to an analog input pin number, not a digital pin number, and the output, rather than being LOW or HIGH, is a number from 0 to 1023 (10 bits of resolution). 0 V will give you a 0, and 5 V will give you 1023. In-between values will give you an in-between result.

Because of this, we can rework the darkness sensor we developed in Chapter 11 to use the Arduino. Since the photoresistor is just a resistor, we *still need* to make it part of a voltage divider to convert the resistance value to a voltage. However, we no longer need the voltage comparator to get it to work—we can just directly connect it to an analog port on the Arduino!

Figure 15-1 shows the darkness sensor rebuilt for the Arduino. Notice that we have a lot fewer custom components, because the control has been moved from hardware to the Arduino's software. We don't need a reference voltage, and we don't need a voltage comparator. We just have one voltage divider to convert the photoresistor's resistance to a voltage (with a wire going to the Arduino's Analog Input Pin 1) and an LED with a current-limiting resistor for the output (fed from Digital Pin 2). Everything else comes from software.

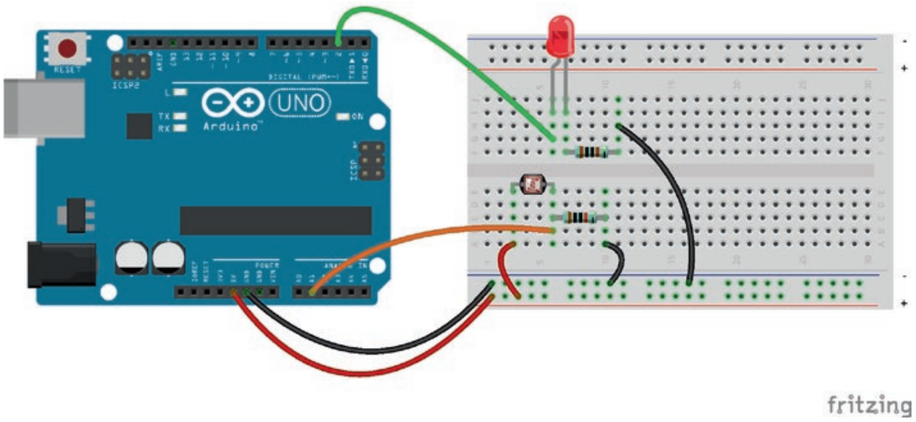

Figure 15-1. *The Darkness Sensor Rebuilt for Arduino*

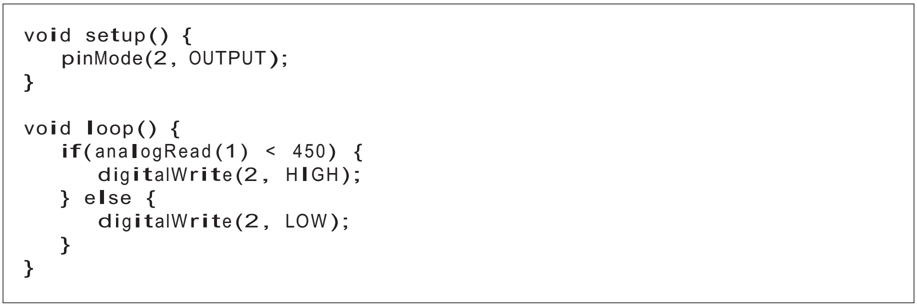


```
void setup() {
   pinMode(2, OUTPUT);
}

void loop() {
   if(analogRead(1) < 450) {
      digitalWrite(2, HIGH);
   } else {
      digitalWrite(2, LOW);
   }
}
```

Figure 15-2. *Code for the Arduino Darkness Sensor*

Figure 15-2 shows the code that will run the sensor. Note that in the `loop()` function, we are now using `analogRead()` rather than `digitalRead()`. Now, instead of it returning HIGH or LOW, it is returning a number. We can then compare that number to a baseline number to tell us whether we should turn the LED on or off.

Now, you may wonder where I got the value to compare against (i.e., 450). What I did was to test the sensor in a variety of conditions and see which value turned off the light when I wanted it to!

However, you may be wondering what exactly the values are that it is reading. Thankfully, the Arduino environment allows a way for us to get feedback from the device while it is running, if it is connected to the computer. To do this, we use what is known as the **serial** interface to the Arduino. This interface communicates over USB so that we can let our computer know how things are going in the program.

To use the USB serial interface, in your setup function, you add the following line:

```
Serial.begin(9600);
```

This tells the chip to initialize its serial interface at 9600 baud (**baud** is an old term meaning "bits per second"), which allows us to talk back to the computer. However, it is important to note that if you use the `Serial` functions, you should not have anything connected to Digital Pin 0 or Digital Pin 1 of the Arduino.

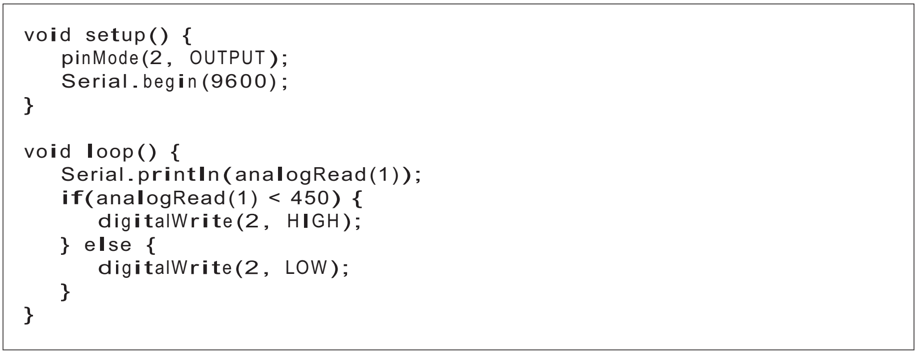
Now, in your program, you can do `Serial.println()` to output any value you want. We will do

```
Serial.println(analogRead(1));
```

to let us know what the current value of the analog input is reading at. The new program, with the added feedback, is shown in Figure 15-3. After uploading this code to the Arduino, to see your output, click the magnifying glass on the top right of the screen. You can also go to the "Tools" menu and select "Serial Monitor." Either way gets you to the same screen. When the code is running, it should be spewing out pages and pages of numbers. Each of these numbers is the current value of `analogRead()` when it is encountered in the code, which happens hundreds or thousands of times each second (it is slowed down a bit by the USB communication, and you could slow it down even further by adding `delay` commands at the end of the `loop` function). This outputting of data in order to better see what is happening within your program is known as **debugging** and is useful for tracking down problems within your code.

15.2 Analog Output with PWM

So we have discussed analog *input*, but what about analog *output*? Truthfully, the Arduino does not support analog output as such. However, analog output is *faked* on an Arduino using a technique known as **pulse-width modulation**, abbreviated as **PWM**. The Arduino only outputs 5 V on its output pins. But let's say we wanted to fake a 2.5 V signal. What might we do? Well, if we turned the pin on and off rapidly so that it was only on for half the time, that would give us about the same amount of electrical power as a continuous output of 2.5 V. That's what PWM does—it fakes lower voltages by just flipping the power to the pin on and off very rapidly so that it "looks" like a lower voltage. In Chapter 22, we will see how to actually convert this to a "true" voltage.



```
void setup() {
   pinMode(2, OUTPUT);
   Serial.begin(9600);
}

void loop() {
   Serial.println(analogRead(1));
   if(analogRead(1) < 450) {
      digitalWrite(2, HIGH);
   } else {
      digitalWrite(2, LOW);
   }
}
```

Figure 15-3. *Darkness Sensor with Serial Feedback*

Arduino programs use the function `analogWrite()` to use a pin for PWM. This function is a little confusingly named because (a) it uses digital pins, not analog pins, and (b) the value is between 0 and 255, not 0 and 1023 like `analogRead()`. Other than that, it basically does what you might expect. `analogWrite(3, 0);` will turn off Digital Pin 3, `analogWrite(3, 255);` will turn it all the way on, `analogWrite(3, 127);` will flick it on and off pretty evenly, and `analogWrite(3, 25);` will keep Digital Pin 3 on only a short time relative to how long the pin stays off.

To get a flavor for PWM, we will do a very simple PWM project—a dimmed LED. Figure 15-4 shows what the connection will look like—just an LED with a current-limiting resistor attached to Digital Pin 3 (which is marked with a ˜ to indicate that it is capable of PWM). Figure 15-5 shows the code to dim the output.

This code is a little more complicated. It's alright if you don't understand it fully, as this isn't a programming book. But I think if you think about it long enough, you can get it.

In short, it creates a **variable**, which is a named temporary storage location for a value (we are calling it `i` for a short name). It is declared an `int`, which means it will hold an integer, and we set it with a starting value of zero.

The `while` command means that this will repeat (or **loop**), executing everything within the block of code between `{` and `}` over and over again, as long as `i` is less than `255`. Within this block, we write the value of `i` to pin `3` using `analogWrite()`. Then, we delay for 10 milliseconds to make sure the change is visible (you can adjust this value to the speed you want the brightness to change at). Then, we increase `i` by one to go to the next value.

The next `while` loop does the same thing but goes the other way. It starts at `255` and progresses down to `0`. Then, when it is all the way to zero, the `loop()` function completes. Then, the Arduino runs the `loop` function over again.

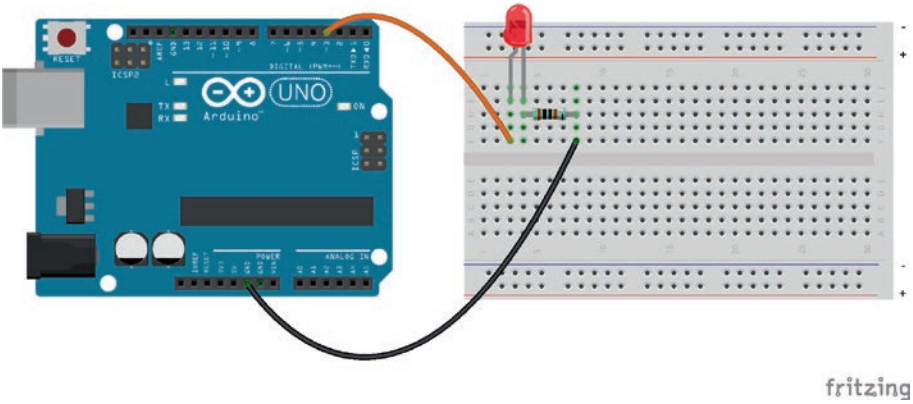


Figure 15-4. *A Simple Analog Dimmer*

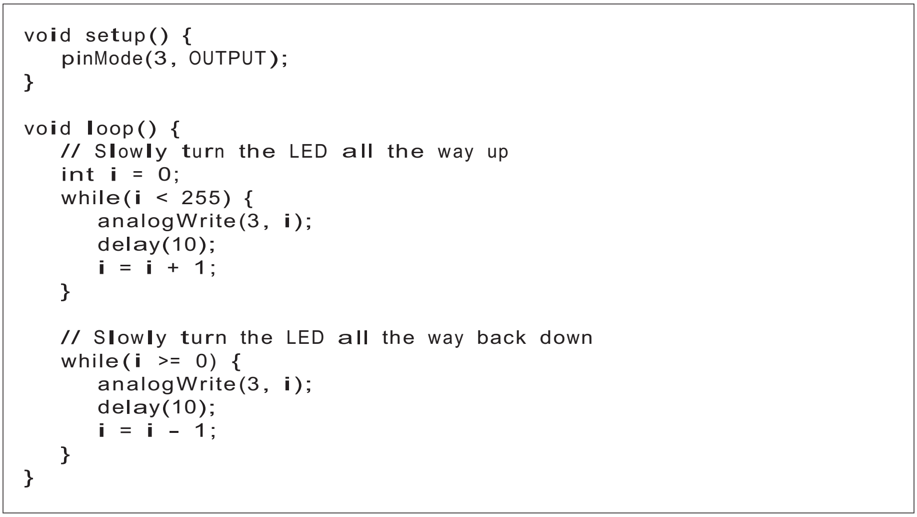
Even though the Arduino is outputting “analog” by switching the pin on and off at different rates, it *looks like* the LED is dimming on and off. It is flickering so fast that we merely perceive it as a lower-energy light than as a pulsing light. In fact, when it gets to about 180 (about 70% on and 30% off), there is not a lot of difference between that and full brightness.



```
void setup() {
   pinMode(3, OUTPUT);
}

void loop() {
   // Slowly turn the LED all the way up
   int i = 0;
   while(i < 255) {
      analogWrite(3, i);
      delay(10);
      i = i + 1;
   }

   // Slowly turn the LED all the way back down
   while(i >= 0) {
      analogWrite(3, i);
      delay(10);
      i = i - 1;
   }
}
```

Review

In this chapter, we learned the following:

1. The Arduino can read voltage values between 0 V and 5 V through the analog input pins, using the `analogRead()` function.
2. The values given from the analog input pins will be integers between 0 and 1023, where 0 represents 0 V, 1023 represents 5 V, and the numbers in between represent in-between voltages.

3. When using resistive sensors, you still need to incorporate the resistive sensors into a voltage divider circuit in order to convert the varying resistance into a varying voltage.
4. We can send debugging information back to the Arduino IDE with the USB serial interface, using the `Serial` object and its related commands.
5. Analog output on Arduino is done with the Arduino *digital* pins (not the analog pins), but only on the ones labeled with a tilde (˜), using the `analogWrite()` function.
6. Analog output on Arduino is done using pulse-width modulation (PWM), which switches the output pin on and off very rapidly to simulate a partial voltage.
7. The analog level of the analog output on the Arduino is specified by a number between 0 and 255, where 0 means no voltage, 255 means to keep the pin at 5 V the whole time, and the numbers in between cause the pin to switch back and forth rapidly to emulate a voltage between the two values.
8. In computer programming, a variable is a temporary storage location for a value.
9. In computer programming, a `while` loop repeats the inside of the while loop over and over again until its condition is no longer valid.

Apply What You Have Learned

1. What do you have to do to a resistive sensor in order to read the value of the sensor on the analog input?
2. In the code that dimmed the lights, how would we slow down the dimming process?
3. Modify the darkness sensor circuit and code so that it will output a dimmed (analog) value to the LED.
4. Further modify the darkness sensor circuit so that, at different darkness levels, the LED has different levels of brightness.
5. Think of your own modifications to the circuits in this chapter. Come up with a new way of putting together the pieces to which you have learned to create some amount of modified functioning. Implement this new design.

PART III

Capacitors and Inductors

CHAPTER 16

Capacitors

In this chapter, we will start looking at the **capacitor.**

16.1 What Is a Capacitor?

Before we begin discussing the capacitor, we need to quickly review the concepts from Chapter 3 on the relationship between charge, current, and voltage. In fact, it might be helpful to reread that chapter if you find that you have forgotten how those terms related to each other.

To review

- Charge is essentially the amount of electrical "stuff" (positive or negative) that something contains, measured in coulombs.
- Current is the *movement* of charge, measured in coulombs per second, also known as amperes.
- Voltage is the amount of force that each coulomb will produce. You can think of it as the amount of electric energy that each coulomb is capable of producing or the amount of power that each ampere of current yields.

A capacitor is a storage device which stores electric energy by holding two opposing charges (i.e., positive and negative). The amounts of charge that the capacitors that we will be working with can store is very small, but some capacitors can store very large amounts of charge. One way to think of a capacitor is as a very, very, very tiny rechargeable battery. However, unlike batteries, instead of storing a fixed voltage, a capacitor stores opposing charges. Unlike a battery, the actual voltage a capacitor yields when it discharges will depend on both the size of the capacitor and the amount of charge it is holding, and the voltage will decrease as the charge is reduced.

Figure 16-1. *The Symbol for a Capacitor*

The size of a capacitor is known as its **capacitance**, and it is measured in **farads** (abbreviated with the letter F), named after the influential scientist Michael Faraday. A capacitance of 1 farad means that if a capacitor stores 1 coulomb of charge, it will discharge with a force of 1 V. Most capacitors, however, have a capacitance much lower than a farad. Capacitors are usually measured in microfarads (1 millionth of a farad, abbreviated as μF or uF), nanofarads (1 billionth of a farad, abbreviated as nF), or picofarads (1 trillionth of a farad, abbreviated as pF). Capacitors are rarely rated in millifarads (1 thousandth of a farad).

So, to convert from microfarads to farads, multiply the capacitance by 0.000001. To go back from farads to microfarads, multiply the capacitance by 1000000. To convert from picofarads to farads, multiply the capacitance by 0.000000000001. To go back from farads to picofarads, multiply the capacitance by 1000000000000.

16.2 How Capacitors Work

The symbol for a capacitor in a circuit is shown in Figure 16-1. This symbol provides a visual reference for how a capacitor works. Capacitors usually work by having two conductive plates or surfaces that are separated by some sort of nonconductive material. Since the two plates are *near* each other, having a charge in one of the plates will pull charge into the other plate due to the **electric field**. An electric field is generated any time a charge accumulates. Essentially, an electric field pulls an opposing charge closer in.

Electric fields influence nearby charges even though they don't directly touch. The field will pull opposite charges closer to itself. Therefore, having a charge in one plate will attract the opposite charge in the other plate. However, since the plates are not actually touching, the electrons cannot actually jump the gap. Therefore, the capacitor will accumulate a certain amount of charge and hold it in its plates.

To understand this better, imagine that you are a positive charge. You are moving through the circuit, but why? What are you moving toward? As a positive charge, you are trying to move to the negative charge. So then, moving along, you see this big swimming pool (i.e., a capacitor). At the bottom of the swimming pool, the barrier is so thin that you can see to the other side. And what do you see there? It's the negative charges—right there at the bottom of the swimming pool! The negative charges have their own swimming pool the size of your own, separated by a barrier so thin that you can see each other.

Because you can see them, you go down into the swimming pool to see if you can interact. A lot of other bits of positive charge see this too, and they go down to see what is going on. However, when you get there, you realize that no matter how hard you try, you can't get to the negative charge that you can see. As more and more charge fills up the swimming pool, it starts to get crowded in the swimming pool. This creates *pressure* in the swimming pool—also known as *voltage*. As the swimming pool gets more and more crowded, it is harder and harder to fit new charge into it, and so the rate that it gets filled goes down, and the voltage (the pressure pushing the charge out of the pool) goes up. The same thing is happening to the negatively charged swimming pool on the other side.

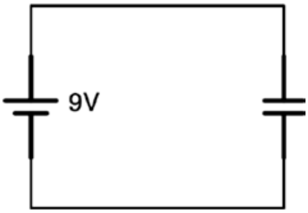

Figure 16-2. *A Simple Circuit to Charge a Capacitor*

When the pressure (voltage) to push charge out of the swimming pool equals the pressure (voltage) of the pipe (wire) leading to the swimming pool (capacitor), then the capacitor is full. When the voltage on the wire goes down (i.e., the battery disconnects), then the pressure of the charges in the capacitor pushes them back out into the wire, discharging the capacitor.

So, if one terminal of the capacitor is connected to the positive side of a battery and the other terminal is connected to the negative side of a battery, charge will quickly flow into the capacitor, as happened in our example with the swimming pool. Figure 16-2 shows this circuit setup. The exact amount of charge that flows in depends on the voltage of the battery and the capacitance of the capacitor (i.e., the size of the swimming pool). Note that this is not a short circuit, because the two plates of the capacitor are *not actually connected*. They are just close enough to attract the opposite charge onto the opposite plate.

In a setup like Figure 16-2, there is an equation that tells you the amount of charge that can be stored in a capacitor for a given voltage:

$$Q = C \cdot V \tag{16.1}$$

In this equation, V is the voltage applied, C is the capacitance (in farads), and Q is the amount of charge (in coulombs) stored in the capacitor's plates.

> **Example 16.7** If I attached a 66 μF capacitor to a 9 V source, how much charge gets stored on the capacitor?
>
> Well, first, we need to convert the capacitance from microfarads to farads. 66 μF is 66 millionths of a farad, so it would be 0.000066 F. Now, we just need to plug the numbers into the equation:
>
> $$\begin{aligned} Q &= C \cdot V \\ &= 0.000066.9 \\ &= 0.000594 \text{ coulomb} \end{aligned}$$
>
> Therefore, if I attached a 66 μF capacitor to a 9 V source, the capacitor would store 0.000594 coulomb of charge.

After my capacitor is charged up, I can use it as a very tiny battery. That is, I could disconnect it from the circuit in Figure 16-2 and reconnect it as the battery for another circuit. However, as I mentioned, this will be a very, very tiny battery. Additionally, as the charge leaves the capacitor, the voltage of the battery will decrease as well.

If we use the capacitor as a battery, if we know how much charge is stored in the capacitor, we can rearrange Equation 16.1 slightly to figure out how much voltage it will deliver when it begins to discharge:

$$V = \frac{Q}{C} \tag{16.2}$$

Now, as the capacitor discharges, since the charge it is holding will decrease, so will the voltage it delivers. If we know how much charge is left at any given moment, we can calculate the present voltage.

> **Example 16.8** If I have a charge of 0.0023 coulomb stored in a 33 μF capacitor, if I discharge the capacitor, what voltage will it begin to discharge at?
>
> The first thing to do here is to convert the capacitance to farads. A microfarad is 1 millionth of a farad, so 33 μF = 0.000033 F. Now we can just plug numbers into the equation:
>
> $$\begin{aligned} V &= \frac{Q}{C} \\ &= \frac{0.0023}{0.000033} \\ &\approx 69.7\text{V} \end{aligned}$$
>
> Therefore, when the capacitor discharges, it will discharge at 69.7 V.

Within a circuit, capacitors are typically used in places where voltages vary. Until the voltage in the capacitor equals the voltage in the circuit, the capacitor will pull charge out of the circuit. When the voltage in the capacitor exceeds the voltage in the circuit, the capacitor will put charge back into the circuit. This dynamic will serve as the core principle used when designing circuits with capacitors.

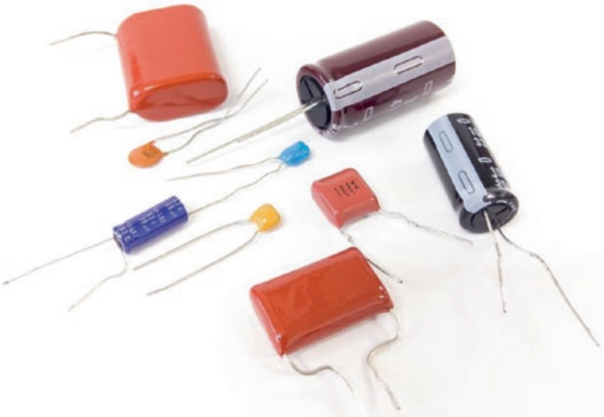

Figure 16-3. *Several Different Types of Capacitors (Shutterstock/ Muhammad Anuar bin Jamal)*

16.3 Types of Capacitors

There are numerous types of capacitors available, each varying in the types of materials they are made of, the internal geometry of the capacitor, and the packaging. Figure 16-3 shows many different types of capacitors that are available.

However, the most important feature of capacitors besides their capacitance is whether they are **polarized** or **non-polarized**. In a *non-polarized capacitor*, it doesn't matter which way you attach the leads. Either side can be the more positive or more negative side. The most common type of non-polarized capacitor is the circle-shaped ceramic disk capacitor. While ceramic disk capacitors are easy to use, they suffer from having limited capacitance.

In a *polarized capacitor*, however, one lead *must* stay more positive than the other lead, or you risk damaging the capacitor. The most common type of polarized capacitor is the electrolytic capacitor. Electrolytic capacitors look like little barrels with leads coming out of them. They usually have much higher capacitances than ceramic disk capacitors, but you have to be sure that the polarity is correct and never switches direction.

On polarized capacitors, it is important to know which lead is positive and which is negative. There are several different ways that a manufacturer might indicate this:

Figure 16-4. *A Polarized Capacitor Symbol*

1. One or both of the leads can be marked with their respective polarities (+ or -).
2. The negative lead can be marked with a large stripe.
3. The positive lead can be longer than the negative.

Many manufacturers do all three.

In a circuit schematic, if a polarized capacitor is called for, it will use a special capacitor symbol as shown in Figure 16-4. The only difference is that one side is curved. In a polarized capacitor, the straight side is the positive side, and the curved side is the negative side. Sometimes polarized capacitors are marked with plus (+) and minus symbols (-) instead of (or in addition to) having a straight side and a curved side.

On any capacitor, it is important to know the capacitance of the capacitor you are looking at. On larger capacitors (especially on electrolytics), manufacturers can print the full capacitance including the units directly on the capacitors. However, many capacitors are extremely small and can't fit that much information on them.

For smaller-sized capacitors, the capacitance is described by three digits and an optional letter. The third digit is how many zeros to add to the end of the other two digits, and then the whole number is the capacitance in picofarads. So, if the number is 234, then the capacitance is 230,000 pF (23 followed by four zeros). If the number is 230, then the capacitance is 23 pF.

The letter at the end tells the *tolerance* of the capacitor—how much the capacitance is likely to vary from its markings. Common letters are J (±5%), K (±10%), and M (±20%).

16.4 Charging and Discharging a Capacitor

To charge up a capacitor almost instantly to a specific voltage, you can (as we also did earlier in the chapter) directly connect the positive and negative leads of the battery to the leads of the capacitor. Once it it charged, you can use the capacitor as a very tiny battery for a project.

In Figure 16-5, we see two simple circuits and an electrolytic capacitor. For this circuit to really work, it helps to have an electrolytic capacitor at least 100 µF and a resitor at least 10 kΩ. So, first, build the LED circuit on the right side of Figure 16-5 on a breadboard. However, don't connect any power to the power rails. Next, take the capacitor, and touch the positive lead of the capacitor to the positive terminal of the 9 V battery and the negative lead of the capacitor to the negative terminal. *Do not let the leads of the capacitor touch each other*. Hold it there for a second or two to allow the capacitor to fully charge. Now, *without touching the leads of the capacitor*, place the capacitor so that the positive lead goes into the positive rail of your breadboard and the negative lead goes into the negative rail of your breadboard. When you do this, the capacitor will power your LED project for a few seconds.

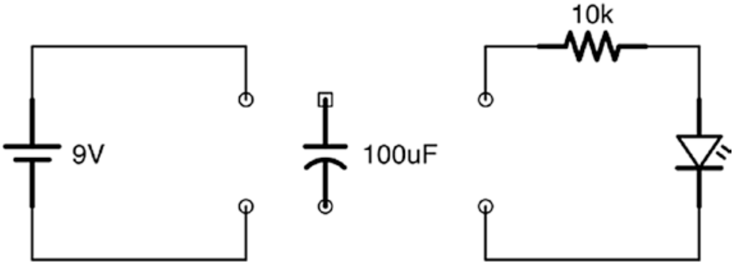

***Figure 16-5.** Using a Capacitor as a Battery*

Now, you will notice that the LED gets dimmer before it goes out. Why does this happen?

Remember that the voltage that the capacitor yields is based on the charge that is present in it. So, going back to Equation 16.2, we can see that the voltage is based on the charge that is in the capacitor. When the capacitor is connected, it will start with a 9 V discharge, since that is what the battery was able to put into the capacitor. However, the capacitor is using up its charge to power the project. This means that as soon as its charge starts leaving, the voltage starts going down, since the voltage is related to how much charge is inside the capacitor.

> **Example 16.9** If we use the components listed in Figure 16-5, how much charge does the battery initially store in the capacitor?
>
> We can use Equation 16.1 to determine this:
>
> $$\begin{aligned} Q &= C \cdot V \\ &= 100\mu F.9\text{V} \\ &= 0.000100\text{F}.9\text{V} \\ &= 0.0009\text{coulombs} \end{aligned}$$

> **Example 16.10** After 0.0003 coulomb of charge has been discharged, what voltage is the capacitor discharging at?
>
> To find this out, we first have to find out how much charge is *remaining* in the capacitor. So, to find this out, we just subtract the amount of charge that has been discharged from our starting charge. This gives 0.0009 – 0.0003 = 0.0006 coulomb.
>
> Now, we can use Equation 16.2 to find out what voltage the capacitor is discharging at:

$$\begin{aligned} V &= \frac{Q}{C} \\ &= \frac{0.0006}{0.000100} \\ &= 6\text{V} \end{aligned}$$

Therefore, the capacitor is discharging at 6 V.

16.5 Series and Parallel Capacitances

Just like resistors, capacitors can be used either in series or in parallel. In fact, they use the same equations for series and parallel capacitance as do resistors. However, there is *one big difference*. The parallel and series versions of the equations are *reversed* for capacitors.

If we want to double resistance in a circuit, we simply add another resistor of the same size in series. If I want to double my capacitance, I can add in another capacitor of the same size. However, for the capacitor, we would add the capacitor *in parallel*. The following is the formula for adding capacitance in parallel:

$$C_T = C_1 + C_2 + \dots \qquad (16.3)$$

If we want to put capacitors in series, we would use a formula that is exactly like the formula for resistors in parallel:

$$C_T = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \dots} \qquad (16.4)$$

Example 16.11 If I have a 100 µF capacitor in series with a 200 µF capacitor, how much total capacitance do I have?

To do this, we use Equation 16.4. It is best to convert our capacitances to farads first. It does not matter as long as the units are the same, but it is good practice to convert to farads so you don't forget when you start doing capacitances in different units. 100 µF is the same as 0.0001 F, and 200 µF is the same as 0.0002 µF.

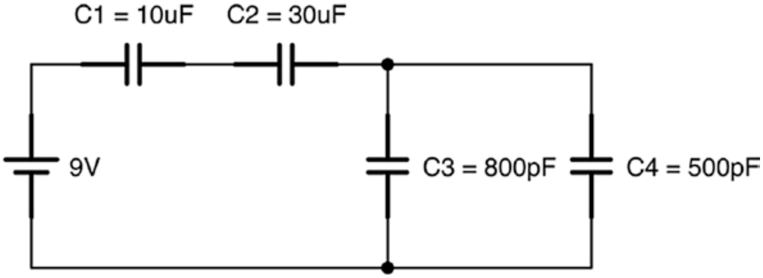

Figure 16-6. *Capacitors in Series and Parallel*

Now, we will plug these values into the equation:

$$
\begin{aligned}
C_T &= \frac{1}{\frac{1}{C_1}+\frac{1}{C_2}} \\
&= \frac{1}{\frac{1}{0.0001\mathrm{F}}+\frac{1}{0.0002\mathrm{F}}} \\
&= \frac{1}{10000+5000} \\
&= \frac{1}{15000} \\
&= 0.0000666\mathrm{F} \\
&= 66.6\mu F
\end{aligned}
$$

Example 16.12 Just as we did for resistors, we can combine a variety of parallel and series capacitances for a single capacitance value. For instance, take the circuit in Figure 16-6. What is the total capacitance of this circuit?

First, we can start by converting all of the capacitances to farads. This will make combining everything easier down the road. In that case, $C_1 = 0.00001$ F, $C_2 = 0.00003$ F, $C_3 = 0.0000000008$ F, and $C_4 = 0.0000000005$ F. C3 and C4 are in parallel, so we can combine them using the parallel formula (Equation 16.3):

$$\begin{aligned} C_T &= C_3 + C_4 \\ &= 0.000000000\text{F} + 0.0000000005\text{F} \\ &= 0.0000000013\text{F} \end{aligned}$$

Now, if we substitute that capacitance in for C3 and C4, we can use the series formula (Equation 16.4) to find the total capacitance of the circuit:

$$\begin{aligned} C_T &= \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_{3\&4}}} \\ &= \frac{1}{\frac{1}{0.00001} + \frac{1}{0.00003} + \frac{1}{0.0000000013}} \\ &= \frac{1}{100000 + 33333.33 + 769230769.23} \\ &= \frac{1}{769364102.56} \\ &= 0.0000000013\text{F} \\ &= 1.3\text{nF} \end{aligned}$$

So the total capacitance of the circuit is 1.3 nF.

16.6 Capacitors and AC and DC

One important characteristic of a capacitor is that it *allows* the flow of AC (alternating current) but it blocks the flow of DC (direct current). To understand why this is, let's think about how capacitors operate.

Capacitors, when they are charging, essentially act as short circuits. As positive charge flows into the capacitor at one terminal, negative charge flows into the other side. An *inflow* of negative charge to that side means that there is a net *outflow* of positive charge on that side. So, *even though the physical electrons never cross the boundary between the plates*, the total charge *actually moves* from one side to the other.

However, this situation is *temporary* because, as the capacitor gets more full of charge, new charge is less likely to enter. Once the capacitor is fully charged (based on the voltage), no new charge can flow into one side to cause the charge to go out to the other.

Once the capacitor is charged, *current stops flowing through it*. If the voltage level on one of the leads *changes*, then charge will flow until the change is compensated for by the capacitor charging or discharging.

Thus, because there is a barrier between the two sides of a capacitor, it is only when the voltage *changes* that the current flows *through* a capacitor. If the voltage stays the same, then charge will stop flowing through the capacitor as soon as it reaches capacity for that voltage.

Because of this, we say that capacitors *allow* AC but *block* DC. This rule of thumb will help us use capacitors in a variety of circuits later on.

16.7 Using Capacitors in a Circuit

In this section, we will discuss the uses of capacitors in a circuit. We haven't discussed enough to actually use capacitors in these ways, but I thought it would be helpful to see why capacitors are used so you can see why you should care about these things.

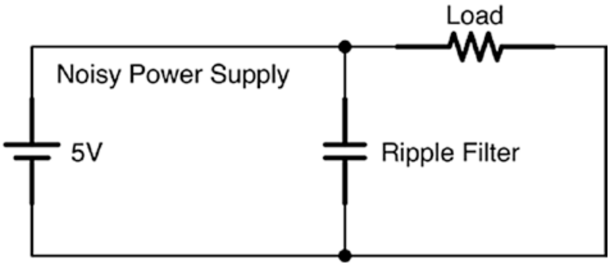

Figure 16-7. *A Capacitor Filtering a Noisy Power Supply*

The first thing that capacitors are used for is for filtering noisy signals, especially in power sources. Imagine that you had a power source which, instead of delivering a constant voltage, the voltage would wobble a bit. If you placed a capacitor in parallel with this circuit, the power source would charge the capacitor up. Then, if the power source dropped a bit, the capacitor would start discharging to compensate. Likewise, if the power source increased, the capacitor would absorb some of that increase by storing the charge.

Thus, by acting as a temporary location to store extra charge, the capacitor can smooth out ripples in a signal, as seen in Figure 16-7. This sort of usage is known as a *filtering* capacitor because it filters out noise.

This can be seen as another implementation of our rule that capacitors allow AC to flow but block DC. When the source voltage has a ripple, the *ripple itself* gets shunted to ground by the capacitor. However, under normal operation, the DC part of the current can't flow through the capacitor and just continues on to the load.

On many ICs that have fluctuating power requirements, you will find many of their spec sheets recommending one or more capacitors on their power supply or other pins in order to filter out the noise.

Another way of using capacitors is as a **coupling capacitor**. A coupling capacitor is used when you have *both* an AC signal and a DC signal combined. This will happen a lot when we talk about amplification. What happens is that we will have an amplified signal, but we *only* want the AC portion of the signal. We can do that by adding in a capacitor to join the segment of the circuit that has both AC and DC components to the segment of the circuit that only wants the AC component. Only the variations in the voltage, not the base voltage, will be transmitted through the capacitor.

Another way that capacitors are used is for filtering specific frequencies. Higher-frequency signals are easily transmitted through a capacitor, but low-frequency signals are essentially blocked as if they were DC. The frequencies that are allowed are based on the capacitance. If you put a capacitor in series with the signal path, then it will only allow higher frequencies. If you put a capacitor in parallel with the signal path, then it will ony allow lower frequencies (the higher frequencies will be shunted to ground).

CAPACITOR SAFETY

If you see a capacitor in any sort of equipment, do not touch it, even with the power off. Because capacitors store charge, they can still hold onto the charge even after the power is off. If you need to touch a capacitor for some reason, use a resistor to discharge it. Placing a large (megaohm) resistor between the leads of a capacitor (without touching the leads yourself!) for a few seconds should drain most capacitors. You can also use a multimeter to determine that the capacitor is drained (0 volt).

Review

In this chapter, we learned the following:

1. An electric field is generated wherever there is an accumulated charge.
2. A capacitor is a device that stores electric energy by holding two opposing charges.
3. Capacitors are sized by their capacitance which is measured in farads.
4. Because a farad is so large, capacitors are usually measured in microfarads, nanofarads, or picofarads.
5. Polarized capacitors (usually electrolytic capacitors) have distinct positive and negative terminals, while non-polarized capacitors (usually ceramic disk capacitors) can go either way.
6. When a battery is connected to a capacitor, it will store a charge on the capacitor.
7. The equation for the charge (Q) stored on the capacitor when a battery is connected is $Q = C \cdot V$ where C is the capacitance in farads, V is the voltage, and Q is the charge in coulombs.
8. By rearranging the equation, we can determine, for a given amount of charge, how much voltage a capacitor will discharge when it is allowed to: $V = \frac{Q}{C}$.
9. As the capacitor discharges its charge through the wire to create current, the amount of charge remaining will decrease, which will also lower the voltage it is putting out.

10. Capacitors with small packages are often marked with a three-digit code, where the third digit is the number of zeros to add to the other two digits and the final number is in picofarads.
11. When multiple capacitors are used together, their capacitances can be combined similar to resistors, but with the series and parallel equations switched.
12. The series capacitance equation is as follows:

    $$C_T = \frac{1}{\frac{1}{C_1} + \frac{1}{C_2} + \ldots}$$

13. The parallel capacitance equation is as follows: $C_T = C_1 + C_2 + \ldots$
14. Capacitors allow the flow of AC through them but block the flow of DC.
15. Capacitors can be used to split AC (high-frequency) and DC (low-frequency) portions of a signal. The AC portion will travel through the capacitor, while the DC portion will remain on one terminal side.
16. Capacitors can be used to filter audio frequencies, filter power supply ripples, operate as voltage boosters, and couple together a combined AC/DC circuit with an AC-only circuit.

2. Convert 15 μF to farads.
3. Convert 35 pF to farads.
4. Convert 0.0002 F to microfarads.
5. Convert 0.0030 μF to farads.
6. If a voltage of 6 V is applied to a 55 μF capacitor, how much charge would it store?
7. If a voltage of 2 V is applied to a 13 pF capacitor, how much charge would it store?
8. If a 132 μF capacitor is holding 0.02 coulomb of charge, how many volts will it produce when it begins to discharge?
9. If a 600 pF capacitor is holding 0.03 coulomb of charge, how many volts will it produce when it begins to discharge?
10. A 121 μF capacitor is connected to a battery. After some fluctuation, the capacitor has 0.00089 coulomb of charge stored in it, and the battery is reading 8.9 V. Is the capacitor going to be charging or discharging at this point?

CHAPTER 17

Capacitors as Timers

In this chapter, we are going to learn how to measure the time it takes for a capacitor to charge. Once we learn this, we can use capacitors for timers—both for delaying a signal and for creating an oscillating circuit.

17.1 Time Constants

As we learned in Chapter 16, when a voltage is applied to a capacitor, it will store energy by storing a charge on its plates, the amount of charge being based on the voltage supplied and the capacitance of the capacitor (see Equation 16.1).

The cases we examined in Chapter 16 generally had the battery connected directly to the capacitor. In such cases, the capacitor charges to the source voltage almost immediately. However, if a capacitor charges through a resistor (instead of being directly connected to the battery), then it takes much longer to fill the capacitor to capacity than if it were connected to the battery directly. In fact, it never *fully* reaches capacity, though it gets close enough that we say that it does.

Having a resistor in series with a capacitor is a configuration known as an **RC (resistor-capacitor) circuit**. The amount of time it takes a capacitor to charge is based on both the resistance of the resistor and the capacitance of the capacitor. The actual equation for this is kind of complicated, but there is a simple trick that suffices for nearly every situation, known as the RC time constant.

J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_17

The RC time constant is merely the product of the resistance (in ohms) multiplied by the capacitance (in farads) which will yield the RC time constant in seconds. The RC time constant can be used to determine how long it will take to charge a capacitor to a given level (we will talk about what this level is in a moment). So, for instance, if I have a 100 μF capacitor and a 500 Ω resistor, the RC time constant is 0.0001 ∗ 500 = 0.05 second.

This constant can then be used with the table in Figure 17-1 to determine how long it will take to charge a capacitor to a given level.[1]

# of Time Constants	**% of Voltage**	**% of Current**
0.5	39.3%	60.7%
0.7	50.3%	49.7%
1	63.2%	36.8%
2	86.5%	13.5%
3	95.0%	5.0%
4	98.2%	1.8%
5	99.3%	0.7%

Figure 17-1. *RC Time Constants*

For instance, if I wait for 2 time constants (in this case, 0.05 * 2 = 0.1 second), my capacitor will be charged to 86.5% of the supply voltage. The current flowing through it will be at 13.5% of what current would be flowing if there was just a straight wire instead of a capacitor.

---

[1] For those curious how these numbers are calculated, see Appendix D, Section D.7.3, "Time Constants."

While a capacitor is never really “fully charged” (because it never fully reaches 100%), in this book, we will use 5 time constants to consider a capacitor fully charged.

> **Example 17.13** I have a power supply that is 7 V and a capacitor that is a 100 μF capacitor. I want it to take 9 seconds to charge my capacitor. What size of a resistor do I need to use to do this?
>
> To solve this problem, we need to work backward. Remember, we are considering 5 time constants to be fully charged. Therefore, the time constant we are hoping to achieve is 9/5 = 1.8 seconds. The capacitance is 100 μF, which is 0.0001 F. Since the time constant is merely the product of the capacitance and resistance, we can solve for this as follows:

$$\begin{aligned} RC\ \text{TimeConstant} &= \text{capacitance} \cdot \text{resistance} \\ 1.8 &= 0.0001 * R \\ 0.0001 * R &= 1.8 \\ R &= \frac{1.8}{0.0001} \\ R &= 18000 \end{aligned}$$

Therefore, to make it take 9 seconds to charge the capacitor, we need to use an 18 kΩ resistor.

In the same way, if we connect the capacitor to ground through the resistor instead of to the voltage supply, the capacitor will discharge in the same way that it charged. It will begin discharging a lot, but then, as it gets closer to zero, it will level off the amount that it is discharging. You would then read Figure 17-1 to know what percentage of the voltage/current the capacitor has *discharged*.

Example 17.14 Suppose a 100 μF capacitor has been charged up to 7 V and then is disconnected from the power supply, but the ground connection remains. We then connect the positive terminal of the capacitor to a 5 kΩ resistor that connects to ground. After 2 seconds, how much voltage is remaining in the capacitor?

To find this out, we first need to find the RC time constant of the circuit.

$$\begin{aligned} T &= 5k\Omega * 100\mu F \\ &= 5{,}000\,\Omega * 0.0001\,\mathrm{F} \\ &= 0.5\ \text{seconds} \end{aligned}$$

So the RC time constant is 0.5 second.

So, after 2 seconds, we have performed 4 RC time constants. Looking at Figure 17-1, we have discharged 98.2% of the capacitor's voltage. This means that the amount of voltage *lost* should be 0.982 * 7 V = 6.874 V. If we have lost that much voltage, that means we should subtract it, so the remaining voltage is 7 V – 6.874 V = 0.126 V.

So the voltage after 2 seconds will be 0.125 V.

17.2 Constructing a Simple Timer Circuit

Let's say that we want a circuit that, when turned on, *waits* for a certain amount of time and then does something. How might we do it?

Think of it this way. We can use capacitor charging to give us a time delay. However, we need something that "notices" when the time delay is finished. In other words, we need a way to trigger something when a certain threshold is crossed.

What happens to the capacitor as it charges? The voltage across its terminals changes. When it is first connected to the circuit, there is zero voltage across its terminals. As it charges, the voltage across the capacitor's terminals keeps going up until it matches the supply voltage. Therefore, we know when we have hit our target time based on when the voltage is at a certain level. But how will we know when we are at the right voltage? Have we done a circuit so far that detects voltages? What component did we use?

If you remember back in Chapter 11, we used the LM393 to compare voltages. We supplied the LM393 with a *reference* voltage, and then it triggered when our other voltage went above that voltage. We can do the same thing here.

What we will construct is a circuit that waits for 5 seconds and then turns on an LED. In order to do this, we will need to choose (a) a reference voltage to use, (b) a resistor/capacitor combination that will surpass the reference voltage after a certain amount of time, and (c) an output circuit that lights up the LED.

There are virtually infinite combinations we could choose from for our reference voltage, resistance, and capacitance. In fact, the supply voltage doesn't matter so much since what we are looking at are *percentages* of the supply voltage, which will be the same no matter what the actual voltage is.

For this example, we will use a basic 5 V supply and make the reference voltage to be half of the supply voltage. This allows us to use any two equivalent resistors for a voltage divider to get our reference voltage.

Now, since the reference voltage is half of our supply voltage, we will use the table in Figure 17-1 to determine how many time constants that needs to be. The table says that for 50% of voltage, it will take 0.7 time constant (it is actually 50.3%, but we are not being that exact).

Therefore, the equation for our resistor and capacitor is

$$\begin{aligned} T &= 5 \text{ seconds} \\ 5 \text{ seconds} &= 0.7 \cdot R \cdot C \\ \frac{5}{0.7} &= R \cdot C \\ 7.14 &= R \cdot C \end{aligned}$$

So we can use any resistor and capacitor such that the ohms multiplied by the farads equals 7.14. I usually use 100 μF capacitors for larger time periods such as this because they are larger and because being exactly 0.0001 F, it makes it easier to calculate with. Therefore, we can very simply calculate the needed resistor for this capacitor:

$$\begin{aligned} 7.14 &= R \cdot C \\ 7.14 &= R \cdot 0.0001 \\ \frac{7.14}{0.0001} &= R \\ 71400 &= R \end{aligned}$$

Therefore, we need a resistor that is about 71, 400 Ω. We could choose a combination of resistors that hits this exactly, but for our purposes, we only need to get close. In my case, the closest resistor I have is 68,000 Ω (i.e., 68 kΩ). That is close enough (though I could get even closer by adding in a 3 kΩ resistor in series).

Figure 17-2 shows the full circuit. When building this circuit, don't forget that the comparator also has to be connected to the supply voltage and ground as well! As you can see, R2 and R3 form the voltage divider that provides the reference voltage for the comparator at half of the supply voltage. The values for R2 and R3 are arbitrarily chosen, but they must be equal to get the reference voltage. I chose medium-high values for these resistors so as to not waste current with the voltage divider. The circuit made by R1 and C1 is the timing circuit. When the circuit is first plugged in, C1 is at voltage level 0, essentially acting as a short circuit while it first begins to store charge. At 0 volt, this is obviously less than our reference voltage. However, as the capacitor charges, less and less current can flow into C1. Its voltage level increases under the rules of the RC time constant. After 0.7 time constant, the voltage will be above the voltage level set by the reference voltage, and our voltage comparator will switch on.

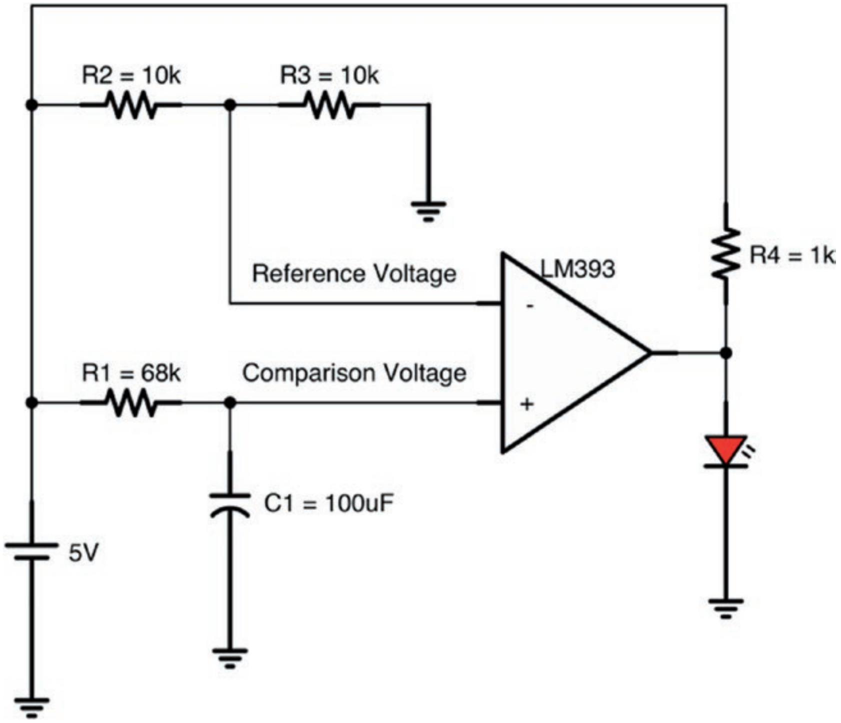

Figure 17-2. *A Simple Timer for an LED*

Remember, though, from Chapter 11, that the LM393 operates using a pull-up resistor. That is, the comparator doesn't ever source current. It will sink current (voltage level 0 when the + input is less than the – input) or disconnect (when the + input is greater than the – input). Therefore, R4 is providing a pull-up resistor to supply power to the LED when the LM393 disconnects.

Figure 17-3 shows this circuit laid out on the breadboard. We are using the second voltage comparator of the LM393 just because it was a little easier to show the wiring for it. If you need to see the pinout for the LM393 again, it was back in Figure 11-4.

Notice the prominence of our basic circuits from Chapter 9 on the breadboard. On the top, we have a combination pull-up resistor which is also acting as a current-limiting resistor (as they often do). On the bottom left, we have a voltage divider.

On the bottom right, we have our new timing circuit, which looks a lot like a voltage divider. In fact, it acts like one too, where the voltage varies by time! If you think about what the capacitor is doing, when we first apply voltage, it acts like a short circuit—in other words, no resistance. This means that there is 0 volt across the capacitor and the resistor is eating up all of the voltage. But, as the capacitor fills up, it increases voltage, which it is *dividing* with the resistor! Just like before where we had a sensor which created a sensor-based variable voltage divider, here we have what is essentially a time-based variable voltage divider.

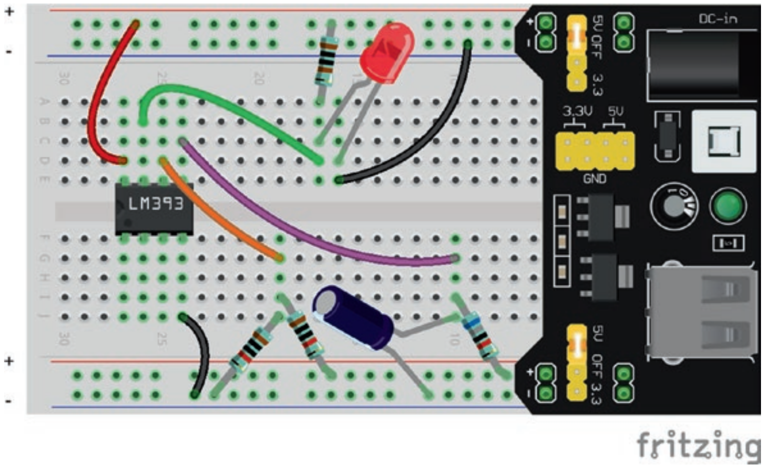

Figure 17-3. *The Capacitor Timer Circuit on a Breadboard*

17.3 Resetting Our Timer

The timer is great, except for one thing—how do we turn it off? You might have noticed that, even if you disconnect power to the circuit, when you turn it back on, it doesn't do any timing anymore! Remember, the capacitor is *storing* charge. When you turn off the circuit, it is *still* storing the charge.

Now, you can very simply get rid of the charge by putting a wire between the legs of the capacitor. However, for larger capacitors, you would need to do this with a resistor instead of a wire in order to keep there from being a dangerous spark (the resistor limits the current, which makes the discharge slower). But how do we do this with a circuit?

What we can do is add a button or switch that will do the same thing as putting a wire or resistor across the legs of the capacitor. Figure 17-4 shows how to do this.

Now let's look at how this circuit works. First of all, we added two components, the switch and the R5 resistor connected to it. To understand what this does, pretend for a minute that the resistor isn't there. What happens when we push the button? That would create a direct link from the positive side of the capacitor to ground. Since the negative side of the capacitor is also connected to ground, that means that these two points would be directly connected. Thus, they would be at the *same* voltage. This would be achieved by the charge suddenly rushing from one side to another to balance out.

If the capacitor were larger or the voltages greater, this might be somewhat dangerous. You would have a large current and a large voltage for a short period of time (which would yield a large wattage), which could blow something out. Therefore, it is good practice to use a small resistor between the button and ground. The resistor should be *much* smaller than the resistor used to charge the capacitor. The specific size doesn't matter too much—it needs to be small enough to discharge it quickly and large enough to prevent a spark when you push the button. You can use the same time constants for discharging the capacitor that you used for charging it. However, keep in mind that the charging circuit is still running! That's why the resistor has to be small—it has to discharge the capacitor *while* the other resistor is trying to charge it.

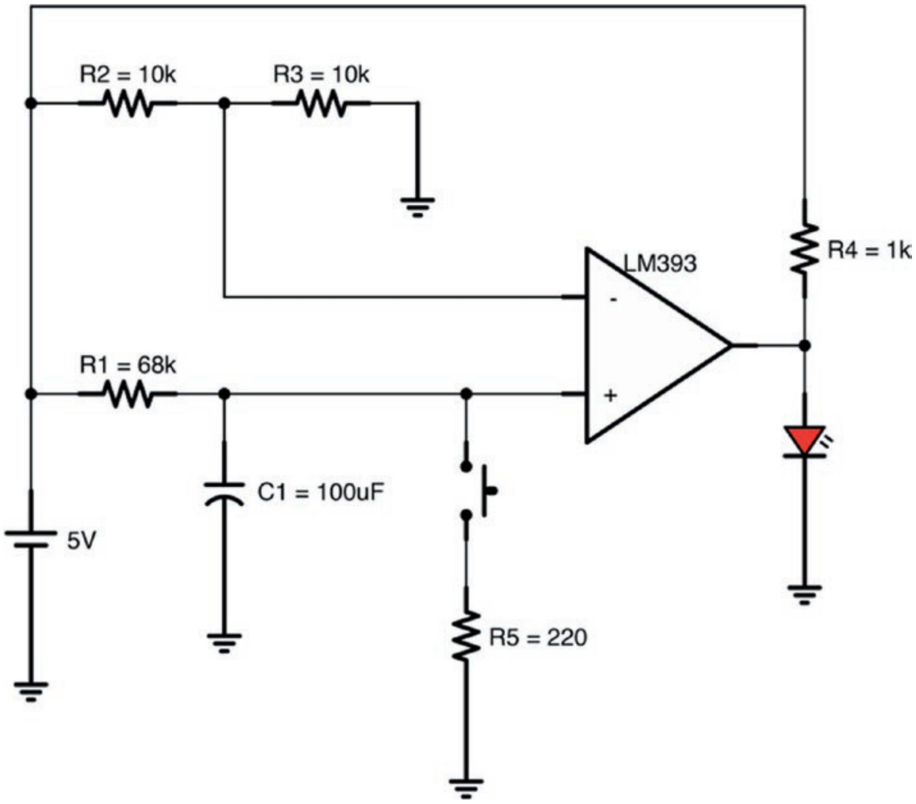

Figure 17-4. *Adding a Reset to the Capacitor*

Also notice R1 and R5. When the button is being pushed, what is happening to them? Think back to our basic resistor circuits. If we have two resistors, with a wire coming out of the middle, what is that? It's a voltage divider! So not only is R5 being a current-limiting resistor for the button, it is also acting as a voltage divider in concert with R1.

What this means is that the capacitor will only discharge down to the level of voltage division between these resistors. That's fine, as long as it is low enough. You will find that in electronics, "close enough" often counts. The trick is knowing how close is close enough and how close is still too far.

However, usually we can perform some basic calculations to figure this out. Since R1 is 68 kΩ and R5 is 200 Ω, what is the voltage at the point of division? If we use a 9 V supply, using the formula from Equation 9.1, then we can see that

$$\begin{aligned} V_{OUT} &= V_{IN} \cdot \frac{R_5}{R_1 + R_5} \\ &= 9 \cdot \frac{220}{68000 + 220} \\ &= 9 \cdot \frac{220}{68220} \\ &\approx 9 \cdot 0.00322 \\ &\approx 0.029\text{V} \end{aligned}$$

So, as you can see, when the button is pushed, the final voltage of the capacitor, while not *absolutely* 0 volt, is pretty darn close.

Also note that, if we wanted, we can reverse the action of this circuit. By swapping our two inputs to the voltage comparator, we can make the circuit be on for 5 seconds and then switch off.

Review

In this chapter, we learned the following:

1. Having a resistor and capacitor in series with each other is known as an RC circuit.
2. In an RC circuit, the amount of time it takes for a capacitor to charge to the supply voltage is based on the capacitance of the capacitor and the resistance of the resistor.

3. The RC *time constant* is a convenient way to think about how long it takes for a capacitor to charge in RC circuits.

4. The RC time constant is calculated by multiplying the resistance (in ohms) by the capacitance (in farads) with the result being the number of seconds in 1 RC time constant.

5. The table in Figure 17-1 shows how long it takes to charge a capacitor to different percentages of supply voltage as a multiple of RC time constants.

6. The RC time constant chart can also be used to calculate the amount of time it takes for a capacitor to discharge to ground if it is disconnected from its source and connected through a resistor to ground. In this case, Figure 17-1 is used to tell what percentage of the voltage has been *discharged*.

7. A timer can be constructed by using a comparator and an RC circuit along with a reference voltage provided by a voltage divider. By tweaking the RC circuit, the timing can be changed.

8. After charging a capacitor, a means needs to be provided to discharge it as well, such as a button leading to ground.

9. Such discharge methods need to have resistance to prevent sparks and other failures, but not too much resistance as they can accidentally form voltage dividers with other resistors in the circuit and prevent full discharge.

10. Even as our circuits get more advanced, the basic circuits we found in Chapter 9 are still dominating our circuit designs.

Apply What You Have Learned

1. If I have an RC circuit with a resistor of 10 Ω and a capacitor of 2 F, what is the RC time constant of this circuit?
2. In the previous question, how many seconds does it take to charge my capacitor to approximately 50% of supply voltage?
3. If I have an RC circuit with a resistor of 30,000 Ω and a capacitor of 0.001 F, what is the RC time constant of this circuit?
4. In the previous question, what percentage of the capacitor's voltage is charged after 60 seconds?
5. If I have an RC circuit with a resistor of 25 kΩ and a capacitor of 20 μF, what is the RC time constant of this circuit?
6. Give a resistor and capacitor combination that will yield an RC time constant of 0.25 second.
7. Reconfigure the circuit in Figure 17-2 to wait for 3 seconds. Draw the whole circuit.
8. Redraw the previous circuit and circle each basic resistor circuit pattern and label it.

CHAPTER 18

Introduction to Oscillator Circuits

In Chapter 17, we learned how to use RC (resistor-capacitor) circuits to create timers. In this chapter, we are going to use our concept of timing circuits to move from one-time timer circuits to *oscillating* circuits.

18.1 Oscillation Basics

So far, most of the circuits we have made have been fairly directional. You do an action (i.e., press a button) and then something happens, but then the circuit just maintains a steady state after that. In Chapter 17, we at least added a delay—allowing the circuit to do something *later*.

However, if you want actions to continue on into the future, you need to not only have delays, you need to have *oscillations*. **Oscillation** means to go back and forth. An oscillating circuit is one that goes back and forth continually between two states—usually zero voltage and some positive voltage. Imagine blinking lights at Christmas. These lights go from a state of zero voltage (off) to a state of positive voltage (on). And they go back and forth between these states over and over again as long as there is power in the circuit. These are oscillating circuits.

J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_18

An oscillator is usually described by either its **period** or its **frequency**. The period of an oscillator is how many seconds it takes to go through one complete cycle. So, if I had lights that blinked on for 1 second and then off for 2 seconds (and continued repeating in that fashion), the period would be 3 seconds.

The frequency of an oscillation is the number of times that the system cycles every second, which is merely the reciprocal of the period (i.e., one divided by the period). So, in the example given, since the period was 3 seconds, the frequency is $\frac{1}{3}$ cycle per second. The "cycles per second" unit of frequency also has a special name—**hertz** (often abbreviated as Hz). Therefore, we would say that our blinking lights blinked at a frequency of $\frac{1}{3}$ Hz.

> **Example 18.15** Let's say that we have an oscillator that turns a light on for 4 seconds and then turns off for 4 seconds and repeats this continually. What is the period and frequency of this oscillator?
>
> The period is merely the total time it takes to go through one complete cycle. Therefore
>
> $$\begin{aligned} \text{period} &= 4 \text{ seconds on} + 4 \text{ seconds off} \\ &= 8 \text{ seconds} \end{aligned}$$
>
> So what is the frequency of this oscillator? Simple—just take the reciprocal of the period. That makes the frequency $\frac{1}{8}$ Hz.
>
> **Example 18.16** On a piano, the middle-C key plays a sound with a frequency of 261.6 Hz. What is the period of this sound?

> Since the frequency is the reciprocal of the period, it works the other way around as well—the period is the reciprocal of the frequency. Therefore, the period is simply $\frac{1}{261.6}$ second. Or, as a decimal, this is 0.00382 second.

There are many other factors that are important to various kinds of oscillations, such as the speed of transition between states, what percentage of time each state is achieved, and so on. However, the period/frequency is a good way to summarize the behavior of an oscillator into a single number.

18.2 The Importance of Oscillating Circuits

Oscillating circuits are important in electronics for a number of reasons. First, obviously, is blinky lights. Who goes into electronics without being enamored by blinking lights? But, more importantly, the following are all applications of oscillators in circuits:

> Sound Production: Sounds and tones are made by moving a speaker back and forth, which is moved back and forth by electricity oscillating between different voltages.
>
> Time Clocks: Every clock on earth operates by an oscillator. The clock simply counts the number of oscillations that have occurred to know whether or not to advance another time step (second, minute, etc.).
>
> Hardware Coordination Clocks: In computers and other advanced hardware, system events are coordinated based on signals from an oscillating circuit. When the clock changes state from off to on (or the reverse), then the circuit does the next step in the process. The clock keeps the various circuits synchronized and keeps them from stepping on each other.

> Radio Transmissions: Oscillators are used in radios in order to encode signals onto “carrier waves,” which are just oscillating signals run at a specific frequency.
>
> Servo Motors: A servo is a motor which moves an arm to a specific angle (i.e., think of a car’s steering wheel). Servos are usually operated by frequencies, where each frequency specifies a different angle to move.

Let’s look in more depth about how sound is produced by oscillation. You hear sound through your eardrum, which communicates vibrations it detects to your brain which you interpret as sound. Therefore, any sound that you hear is merely the vibrations of your eardrum. In other words, your eardrum *oscillates* back and forth, which you interpret as sound.

What makes your eardrum move back and forth? The answer is oscillations in the air. What makes those oscillations happen? Oscillations in the sound speaker. When the speaker moves back and forth, it moves the air which produces sound that you hear.

But what moves the speaker back and forth? Oscillations in the voltage and current supplied to the speaker. The speaker has a magnet attached to it which responds to changes in voltage in the wire. As the voltage in the wire increases, it moves the speaker in one direction. As the voltage decreases, the speaker moves in the other direction. Thus, the oscillations in voltage eventually wind up as sound for your ears.

18.3 Building an Oscillator

Let's think for a moment of what it would take to build an oscillator. An oscillator has (at least) two different states—on and off.[1] Then, you have a time period of changing from one state to the other.

What sort of circuit have we looked at that provides a time period?

As we saw in Chapter 17, RC (resistor-capacitor) circuits can provide us with time delays. We can then use these time delays as the time periods between the states of the oscillation. What we need is a circuit that will give out a state (we'll called it S1) for a time period (we'll call it T1) and then move to another state (we'll call it S2) and stay there for another time period (we'll call it T2). After T2 is finished, the circuit moves back to state S1 and begins again.

Now, it is possible that we might be able to build such a circuit using multiple RC timers with multiple comparators. It is doable, but it is harder than it sounds. Thankfully, there is an integrated circuit that is built for making such timers—the NE555, often referred to as just a "555 timer" or just a "555." The NE555 is a very flexible component, and engineers are constantly finding new ways to make use of it. However, we will just focus on using it as a basic oscillator.

It is easiest to describe how a 555 works if we start out by showing a simple circuit with it. The circuit in Figure 18-2 blinks an LED on and off.

The order of the pins on the actual 555 chip is a little confusing (see Figure 18-1). In order to make understanding the circuit in Figure 18-2 easier, I have simply put tags for each pin in the diagram, so you can see where they each belong *functionally*.

Figure 18-2. *A Schematic of a Simple 555 Oscillation Circuit*

First, let's look at the pins on the left-hand side of Figure 18-1 that are directly connected to the power rails. Pin 1 (`Ground`) and pin 8 (`VCC`) are easy enough—they are connected to ground and positive voltage, respectively. Pin 4 ($\overline{\text{Reset}}$) gets connected to the voltage source too. That is a reset pin which is activated if the pin receives a *low* voltage signal. Pins that are activated by low-voltage signals are often shown with a line over them.[2] In our case, we never want to reset the chip, so we will just tie the reset pin to positive voltage which will prevent any accidental resets from changes in voltages in the environment.

Now, on the right-hand side at the top, you can see the LED connected to pin 3 (`Output`). Pin 3 is simply the output pin. It is an active output, meaning that it will supply current to the output on its own. We don't need a pull-up resistor as we did for the LM393. Instead, we just need a current-limiting resistor for the LED. The regular NE555 output yields a voltage that is about 1.7 V less than the supply voltage and sources up to 200 mA before it breaks.

Note that there are other, low-power versions of the 555 timer that have other output characteristics. For instance, the LMC555 has an output voltage that is equal to the input voltage, but can only source about 100 mA. For our purposes, either one would work, as we are not doing anything precise with our output, nor are we sourcing very much current. However, any calculations we do will assume a typical NE555 component.

On the bottom right, pin 5 (`Control`) is connected through a 10 μF capacitor to ground. This is just a standard part of using the chip. You can't effectively include capacitors in integrated circuits larger than a few picofarads, so many chips specify certain capacitors be attached to certain pins. The NE555 uses a 10 μF capacitor on pin 5 to provide voltage stability. In Chapter 16, we learned that capacitors act essentially like little batteries. This capacitor is doing just that. It is providing a short-term supply of charge in case there is a sudden change in current needs within the chip. For instance, when the output goes active, there may be a sudden need for charge. This capacitor supplies a quickly available reservoir of charge to the chip so that sudden changes in current needs will not affect other chip properties.[3]

---

[2] Since most pins are activated by a higher voltage, pins that are activated with a lower voltage get the special designator.

[3] For most of our uses of the NE555, you can actually leave pin 5 unconnected—our usage of the chip is not so precise or power-hungry as to be affected in this way. Nonetheless, I show it connected so that you can see how it is *supposed* to be connected.

Down the middle of the schematic is where all of the action happens. This is what controls the oscillation. It is essentially an RC circuit with (a) an extra resistor and (b) a few tie-ins to the chip. As we will see shortly, the capacitor will alternately charge and discharge. The capacitor itself is attached to two voltage sensors on the chip. The first sensor, $\overline{\text{Trigger}}$, watches the voltage on the capacitor and activates if the voltage falls below $\frac{1}{3}$ of the supply voltage (the line over the name of the pin indicates that it activates on a low value). The second sensor, `Threshold`, watches the voltage and will activate if the voltage goes above $\frac{2}{3}$ of the supply voltage.

The oscillator works by moving the capacitor voltage back and forth between $\frac{1}{3}$ and $\frac{2}{3}$ of the supply voltage. It is fairly obvious to see how the capacitor charges—it is a basic RC circuit using both of the resistors R1 and R2. So how does the capacitor discharge? The capacitor discharges through the action of the `Discharge` pin, pin 7. When the 555 starts up, pin 7 essentially acts as if it were not connected to anything, so you can basically ignore it. When the capacitor goes over the $\frac{2}{3}$ supply voltage and triggers the `Threshold` pin, the 555 will then connect pin 7 to ground.

Think about what will happen if pin 7 is connected to ground. Will the capacitor charge? No, the current coming in through R1 will immediately go to ground because it is the easiest path. If the capacitor is charged up, is it above or below ground? It is obviously above ground. Therefore, current will flow *out of* the capacitor, through R2, and to ground. Thus, the capacitor discharges, but at a *different* rate than it charged. The RC circuit for the charging of the capacitor used both R1 and R2 for the resistance. However, the discharge of the capacitor only uses R2. Therefore, the discharge from $\frac{2}{3}$ voltage down to $\frac{1}{3}$ voltage will be faster than the charge up.

Figure 18-3. *Current Flow During the Charge and Discharge Phases*

Once the capacitor discharges down to $\frac{1}{3}$ of supply voltage, pin 2 ($\overline{\text{Trigger}}$) will detect this event and turn pin 7 off so that the capacitor can recharge again. Therefore, the capacitor will be continually charging and discharging from $\frac{1}{3}$ to $\frac{2}{3}$ of supply voltage, as the 555 turns pin 7 (connected to ground) on and off. This is also why having two resistors is so important. If we didn't have R1, when pin 7 connected to ground, it would make a short circuit between the supply voltage and ground.

Figure 18-3 shows the different current flows of this part of the circuit during the charging and discharging phases.

You may be wondering why there are two detectors connected to the capacitor and not just one. The reason for this is that having two different detectors allows for a *lot* of flexibility in how the 555 is wired. As mentioned earlier, there are a huge number of ways the 555 has been used, and some uses tie $\overline{\text{Trigger}}$ and `Threshold` to different parts of the circuit. For our purposes, both of these will always be used together.

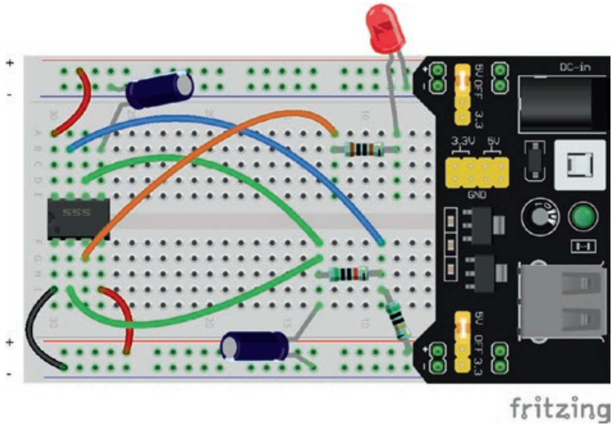

Figure 18-4. *The 555 Oscillator Circuit on a Breadboard*

So how does this charging and discharging of the capacitor affect the output? Quite simply, when the capacitor is *charging*, the output is *on*. When the capacitor is *discharging*, the output is *off*. Note that when we first turn on the 555, the output will be on for a little bit longer than for the rest of the time. This is simply because when the circuit first starts up, it is charging all the way from 0 V instead of from $\frac{1}{3}$ of supply voltage.

You can see the completed 555 circuit on a breadboard in Figure 18-4. This should blink the light on for about two-thirds of a second and off for about a third of a second. This gives the total period of about 1 second and a frequency of about 1 Hz. In the next section, we'll see how to use RC time constants to calculate our own on and off times.

18.4 Calculating On and Off Times with the 555

Remember that the capacitor is charging and discharging through an RC circuit. Therefore, we can use what we know about RC circuits to determine how long the output circuit will be high and low.

When the capacitor is *charging*, the capacitor is charging through *both* R1 and R2. In this situation, what is the RC time constant? First, we need to know the resistance. Since the resistance here is a series resistance, we can simply add them together:

$$\begin{aligned} R_T &= R_1 + R_2 \\ &= 50,000 + 50,000 \\ &= 100,000 \end{aligned}$$

So the resistance is 100,000 Ω, and we are using a 10 μF capacitor (which is 0.00001 F). Therefore (based on Chapter 17), the RC time constant is 100,000 $*$ 0.00001 = 1. So our RC time constant is 1 second. However, we are charging/discharging the capacitor in a strange way. We are not starting from zero (except for the first time)—instead we are usually starting from $\frac{1}{3}$ of supply voltage.

Go back to Chapter 17 and look at Figure 17-1. While we don't have a time constant for *exactly* $\frac{1}{3}$ of supply voltage, we do have one for 39.3%, which is pretty close. So, in the table, that occurs as 0.5 time constants. In this case, that is our *starting* value. Our ending value is when the capacitor is $\frac{2}{3}$ charged. That is very close to 63.2%, which is at 1 time constant.

Therefore, the *difference* between the points where we are $\frac{1}{3}$ charged and $\frac{2}{3}$ charged is $1 - 0.5 = 0.5$ time constants.

Since we were using approximate values from the table, this is only an approximation to see how this idea works. The distance from $\frac{1}{3}$ to $\frac{2}{3}$ of supply voltage actually takes 0.693 time constant. This is an important number to remember when using the NE555, as it will be used in all of your time calculations. Since our time constant is 1 second, that makes the calculation really easy: $1 * 0.693 = 0.693$ seconds.

Now, for discharge, remember that the point that the capacitor is discharging to is pin 7. This is *between* R1 and R2. That means that it is *only* using R2 to discharge, so the RC time constant will be based only on R2 and the capacitor. So the RC time constant is $50{,}000 * 0.00001 = 0.5$ seconds. Since the charge/discharge time between $\frac{1}{3}$ and $\frac{2}{3}$ is 0.693 time constants, the resulting time to discharge from $\frac{2}{3}$ down to $\frac{1}{3}$ is $0.693 * 0.5 = 0.347$ seconds.

The total period will be the total time for one cycle. This will be our charge time (0.693 second) plus the discharge time (0.347 second) which will give us a total of 1.04 seconds.

The value 0.693 looks like a strange number, but that will *always* be the value used for the number of time constants for charging/discharging between $\frac{1}{3}$ and $\frac{2}{3}$ of supply voltage. If you are going to use the 555 timer, it is best to just memorize it.

Also note that since the charging goes through *both* resistors while the discharge only goes through *one* resistor, the charge time (with the output on) will *always* be longer than the discharge time (with the output off).

> **Example 18.17** Let's say we have the basic oscillator circuit shown in Figure 18-2, but with a 2,000 Ω resistor for R1, a 6,000 Ω resistor for R2, and a 10 μF capacitor for C1. What will be the charge time, the discharge time, the period, and the frequency for our oscillator?

To find this out, it is easiest to first calculate the charge and discharge times separately and then use those to find period and frequency. The charge time will be calculated based on *both* resistors in our RC circuit. So the resistance will be 2,000 Ω+6,000 Ω = 8,000 Ω. The capacitance is 10 μF = 0.00001 F. This means that the RC time constant will be 8,000 Ω ∗ 0.00001 F = 0.08 seconds.

The number of time constants it takes to charge from $\frac{1}{3}$ to $\frac{2}{3}$ is 0.693. This means that the charge time will be 0.08 ∗ 0.693 = 0.0554 seconds.

The discharge happens only through R2. This means that the RC time constant will be 6,000 Ω ∗ 0.00001 F = 0.06 seconds. Since we will use 0.693 time constants, the total time it takes to discharge from $\frac{2}{3}$ down to $\frac{1}{3}$ is 0.693 ∗ 0.06 = 0.0416 seconds.

Now that we have the charging and discharging times, we find the period by merely adding them together. This means the period is 0.0554 + 0.0416 = 0.097 seconds.

The frequency is merely the reciprocal of this number, or $\frac{1}{0.097}$, which gives us 10.3 Hz.

Example 18.18 Now let's say that we want to

build an oscillator for which the LED stays on for 3 seconds and then goes off for 2 seconds. Assuming we keep our 10 μF capacitor, what values should we use for each resistor?

To do this, we need to solve for R2 first, since it is much easier. The discharge will be 2 seconds, which will be the same as 0.693 time constants. Therefore, we can write this as an equation:

$$\begin{aligned}
&2\text{seconds} = R \cdot C \cdot 0.693\\
&2\text{seconds} = R \cdot 0.00001 \cdot 0.69\\
&2\text{seconds} = R \cdot 0.0000069\\
&\frac{2\text{seconds}}{0.0000069} = R\\
&289{,}855\Omega \approx R
\end{aligned}$$

So the resistor, R2, needs to be 289,555 Ω.

The time to charge the capacitor, however, needs to be 3 seconds. This means the resistance (which will be *both* R1 and R2) will need to be calculated for this as well. Therefore, we will use a similar equation:

$$\begin{aligned}
&3\text{seconds} = R \cdot C \cdot 0.693\\
&3\text{seconds} = R \cdot 0.00001\text{F} \cdot 0.693\\
&3\text{seconds} = R \cdot 0.00000693\\
&\frac{3\text{seconds}}{0.00000693} = R\\
&434{,}783\Omega = R
\end{aligned}$$

So the resistance for charging the capacitor needs to be 434,783 Ω. However, this is the *combined* resistance for R1 and R2. Thankfully, though, we already know what we want for R2—289,855 Ω. Therefore, we can put these into an equation and solve for R1:

$$
\begin{aligned}
R_1 + R_2 &= 434,783\Omega \\
R_1 + 289,855\Omega &= 434,783\Omega \\
R_1 &= 434,783\Omega - 289,855\Omega \\
R_1 &= 144,928\Omega
\end{aligned}
$$

So now we know our values for R1 and R2—144,928 Ω and 289,855 Ω. Depending on our application, we would probably simply choose resistors that were close to that amount (like 150 kΩ and 300 kΩ) rather than trying to find a combination of resistors that hit that precise resistance. But, for solving equations, it is best to use exact values.

18.5 Choosing the Capacitor

Ultimately, there are no hard-and-fast rules for choosing capacitors. As long as the RC time constant yields the right value, then you can compensate for pretty much any size capacitor with the right size of resistor. However, sometimes just having a little guidance helps people get started, and there are a few situations that you need to watch out for.

First of all, the size of the capacitor will affect the size of the resistor you need for a given time constant. If all you have are smaller-sized resistors, then you should probably use a larger capacitor to compensate.

However, using a smaller capacitor with larger resistors gives a very large advantage in the amount of wasted current. If you are using smaller resistors, then Ohm's law indicates that we will have larger currents for a given voltage. Since $V = I \cdot \mathrm{R}$, if you lower the R, you will increase the I. So having a higher resistance means that your RC circuit will use much less current.

Remember that we aren't actually *using* the current to *do* anything except keep time. The current in our RC circuit is not used to power the LED (the 555 does that through the power source), and it isn't used for anything else; it is just used to keep time. Therefore, pretty much all current used by the RC circuits is wasted. We have to use it, but any smaller currents we can get away with, we should!

This gets even more pronounced when the capacitor is discharging. When pin 7 (`Discharge`) switches to ground, not only does it discharge the capacitor but it also creates a useless waste of current going from the voltage source through R1. In our oscillator configuration, you can't get rid of this, but having larger resistors will reduce the amount of waste.

So, in short, if you have higher-valued resistors to compensate, your circuit will waste much less current by using smaller capacitors.

Review

In this chapter, we learned the following:

1. Because this material is based so heavily on RC circuits, you may want to review the material in Chapter 17.
2. When something oscillates, it moves back and forth between a set of values.
3. In electronics, oscillators usually refer to circuits whose output voltages go back and forth between two different values.
4. Oscillations are usually described by their period or frequency.
5. The period of an oscillation is the time that it takes to go through one entire cycle (usually in seconds).
6. The frequency of an oscillation is the number of times that an oscillation occurs per second, which is simply the reciprocal of the period (i.e., $\frac{1}{\text{period}}$), with a unit of hertz (cycles per second).

7. Oscillating circuits are used in a number of circuit applications, including sound production, time keeping, coordinating activities, radio transmissions, and motor control.

8. Oscillating circuits are often built with RC time circuits which control the time periods of the oscillations.

9. The NE555 (often referred to as a 555 timer or just the 555) is an integrated circuit which allows for several timing applications including making oscillating circuits.

10. The NE555, when set up as an oscillator, is controlled by two resistors and a capacitor.

11. The NE555 can be set up to monitor the charge of the capacitor. It has two pins for monitoring the voltage, $\overline{\text{Trigger}}$ (which checks for the capacitor to drop below $\frac{1}{3}$ of supply voltage) and `Threshold` (which checks to see when the capacitor is charged above $\frac{2}{3}$ of supply voltage).

12. The NE555 cycles between charging and discharging the capacitor from $\frac{1}{3}$ of supply voltage to $\frac{2}{3}$ of supply voltage and back (using $\overline{\text{Trigger}}$ and `Threshold` to check the voltage level).

13. The `Discharge` pin of the NE555 acts like it is disconnected when the capacitor is charging and is connected to ground to allow for a path for the capacitor to discharge when in the discharge part of the cycle.

14. The `Output` pin of the NE555 is turned on (higher voltage level) while the capacitor is charging and off (low voltage level) when the capacitor is discharging.
15. The NE555 output operates at about 1.7 V less than the source voltage when on and can source a maximum of 200 mA to the output circuit.
16. The $\overline{\text{Reset}}$ pin can be given a low voltage to reset the whole device. If it is unused, it should just be tied to a positive voltage line.
17. The `Control` pin is attached to a capacitor in order to regulate and stabilize the circuit operation.
18. The RC circuit takes 0.693 time constants to charge from $\frac{1}{3}$ voltage to $\frac{2}{3}$ voltage or to discharge the other way. Therefore, once you have the RC time constant, multiply by 0.693 to find the actual time it will take.
19. The RC circuit utilizes *both* resistors when charging, but only *one* resistor when discharging. This means that charging and discharging each have their own RC time constants.
20. Because the charge circuit uses two resistors while the discharge circuit only uses one, the charging portion of the oscillation period will always be at least a little longer than the discharging portion.
21. The period of the oscillation is the combination of both the charge time and the discharge time.

22. When calculating for resistors for an RC time circuit, it is best to calculate the discharge resistance first, since it only uses one resistor (R2). Then you can calculate the combined resistance for the charge circuit, which allows you to deduce what the R1 resistor should be.

23. When choosing components for a given RC time constant, you can choose a variety of combinations of capacitor/resistor values for the same result. Choosing a smaller capacitor and a larger resistor will save power in the circuit.

24. An equation for determining the frequency of a 555 oscillator circuit can be found in Appendix D, Section D.4, "555 Timer Oscillator Frequency Equation."

Apply What You Have Learned

Figure 18-2 will be used as the basis for the problems in this section:

1. Copy Figure 18-2 to a piece of paper including the current flows on charge and discharge.

2. Why is R1 important? What would happen if we just replaced it with a wire?

3. Why are there two different pins on the NE555 connected to the capacitor? What type of circuit (that we have discussed in this book) do you think they are connected to inside the chip?

4. Why is the charging time of the NE555 always at least a little longer than the discharging time?

5. Why does the NE555 stay in the on state a little longer when the circuit is first turned on?
6. Let's say that we wanted our circuit to be on for 2 seconds and off for 1 second. Keeping the same capacitor, what values should we use for R1 and R2 to accomplish that?
7. Let's say that we wanted our circuit to be on for 10 seconds and off for 3 seconds. Keeping the same capacitor, what values should we use for R1 and R2 to accomplish that?
8. The factory called and said that they were out of the capacitor we wanted for the circuit and instead only had a 23 µF capacitor that we could use. Recalculate the previous problem using this new capacitor value.
9. How much current is our output sourcing from the chip?
10. When the chip first turns on (and thus the capacitor is empty and at 0 V), how much current is the RC circuit in Figure 18-2 using?

CHAPTER 19

Producing Sound with Oscillations

In Chapter 18, we learned to make an oscillator circuit. Oscillations affect a lot of areas of electronics, but the one that is most directly usable (well, besides making blinky lights) is in making sounds.

19.1 How Sound Is Produced by Speakers

As we mentioned in Chapter 18, sound is the result of vibrations (i.e., oscillating motions) in the air. These vibrations are produced in electronics with a speaker when the speaker oscillates back and forth. The speaker oscillates back and forth because it is connected to a magnet and a coil. When the electricity in the coil oscillates between more positive and more negative charges, the magnet is attracted to and repelled from the coil, moving the speaker back and forth.

The frequency of this oscillation will determine the pitch of the sound (i.e., how high or low the sound is). If the frequency is higher (shorter periods), then the pitch is higher. If the frequency is lower (longer periods), then the pitch is lower.

© Jonathan Bartlett 2020

J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_19

Now, compared to the blinking lights we worked with in Chapter 18, sounds that you can hear are all of a much higher frequency. The bottom end of the hearable audio is about 20 Hz—that is, 20 cycles per second. The top end is about 20 kHz (i.e., 20,000 Hz). These values vary by individual, but this is a pretty good guide for most people. If we tried to blink an LED that fast, we just would not be able to see it—it would just look like a dimmer-than-normal light.

19.2 Graphing Electricity

Now, when we deal with circuits that are oscillating quickly, we need to have a way to visualize what is happening. With circuits that have one or two states, we don't need to visualize much—we just need to calculate what the values are. However, with circuits that are continually oscillating (such as sound circuits), it is helpful to be able to graph what the voltages are at different points in time.

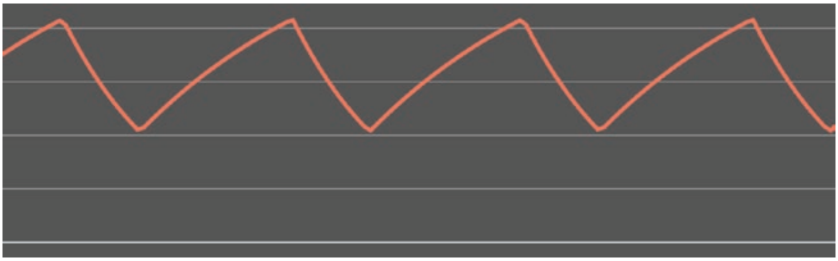

Figure 19-1. *A Graph of the Capacitor Voltage in a 555 Oscillator*

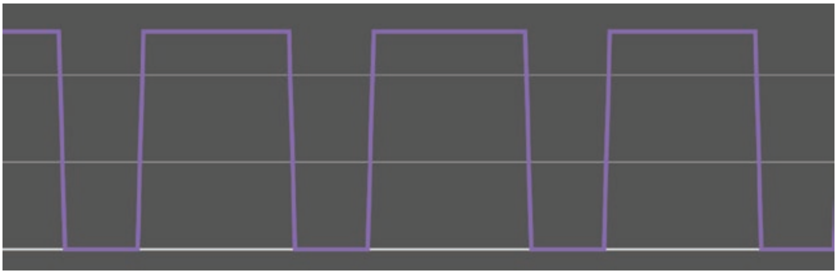

Figure 19-2. *A Graph of the Output Voltage in a 555 Oscillator*

There are several ways to graph electricity. One of the most common ways is to plot *time* on the *x*-axis and *voltage* on the *y*-axis. This gives a visible representation of how the voltage is varying within the circuit. Now, because each point on a circuit has a different voltage, you have to specify *which point* on the circuit you are graphing. For instance, if you take the 555 oscillator circuit from Chapter 18 (i.e., Figure 18-2), the two places whose voltages you might want to graph are (a) right before the capacitor and (b) right after the output pin.

These will give *very* different graphs, but both of them are instructive. The graph of (a) will show you what the input side of the circuit looks like, and the graph of (b) will show you what the output side of the circuit looks like.

Notice that Figure 19-1 changes fairly smoothly (except when it changes directions). This is because capacitor charging causes the voltage to change smoothly over time. It charges up until it reaches $\frac{2}{3}$ of supply voltage and then discharges down to $\frac{1}{3}$ of supply voltage. It does this over and over again as you can see on the graph.

The output, however, is either *on* or *off*. Therefore, Figure 19-2 shows a very jagged graph. This is known as a **square wave**, because it is basically rectangular. The voltage just goes from zero to the target voltage almost instantly, and then after it stays there a bit, the voltage goes back down again just as instantaneously as it rose.

In addition to graphing voltage, we can also graph current in the same way, though it is harder to measure. Because voltage can be measured with simple probes and measuring current requires replacing a wire, most of the time, people just focus on voltage measurements.

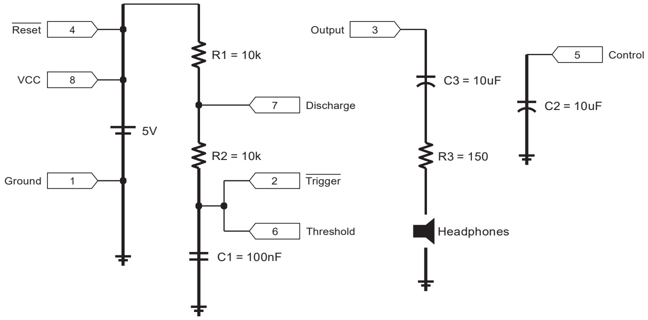

Figure 19-3. *Schematic for a Simple 555-Based Tone Generator*

Special devices known as **oscilloscopes** can be used to measure voltage changes over time. Graphs such as those in Figures 19-1 and 19-2 can be made by hooking up an oscilloscope to the circuit while it is in operation.[1] Oscilloscopes used to cost thousands of dollars, but now you can pick up a small handheld oscilloscope for under $50.

Usage of an oscilloscope is outside the scope of this book, but the basics are simple enough. An oscilloscope usually has an active probe and a ground probe. You hook up the ground probe to the ground on your circuit, and you hook up the active probe to the point on the circuit that you want to measure. Then, you look at the screen, and it will graph for you what the voltage is at that point over a period of time. Most oscilloscopes have all sorts of adjustments, such as how wide of a voltage range you want to measure and how long of a time window you want to show on the screen. In any case, oscilloscopes provide graphical views of oscillating voltages.

19.3 Outputting a Tone to Headphones

In this section, we are going to modify the circuit in Figure 18-2 to add in a headphone output. Figure 19-3 shows the final circuit, and Figure 19-4 shows how to build it. This circuit has several changes to our original circuit that we will discuss in this section.

---

[1] The graphs depicted in the figures are actually idealizations, however, not actual output from an oscilloscope.

The first changes to this circuit are to the RC time circuit. Because we want the circuit to be in audio range, we are making a much higher frequency (i.e., a shorter period). To do this, we swapped out the electrolytic capacitor for a ceramic disk capacitor of 100 nF. Then, we dropped the resistors down to 10 kΩ each. This will make a tone with a period of 0.003 seconds. Taking the reciprocal gives us a frequency of about 333 Hz. This is well within hearing range for most people. You can adjust the resistors and capacitors how you wish for different tone frequencies. We are merely using the equations from Chapter 18 to determine the period and frequency.

The strange change is in the output circuit. When we were blinking the LED, we just used a medium-sized resistor to limit output current. Here, however, we are using a combination of a capacitor and a resistor. This *looks like* an RC time circuit—and it would be, if it had a constant voltage going to it. However, in this circuit, the voltage going to the RC circuit is fluctuating, and that introduces a whole host of new considerations.

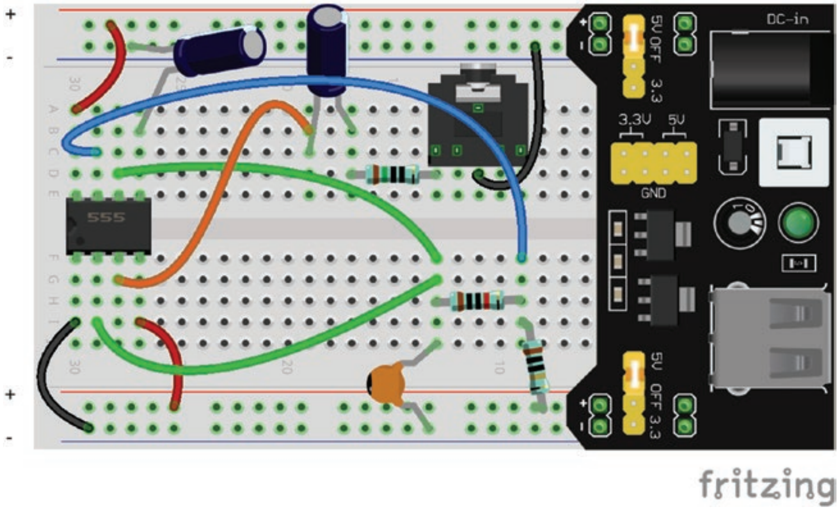

Figure 19-4. *Breadboard Layout for a 555-Based Tone Generator*

19.4 AC vs. DC

In Chapter 3, we introduced the ideas of *direct current* (DC) and *alternating current* (AC). In DC circuits, the circuit has a more-or-less constant voltage. Our power supply is at a certain voltage, our output is at a certain voltage, and so on. In AC circuits, however, the voltage oscillates back and forth. These oscillations introduce a whole new set of considerations.

In pure AC circuits, voltage and current actually swing both to positive and negative values. What is a negative current? A negative current happens when the electricity flows in the *opposite* direction. Thus, in a *pure* AC circuit, electricity flows back and forth, switching between directions while it is running, spending about even time in each direction.

Some components, such as speakers, assume that they are going to receive or process pure ACs. That is, they *expect* the current to switch direction at some point. As mentioned earlier, the speaker is driven by changing voltages in a coil, which alters the attraction of the coil to a magnet. These variations in attraction and repulsion move the coil back and forth, which moves the speaker cone, which vibrates the air, which vibrates your eardrum, which you hear. Speakers expect the oscillating current to go back and forth each direction about evenly.

However, in our circuit, the voltage only swings between a positive voltage and 0 V. If you look at the graph in Figure 19-2, notice that while the voltage goes up to a positive voltage, the *lowest* that it ever goes is zero. Therefore, it is not a pure AC circuit, because it is not centered around 0 V. Instead, the AC has a **DC bias voltage**. That is, the output voltage can be thought of as a combination of an AC voltage signal added to a DC voltage.

19.5 Using Capacitors to Separate AC and DC Components

Sometimes having a DC bias is good, and sometimes we need to separate out our AC and DC signals. Capacitors are excellent at this. Capacitors are said to *allow* AC to flow and to *block* DC. This is a simplistic view, and we will get a little more nuanced in future chapters, but it works for now.

To understand why this happens, let's remember what a capacitor does physically. It stores charge—like a small battery. Remember, even though the pathway between the plates of a capacitor is blocked, when a positive charge accumulates on one side, it pulls electrons onto the other side, which means that the other side beyond the capacitor gets more positive as well. Do you remember what happens when the capacitor *first* starts charging? The capacitor basically acts as a short circuit. As the capacitor fills up, it starts acting more and more like a resistor, preventing current from flowing.

Thus, when given a constant voltage, once the capacitor is nearly full, it essentially stops getting more charge (or comes very close to it). Therefore, once it is full, it is basically *blocking* any more current from flowing. Since what goes onto one side of the capacitor affects what is on the other side, this same blockage will block the *transmission* of the current to the other side as well. Thus, in the long run, if you have a DC voltage, the capacitor will eventually block current flow. Thus, the current on the *other* side of the capacitor will be *zero*.

However, now consider what happens if the voltage *changes*. If the voltage changes, then the capacitor will allow current to flow through. If the voltage goes up, then the capacitor has more storage available (since the amount of storage depends on voltage). While it is charging to the new level, current will be flowing. If the voltage goes down, then the capacitor will actually have to discharge back into the circuit.

Now, if the capacitor discharges back into the circuit, *which way is the current flowing*? Well, that means the current from the capacitor is now flowing in the *opposite* direction!

Thus, what ends up happening is that the capacitor winds up only sending *changes* in voltage to the other side of the circuit! While the capacitor is charging and discharging, charge is moving through both sides of the capacitor. Thus, when the voltage (and therefore the charge) on the capacitor is changing, current is indeed flowing. Now, when the voltage stays the same, no electrons move, no matter what the voltage is. Therefore, even though you have a positive voltage on one side, if the voltage is not changing, no current is flowing. Therefore, on an unchanging current, the voltage on the other side of the capacitor will be zero.

Since the changes go up and down, but the DC bias voltage does not go up and down, this has the effect of sending AC through the capacitor, but blocking the DC bias voltage.

Therefore, capacitors are often used in series in a circuit to couple together parts of the circuit that are pure AC with other parts of the circuit that have a DC bias. Since the output of the 555 is DC biased and speakers generally are optimized for pure AC output, the capacitor in our output circuit filters out the DC bias and gives a pure AC signal.

A capacitor used in this way is known as a **coupling capacitor**.

Alternatively, if for some reason you wanted *only* the DC component, you could wire the capacitor to go to ground. This sends the AC part of the signal to ground, leaving only the DC component in the circuit. In such a scenario, the capacitor is being used as a **filter capacitor**.

Now, using a coupling capacitor does add in a small amount of distortion, both because DC bias voltage does have some effect on the signal and because different capacitor values are optimal for coupling different frequencies. For audio applications, a capacitor somewhere between 10 nF and 10 μF should be used.

19.6 Speaker Wattage

Next in the circuit is the R3 resistor. The R3 resistor is there to limit the output signal to the headphones. Headphones and speakers are all a little strange—there is very little standardization. Different headphones have different resistances in the speakers and different tolerances for how much wattage can be put through them. Speakers are usually rated by (a) how much resistance they normally add to the circuit, (b) how loud they are at a given wattage of power, and (c) what their maximum wattage is. Even though there is quite a bit of variance, for headphones, you can be fairly safe by estimating that the headphones will act as 16 Ω resistors and that they can consume a maximum of 20 mW.

The output of the 555 timer is 1.7 V less than my supply voltage. So, for a 5 V source, the output will be 3.2 V. However, since we have now centered it on 0 V, the output will actually only be half of that—1.6 V. We can use the formula $P = \frac{V}{(R^2)}$ from Chapter 10 to determine how many watts this will supply. If the speaker is 16 Ω, then the power used by the headphone without the extra resistor will be $\frac{(1.6^2)}{16}$ = 0.16 W = 160 mW. Therefore, the R3 resistor pulls out some of that power.

With the resistor, the combined power usage of the resistor and the headphone speaker is 166 Ω. Therefore, the power here is $\frac{(1.6^2)}{166}$ = 0.015 W = 15 mW. Remember, though, that this is the *combined* power of both the resistor and our speaker. The speaker is only supplying about $\frac{1}{10}$ of the resistance, so it is only using up to $\frac{1}{10}$ of the power, or 1.5 mW.

Now, the calculation for this is relatively easy because we are working with square waves. The calculation becomes harder for different types of output, because you have to take into account the *shape* of the wave.

However, we won't go into that in this book. This calculation using the peak voltage provides a simple method which will give you a good starting point, and you can judge for yourself if you need more or less resistance for your own circuits.

19.7 Sound Control

Now, as I mentioned, all headphones are different, and, with the exception of *having* a coupling capacitor, they all have different ranges and need different amounts of power. Usually this is accommodated by having a volume control.

This is usually done with a **variable resistor**. On a variable resistor, you usually turn a knob and the resistance changes. Variable resistors go by different names—variable resistor, adjustable resistor, rheostat, and trimming resistors, though they each have slight differences. Trimming resistors are the easiest to use for this, but probably the hardest to find.

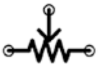

Figure 19-5. *The Potentiometer Symbol*

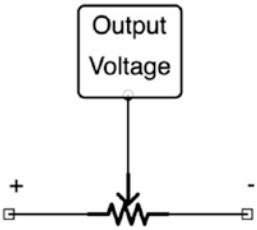

Figure 19-6. *The Potentiometer as a Voltage Divider*

To use a variable resistor, you would need to find one with the right range of values and then simply replace the output resistor R3 with your variable resistor.

A more common type of component which can be used as a variable resistor is a potentiometer. A potentiometer is basically a variable voltage divider. The symbol for the potentiometer is shown in Figure 19-5. It has three leads—input, ground, and output. When you turn the knob, it adjusts the relative resistance of each side of the voltage divider to vary what is coming out of the output.

Potentiometers were built for working as a variable voltage divider. Figure 19-6 shows what this looks like. Essentially, the user controls a knob which alters the voltage coming out by changing the voltage division between the resistors.

However, you can also use a potentiometer as a simple variable resistor by just hooking up one side of the potentiometer. Figure 19-7 shows this configuration.

The simplest way of using the potentiometer for a volume control is simply setting it up like Figure 19-7, with the input coming from the coupling capacitor and the output going to the speaker. Potentiometers vary widely in how much resistance they offer, so if we were to add one as a volume control, we would need to make sure its resistance range approximately matches what is needed (around 150 Ω).

Review

In this chapter, we learned the following:

1. Sound is the result of oscillations in the air that is picked up by your eardrums.
2. Sound can be generated by an oscillating speaker cone vibrating against the air.
3. The oscillations in a speaker cone are made by a magnet being drawn and repelled to another magnet by oscillations in electrical power.
4. Sound generally has higher frequencies (i.e., shorter periods) than what we use for flashing lights.
5. Audible sound frequencies range from 20 Hz to 20 kHz.
6. On circuits where voltage and/or current changes with time, it is often helpful to plot their changes at specific points on a graph to help visualize what is happening.
7. The output of the 555 timer is known as a square wave because it has steep changes in voltage at specific points, making a rectangular-shaped graph.
8. An oscilloscope can be used to measure and record these types of graphs.
9. Voltages that oscillate quickly with time are known as alternating current or AC voltages.
10. Oscillating voltages that do not spend roughly equal amounts of time on either side of 0 volt are said to have a DC bias voltage.

11. The DC bias voltage is how much voltage you would have to subtract from the voltage in order for the voltage to be centered on 0 volt.
12. Most circuits have DC bias voltages, but most output devices (such as speakers) need the DC bias voltage removed and only use the AC component of the signal.
13. DC bias voltage can be removed by placing a coupling capacitor in series with the output signal. The capacitor will only transmit voltage *changes*, thus removing the DC bias voltage.
14. Speakers and headphones vary considerably in their properties.
15. The most important considerations are how many ohms of resistance they have and how many watts are needed to drive the sound.
16. For headphones, a good starting assumption is that the speaker is 16 Ω and needs under 20 mW of output.
17. If your output signal is larger than this, be sure to add a resistor in series to consume some of the output signal's power.
18. The output resistor can be replaced with a variable resistor or a potentiometer to have a user-controlled output setting, also known as a volume control.
19. A potentiometer is a variable voltage divider. However, by using only the positive and output terminals, it can be used as a variable resistor instead.

Apply What You Have Learned

1. Why is the input voltage signal to the 555 timer smooth, but the output is square?
2. Will increasing the resistance of R1 and R2 make the pitch higher or lower?
3. Can you think of a way to modify the circuit so that the pitch of the sound can be adjusted while the circuit is on?
4. Given the circuit in Figure 19-3, what power would be delivered to your headphones if you were using an 8 Ω speaker instead of the 16 Ω speaker? What about a 100 Ω speaker?
5. The frequency of the A note above middle-C on the piano is 440 Hz. Design a modification to this circuit that will yield this frequency.
6. The output of the 555 is 1.7 V less than the power supply used. What is the effect on the wattage to the headphones if we change the power supply to be a 9 V power?

CHAPTER 20

Inductors

In this chapter, we will begin our study of **inductors** and **coils**.

20.1 Inductors, Coils, and Magnetic Flux

In Chapter 16, we learned that capacitors stored charge by using an electric field. We also learned that capacitors continued to hold their charge even after they were disconnected from the rest of the circuit. We learned in Chapter 19 that capacitors blocked DC signals but allowed AC signals to pass through.

20.1.1 What Is an Inductor?

An inductor is kind of like the capacitor's evil twin. It behaves in some ways that remind us a lot of capacitors, but it is operating on a different aspect of electrical behavior. Capacitors store charge and release it in response to voltage changes. Inductors, instead, store **magnetic flux** and release it in response to current changes. Thus, capacitors tend to even out voltages, and inductors tend to even out currents.

Figure 20-1 shows what an inductor looks like in a schematic. Inductors are non-polarized, so they can be wired in either direction. The symbol loosely represents a coil of wire, because that is what inductors are essentially made of.

20.1.2 What Is Magnetic Flux?

When current moves in a wire, it creates a very tiny magnetic field. It's not large enough to pick up anything, but it is present. Flux is the total amount of magnetism present in an inductor. Since this is an engineering book, not a physics book, we won't spend a lot of time trying to come to grips with what flux is and how it works. We will simply understand that it is the total size of the magnetic field of a component, and it is measured in Webers (Wb). To get a feel for what a Weber is like, a small bar magnet has a flux of around $\frac{1}{1000}$ Wb.

As a sidenote, when we say that something is magnetic, we are usually not talking about the total flux of something, but of the *density* of that flux—the amount of flux in a given area. Flux density is measured in Teslas (1 Tesla is $\frac{1\text{Wb}}{1\text{meter}^2}$), but we will not concern ourselves with Teslas or flux densities for this course.

20.1.3 What Is the Difference Between Electric and Magnetic Fields

Now, when we talked about capacitors, we talked a little bit about electric fields. Electric fields and magnetic fields are related, but different. An electric field is generated by a difference in charge between two surfaces. Electric fields can exist even when no current is moving at all—there just has to be two differently charged surfaces. Basically, any charged object will induce a force on another charged object for a certain distance, and this is the electric field.

The magnetic field, however, only exists when a charge is moving. When a charge is in motion, in addition to the electric field, it also creates a *magnetic* field surrounding itself, going perpendicular to the wire. This field also exhibits a force on charged objects within a small distance, but a much larger distance than the electric field. Additionally, when the current in the wire slows down, the magnetic field will convert its own energy into current in the wire.

The size of a magnetic field within a single wire is very, very small and can be ignored. However, the strength of the magnetic field of a wire can be increased by wrapping (coiling) it around a cylindrical core. This aligns the magnetic fields of the wires so that the fields can each be added together to produce a combined magnetic field. Each turn around the core adds an additional bit to the magnetic field. Devices based on this principle are called coils or **inductors**.

When an inductor is first turned on, most of the current goes into creating the inductor's magnetic field. Then, as the magnetic field is setting up, it allows more and more current to flow, until it hits a steady state. Then, if the current flow reduces, the energy from the magnetic field gets transformed into current and goes out to try to make up the difference.

While a capacitor stores energy as a charge and releases it when there is a voltage change, an inductor stores energy as magnetic flux and releases it when there is a current change. An inductor's inductance is measured using the Henry (H). The core equations of capacitors and inductors are related as well. The defining equation of a capacitor is $Q = C \cdot V$, where Q is the charge in the capacitor. The defining equation of an inductor is just as simple:

$$\phi = L \cdot I \tag{20.1}$$

In this equation, φ is the magnetic flux in the inductor (in Webers), L is the inductance (in Henries), and I is the current (in amperes). The **Henry** is the primary unit of inductance and has an abbreviation of H.

Example 20.19 If I have a 50-microhenry inductor and have a constant current of 2 milliamps, how much magnetic flux is being stored?

$$\begin{aligned}
&\phi = L \cdot I \\
&L = 50\mu H = 0.00005 \text{ H} \\
&I = 2mA = 0.002 \text{ A} \\
&\phi = 0.00005 \cdot 0.002 \\
&\quad = 0.0000001\, Wb = 0.1\ \mu Wb
\end{aligned}$$

Therefore, we have 0.0000001 Weber of flux, or 0.1 microweber of flux.

Therefore, when a relatively constant amount of current flows, it is easy to calculate the amount of flux in the magnetic field.

20.2 Induced Voltages

Changes in the flux of a magnetic field induce voltages. The amount of voltage induced depends on how fast the flux changes. The induced voltage is essentially the change in the flux divided by the number of seconds that it took for the change to occur. If the flux decreases, the energy is converted into voltage, which goes up. If the flux increases, the energy is taken from the voltage, which goes down. So, if there was a decrease of 10 Wb over the course of 2 seconds, then the amount of voltage induced would be $\frac{10\text{Wb}}{2\text{seconds}} = 5\text{V}$.

The formal statement of this is known as Lenz's law. It is given as follows:

$$V_{\text{average}} = -\frac{\text{change in}\,\phi}{\text{change in time}} \tag{20.2}$$

The average voltage produced by the change in a magnetic field over a given time period is the same as the amount of flux that was reduced by the field divided by the same time period.

Now, the amount of flux in the inductor will change with the current, as indicated by Equation 20.1. When the current decreases, it will cause the flux to be converted into voltage. When the current increases, it will add more flux into the magnetic field, using up voltage.

When the amount of flux changes, it creates a voltage. The amount of flux change (in Webers) divided by the amount of time it took to change (in seconds) will yield the voltage produced by the change. Therefore, when the current drops, the flux will be converted to voltage. If we add in voltage, it will also increase the current.

20.3 Resisting Changes in Current

Ultimately, what an inductor is doing is resisting changes in current. When the current goes up, the current is first used to construct the magnetic field, and therefore it takes some time to allow the full amount of current through. When the current goes down, the flux of the magnetic field decreases, which gets converted back to voltage, which induces more current.

The inductor, with regard to current, is the opposite of the capacitor. With direct current, the capacitor, when first connected to the circuit, acts as a short circuit—the current basically flows right through until the capacitor starts to fill up. When the capacitor is full, then it acts like an open circuit—blocking any more current from flowing.

The inductor is the opposite. When first connected to the circuit, the inductor acts like an open circuit—the current is basically being used to construct the magnetic field. As the magnetic field strength increases, more and more current is allowed to flow. Once the magnetic field flux matches what it should be for the given current, the current flows freely, as if the inductor were not even there, like a short circuit.

In summary, we can say that a capacitor acts as an open circuit for sustained DC and as a short circuit for alternating current. The inductor acts as a short circuit for sustained DC and as an open circuit for alternating current.

20.4 Analogy from Mechanics

If you are into mechanics, you can think of an inductor as a flywheel. Flywheels store mechanical energy into the motion of a large or heavy wheel. It takes energy to get the wheel spinning, but once it is spinning, the wheel itself can continue to drive the mechanism. The wheel is used to even out the drive of the other components of the mechanism.

For instance, an engine driven by pistons will have somewhat irregular motion, because the force of the pistons is not constant through their motion. However, attaching a flywheel will even out the energy output. When the pistons are delivering more power, most of the excess will be going to the flywheel, and when the pistons are delivering less power, the mechanism can be driven by the force of the flywheel.

20.5 Uses of Inductors

Inductors are used in a very wide variety of applications—much more so than capacitors. Capacitors are used primarily for their effects *within* electronic circuits—filtering noise, blocking DC, coupling DC-biased circuits, and so on. However, the electric field created on the plates of the capacitor is fairly useless on its own because the field fades so quickly with distance. Inductors are used for similar things as capacitors within circuits (their operation being largely the counterpart of what a capacitor would do), but additionally, the magnetic field of the inductor has innumerable uses because its effects are stronger further away. These uses include the following:

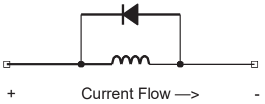

Figure 20-2. *A Snubber Diode*

- Inductors are used to make **electromagnets**, for picking up and setting down large objects.
- Inductors are used to make **transformers**, which use the magnetic field in one inductor to generate a current in another inductor.
- Inductors are used to make motors, where the electromagnetic coils are used to turn a shaft.
- Inductors are used to make speakers, which use the magnetic field to move the speaker diaphragm back and forth.
- Inductors are used to make relays, which use the magnetic field to open and close switches.

These are just some of the uses of inductors. In short, the magnetic field created by the inductor is what allows many of the interfaces between electronic devices and the real world.

20.6 Inductive Kick

One important thing to keep in mind when using inductors is the concept of inductive kick. Lenz's law (Equation 20.2) shows that decreases in the magnetic flux will induce a voltage. Since the magnetic flux is divided by time to get the voltage, that means that a shorter timespan will generate a larger voltage. Thus, a sudden decrease in magnetic flux will cause a voltage spike.

But what controls the flux? If you go back to Equation 20.1, we can see that a decrease in current will decrease the magnetic flux. Therefore, a sudden decrease in current will cause a sudden decrease in the magnetic flux which will then cause a large voltage spike within the inductor itself. This spike is known as an **inductive kick** and can damage nearby electronic components. To avoid an inductive kick, a **flyback diode**, also called a **protection diode** or a **snubber diode**, can be used.

A flyback diode is a regular diode (*not* a Zener diode) wired backward across the terminals of an inductor. Under normal operation, the diode won't conduct. However, when the diode is shut off, it provides a safe path for the generated voltage to pass through (back through the other side of the inductor) and allows the inductor to bleed off voltage in a much more controlled manner.

Figure 20-2 shows how this is wired up. As you can see, under normal operation, the current flows in the direction of the arrow. Since the left-hand side is more positive than the right-hand side, no current can flow through the diode. However, when the current is shut off, the right-hand side becomes more positive very quickly, and the diode feeds the excess current back through the inductor to allow the extra energy to dissipate more slowly.

You might be wondering why the voltage doesn't just shift back to the left side on its own once the right-hand side is more positive. The answer is that the magnetic field that is generating the voltage is itself directionalized within the inductor. The field's movement is such that it is essentially pushing current to the right (which is why a voltage is being produced). Therefore, the flyback diode carries this excess voltage back to the left-hand side of the diode.

Flyback diodes are used with all sorts of inductors (motors, electromagnets, etc.) anywhere where there are components that could be damaged by an inductive kick. For basic applications, nearly any type of diode will work for a flyback diode. However, diodes differ in their speed in reacting to voltage changes. In some circuits, the speed at which a diode reacts to changes in voltage can be important.

Review

In this chapter, we learned the following:

1. Inductors are electronic components that are made of winding wire around a core which allows them to store charge in their magnetic fields.
2. The strength of a magnetic field is the magnetic flux and is measured in Webers (Wb).
3. While an *electric* field is made from the *presence* of charges, the *magnetic* field is made from the *movement* of charges (i.e., the current).
4. When the current going into an inductor increases, the extra current is first used to build up the flux of the magnetic field before achieving a new steady state.
5. When the current going into an inductor decreases, the flux of the magnetic field is converted into a voltage, which increases the output current, resisting the change in current.
6. Inductors oppose changes in current. They act as resistors to AC and as short circuits to DC.
7. An inductor can be thought of similar to a flywheel in mechanics, which stores energy in a rotating wheel.
8. Inductors are useful because not only do they have interesting electric properties, their magnetic field also allows them to interface into the real world because magnetic field effects have a much longer reach than electric field effects.

9. When current to an inductor is suddenly shut off, it creates a large voltage, known as an inductive kick.
10. A snubber diode is used to mitigate against the negative effects of an inductive kick.

Apply What You Have Learned

1. If I want a circuit to block DC but allow AC, should I use an inductor or a capacitor?
2. If I want a circuit to allow DC but block AC, should I use an inductor or a capacitor?
3. Why are inductors used so much in systems that interact with the outside world?
4. Why does inductive kick happen?
5. Draw a schematic of an inductor where the positive side of the inductor has a switch and the negative side is connected to an LED and a resistor. Add in a snubber diode to protect the LED from the effect of turning off the switch.
6. What is the purpose of the snubber diode?
7. If I have an inductor that is 5 H and has a steady current going through it of 2 A, what is the size of the magnetic flux in the inductor's magnetic field?
8. If I have an inductor that is 7 μH and has a steady current going through it of 3 mA, what is the size of the magnetic flux in the inductor's magnetic field?

9. If I have a 4 H inductor with 0.3 Wb of flux in its magnetic field, how much current is flowing through it?
10. If an inductor's magnetic field has 5 Wb of flux and it decreases to 3 Wb of flux over 2 seconds, what is the average voltage produced over that timeframe?
11. If an inductor's magnetic field has 1 μWb of flux and it increases to 2 μWb of flux over 0.4 second, what is the average voltage produced over that timeframe?
12. If the current flowing through a 3 H inductor drops from 7 mA to 1 mA over a period of 0.01 second, what is the average voltage produced over that time period?

CHAPTER 21

Inductors and Capacitors in Circuits

In this chapter, we will look at a few of the basic uses of simple inductors.

21.1 RL Circuits and Time Constants

Just as we had an RC circuit for capacitors, there is a similar circuit for inductors—the RL circuit. Just as inductors are the alter ego of capacitors, RL circuits are the alter ego of RC circuits.

An RL circuit is a circuit consisting of a resistor (R) and an inductor (L) in series with each other. They are similar in construction and usage to the RC circuits we looked at in Chapter 17, but have some important differences.

In RC circuits, the RC time constant was the amount of time it took to charge a capacitor to 63.2% of full voltage when coupled through a resistor. That is, after 1 time constant has passed, the voltage between the legs of the capacitor will be 63.2% of supply voltage.

In RL circuits, the RL time constant is the amount of time it takes to charge the inductor's magnetic field 63.2% of its final value. Since the size of the magnetic field and the current are directly related to each other, this is also the amount of time it takes to get the current up to 63.2% of its final rate.

© Jonathan Bartlett 2020
J. Bartlett, *Electronics for Beginners*, https://doi.org/10.1007/978-1-4842-5979-5_21

The way that the RL time constant is calculated *is different from* the way that RC time constants are calculated. The RL time constant is found by *dividing* the inductance in Henries (L) by the resistance in ohms (R).

$$\tau = \frac{L}{R} \tag{21.1}$$

Figure 21-1 shows the relationship between the number of time constants, the current through the inductor, and the voltage across the inductor. This is the same table as the one for RC time constants (Figure 17-1) except that current and voltage are swapped with each other.

# of Time Constants	% of Current	% of Voltage
0.5	39.3%	60.7%
0.7	50.3%	49.7%
1	63.2%	36.8%
2	86.5%	13.5%
3	95.0%	5.0%
4	98.2%	1.8%
5	99.3%	0.7%

Figure 21-1. *RL Time Constants*

Example 21.20 Let's say that we have a 2 H inductor in series with a 500 Ω resistor connected to a 5 V source. How long will it take before the inductor has 2.5 V across its terminals?

To solve this, recognize that 2.5 V is basically half of the voltage source. Therefore, we need to look at Figure 21-1 and find the one which is closest to having 50% of the voltage. That is 0.7 time constant.

Now, we need to figure out what the time constant for this circuit is. The inductance is 2 H, and the resistance is 500 Ω. Therefore, according to Equation 21.1, we divide the inductance by the resistance:

$$\begin{aligned}\tau &= \frac{2}{500} \\ &= 0.004\text{second}\end{aligned}$$

Therefore, the time constant is 0.004 second. We are wanting 0.7 time constants, so the final answer is 0.004 · 0.7 = 0.0028 seconds.

21.2 Inductors and Capacitors as Filters

As we have mentioned, a general way of thinking about capacitors and inductors is that capacitors allow AC but block DC and inductors are the other way around. Inductors allow DC but block AC.

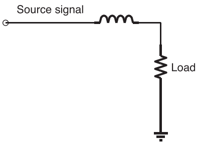

Figure 21-2. *Removing High Frequencies Using an Inductor*

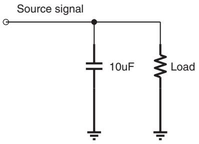

Figure 21-3. *Removing High Frequencies Using a Capacitor*

This can also be thought of in terms of frequency response. When dealing with signals (audio circuits, radio circuits, etc.), you oftentimes want to deal with certain frequencies and not others. With an inductor, the lower the frequency is, the easier it is to pass through from one side to the other. With a capacitor, the higher the frequency is, the easier it is to pass through from one side to the other.

Many audio systems have different speakers optimized for different frequencies. A common setup is to have two speakers—a woofer which handles the low pitches and a tweeter which handles the higher pitches. By using capacitors and inductors, circuit designers can customize which frequencies go to which speakers.

Radio systems also utilize capacitors and inductors. Each radio station operates on a specific carrier frequency. A **carrier frequency** is the dominant frequency used to carry a signal. When building a radio receiver, capacitors and inductors are used to isolate the specific frequency from all of the frequencies being transmitted over the air.

Chapter 22 will discuss the mathematics behind this further.

21.3 Parallel and Series Capacitors and Inductors

Capacitors and inductors can each often take on the role of the other in frequency filtering. As we have mentioned, you can use a capacitor to allow AC signals and block DC and low-frequency signals. Inductors do the opposite—they allow DC and low-frequency signals and block AC signals. However, in a pinch, you can actually get each one to do the job of the other.

Imagine that you want to get rid of noise in a circuit. Noise is essentially high-frequency AC. Using the previously defined rules, we might want to put an inductor in series with the circuit to remove noise. Figure 21-2 shows what this looks like. There is, however, another option.

Instead of putting an inductor in series with the circuit, we can instead wire a capacitor that goes to ground in parallel with the circuit. Figure 21-3 shows this configuration. The way to think about this is that, since AC signals travel through a capacitor, the capacitor is shunting off AC signals to ground before they get to the load.

Likewise, the same can be done for low-frequency filtering. Normally a capacitor is used to block low-frequency or DC signals when wired in series. However, an inductor can be used in parallel to pass off low frequencies to ground while letting high frequencies pass through.

In both of these situations, if the currents going to ground will be significant at all, you might also consider putting a small resistor in the parallel circuit as well. This will lessen the ability of the circuit to pass signals off to ground, but will also prevent short circuit behavior if you get significant signals being shunted off to ground.

Additionally, when you switch from the inline to the parallel version of these circuits, you wind up wasting the power that gets shunted off to ground. In the series versions of the circuit, any unused power is either blocked or stored. Therefore, it doesn't really waste much power. However, in the parallel versions, the filtered power is simply sent to ground, essentially wasting it.

Review

In this chapter, we learned the following:

1. A resistor-inductor series circuit is known as an RL circuit.

2. RL circuits have time constants very similar to RC circuits.

3. The time constant for an RL circuit is given by *dividing* the inductance by the resistance.

4. For RL circuits, the voltage and current values for each time constant are swapped.
5. Inductors and capacitors can be used to filter specific frequencies.
6. Capacitors allow high frequencies to go through, while inductors allow lower frequencies to go through.
7. Using capacitors and inductors together allows a person to define a specific range of frequencies that they wish to either block or allow.
8. Radios use this feature which allows people to filter only the specific radio station frequency they want.
9. Capacitors and inductors can be used for the other's job in filters by wiring them in parallel so that they carry their type of current (AC or DC) to ground instead of letting it pass to the load.

Apply What You Have Learned

1. What is the time constant of a series circuit consisting of a 50 Ω resistor and a 2 H inductor?
2. What is the time constant of a series circuit consisting of a 10 Ω resistor and a 5 μH inductor?
3. If I have a 9 V battery and I connect it to a series circuit consisting of a 1 kΩ resistor and a 23 μH inductor, how much time will it take before the current through the inductor reaches approximately 87% of its maximum value?

4. If I have a 5 V source and I connect it to a series circuit consisting of a 2 kΩ resistor and a 6 μH inductor, how much time will it take before the voltage across the inductor falls below 0.25 V?
5. If I have a circuit that has unwanted high-pitched noise, what component can I wire in series with the circuit to remove the noise?
6. If I have a circuit that has unwanted high-pitched noise, what component can I wire in parallel with the circuit to remove the noise?
7. What types of currents does an inductor (a) block and (b) allow?
8. What types of currents does a capacitor (a) block and (b) allow?
9. If I am building a radio, I need to allow through only very specific frequencies. What component or combination of components would I use to do this?

CHAPTER 22

Reactance and Impedance

22.1 Reactance

We have discussed resistance quite a bit in this book. Resistance is specifically about the ability of a component to be a good conductor of electricity. When a circuit encounters resistance, power is lost through the resistor.

However, another way of preventing current from flowing is known as *reactance*. With reactance, the power isn't dissipated, but rather the current is *prevented from flowing altogether*.

Let's think again about what happens when a voltage is connected to a capacitor in series. The capacitor starts to fill up. As the capacitor gets more and more full, there is less charge that can get onto the plate of the capacitor. This prevents the other side from filling up as well, and current cannot get through the capacitor. This acts *in a similar way to resistance*—it is preventing (impeding) the flow of current. However, it is not dissipating power because it is actually preventing the current from flowing. This is known as **reactance**. For capacitors, it is called **capacitative reactance,** and for inductors, it is called **inductive reactance**.

Reactance is usually frequency dependent. Again, going to the capacitor example, with high frequencies, the capacitor is continually charging and discharging, so it never really gets full, so it never impedes the current flow very much. Therefore, capacitors add very little reactance with high-frequency AC. The lower frequencies, however, give the capacitors time to get full, and when they are full, they impede the current flow. Therefore, for capacitors, lower frequencies create more reactance.

Reactance is measured in ohms, just like resistance. However, they cannot be simply added to resistances, so they are usually prefixed with the letter *j*. So 50 ohms of reactance is usually labeled as *j*50 Ω so that it is understood as a reactance. Reactances can be added to each other, and resistances can be added to each other. We will see how to combine them in Section 22.2, "Impedance." Reactances are usually denoted using the letter *X*.

The reactance of a capacitor (X_C) is given by the following formula:

$$X_C = -\frac{1}{2\pi \cdot f \cdot C} \qquad (22.1)$$

In this formula, *f* is the AC frequency of the signal (in hertz), and *C* is the capacitance. It might seem strange that this produces a negative value. The reason for this will make sense as we go forward. However, it is *not* producing negative impedance—we will see this when we combine reactance with resistance.

> **Example 22.21** What is the reactance of a 50 nF capacitor to a signal of 200 Hz? To find this, we merely use the formula:

$$
\begin{aligned}
X_C &= -\frac{1}{2\pi \cdot f \cdot C} \\
&= \frac{1}{2\pi \cdot 200 \cdot 0.00000005} \\
&\approx \frac{1}{2 \cdot 3.14 \cdot 200 \cdot 0.00000005} \\
&= \frac{1}{0.00000624} \\
&\approx -j160256\Omega
\end{aligned}
$$

You can see from this formula why it is said that a capacitor blocks DC. DC is, essentially, current that does not oscillate. In other words, the frequency is zero. Therefore, the formula will reduce to $\frac{1}{0}$, which is infinite. Therefore, it has infinite reactance against DC.

Also note what happens as the frequency increases. As the frequency increases, the denominator gets larger and larger. That means that the reactance is getting smaller and smaller—closer and closer to zero. As the frequency goes up, the reactance is essentially heading toward zero, but will never get there because the frequency can't be infinite.

The formula for **inductive reactance** (X_L) is very similar:

$$X_L = 2\pi \cdot f \cdot L \qquad (22.2)$$

In this equation, f is the signal frequency, and L is the inductance of the inductor in Henries.

> **Example 22.22** Let's say that I have an 3 H inductor with a 50 Hz AC signal. How much reactance does the inductor have in this circuit?

$$
\begin{aligned}
X_L &= 2\pi \cdot f \cdot L \\
&= 2 \cdot 3.14 \cdot 50 \cdot 3 \\
&= j9420\Omega
\end{aligned}
$$

The reactance in this circuit is $j9{,}420\ \Omega$.

22.2 Impedance

In fact, resistance and reactance are usually combined together in a circuit to get a quantity known as **impedance**, which is simply the combination of resistive and reactive quantities. Impedance is often designated using the letter Z.

Resistance and reactance aren't added together directly; instead, you can think of them acting at angles to each other. Let's say that I start at my house and walk 10 feet out my front door. Then, I turn 90 degrees right and walk another 10 feet. While I have walked 20 feet, I am *not* 20 feet from my door. I am, instead, a little over 14 feet from my door. I can call this my displacement. Figure 22-1 shows what this looks like visually.

Since this is a right triangle, the distance from the start to the end is found on the hypotenuse of this triangle. We can calculate the total displacement using the Pythagorean theorem ($A^2 + B^2 = C^2$). If we solve for C (total displacement), we get

$$C = \sqrt{A^2 + B^2} \tag{22.3}$$

So, in our distance example, if I went forward 10 feet, turned left, and went another 10 feet, the total distance traveled would be

$$\begin{aligned} C &= \sqrt{A^2 + B^2} \\ &= \sqrt{10^2 + 10^2} \\ &= \sqrt{100 + 100} \\ &= \sqrt{200} \\ &\approx 14.14 \end{aligned}$$

The total impedance is like the total distance from your door. Resistance and reactance are like different walking directions (at right angles to each other), and impedance is the total displacement. That's why we use the letter *j* to signify reactance—it is just like resistance but in a different direction.

So how do we calculate impedance? In fact, it is calculated *precisely like* the displacement calculation in Equation 22.3:

$$\text{impedance} = \sqrt{\text{resistance}^2 + \text{reactance}^2} \tag{22.4}$$

Or, using their common abbreviations, we can say:

$$Z = \sqrt{R^2 + X^2} \tag{22.5}$$

Let's see how we can use Equation 22.4 to calculate total impedance. If I have a circuit that has 30 Ω of resistance and *j*20 Ω of reactance, then the formula for total impedance is

$$\begin{aligned}\text{impedance} &= \sqrt{\text{resistance}^2 + \text{reactance}^2}\\ &= \sqrt{30^2 + 20^2}\\ &= \sqrt{900+400}\\ &= \sqrt{1300}\\ &\approx 36.1\Omega\end{aligned}$$

As you can see, when using this formula, we are calculating a total impedance, so the *j* drops away.

> **Example 22.23** If I have a 1 kΩ resistor in series with a 100 nF capacitor with a 800 Hz signal, what is the total impedance to the signal that my circuit is giving?
>
> To find out impedance, we need both resistance and reactance. We already have resistance—1 kΩ. The reactance is found by using Equation 22.1:

$$\begin{aligned}X_C &= -\frac{1}{2\pi\cdot f\cdot C}\\ &= \frac{1}{2\pi\cdot 800\cdot 0.0000001}\\ &\approx \frac{1}{0.0005024}\\ &\approx -j1990\Omega\end{aligned}$$

So the reactance is about $-j1990\ \Omega$.

So, if the resistance is 1000 Ω and the reactance is $-j1990\ \Omega$, what is the impedance? The impedance is found by using Equation 22.4:

$$\begin{aligned}\text{impedance} &= \sqrt{\text{resistance}^2 + \text{reactance}^2}\\ &= \sqrt{1000^2 + (-1990)^2}\\ &= \sqrt{1000000 + 3960100}\\ &= \sqrt{4960100}\\ &\approx 2227\Omega\end{aligned}$$

22.3 RLC Circuits

So far we have discussed RC (resistor-capacitor) and RL (resistor-inductor) circuits. When you combine all of these components together, you get an RLC (resistor-inductor-capacitor) circuit.

When you calculate the impedance of such circuits, you have to be sure you include the reactance of *both* the capacitative and the inductive components. While inductors and capacitors both offer reactance to certain frequencies, their reactances actually oppose each other. That is, the reactance of one cancels out the reactance of the other. This is why the capacitative reactance is negative and the inductive reactance is positive.

Therefore, when calculating reactances that include *both* inductance and capacitance, you can add the reactances just like you would add resistances. However, since the capacitive reactances are negative and the inductive reactances are positive, they wind up canceling each other out to some degree.

Example 22.24 If I have an inductor of 5 mH and a capacitor of 5 μF in series with a 200 Ω resistor, what is the impedance of the circuit for a frequency of 320 Hz?

To solve this problem, we need to first find the capacitative reactance (X_C) and the inductive reactance(X_L). To get the capacitative reactance, we use Equation 22.1:

$$\begin{aligned} X_C &= -\frac{1}{2\pi \cdot f \cdot C} \\ &= \frac{1}{2\pi \cdot 320 \cdot 0.000005} \\ &\approx \frac{1}{0.01} \\ &\approx -j1990\Omega \end{aligned}$$

The inductive reactance is found using Equation 22.2:

$$\begin{aligned} X_L &= 2\pi \cdot f \cdot L \\ &= 2\pi \cdot 320 \cdot 0.005 \\ &\approx j10\Omega \end{aligned}$$

Now, we can just add these reactances together:

$$\begin{aligned} X_{total} &= X_L - X_C \\ &= j10\Omega + -j100\Omega \\ &= -j90\Omega \end{aligned}$$

The fact that this is negative is not a problem because it will be squared (which will get rid of the negative) in the next step. Now that we know the resistance (200 Ω) and the reactance (– *j*90 Ω), we just need to use Equation 22.4 to calculate the total impedance:

$$\begin{aligned} \text{impedance} &= \sqrt{\text{resistance}^2 + \text{reactance}^2} \\ &= \sqrt{200^2 + (-90)^2} \\ &= \sqrt{40000 + 8100} \\ &= \sqrt{48100} \\ &\approx 219\Omega \end{aligned}$$

So the total impedance (opposition to current) in this circuit is 219 Ω.

22.4 Ohm's Law for AC Circuits

In an AC circuit, the current and voltage are continually varying. Therefore, using the traditional Ohm's law, you would have to calculate Ohm's law over and over again in order to find out the relationships between voltage, current, and resistance.

However, there is a form of Ohm's law that works directly on AC circuits of a given frequency. That is, it is essentially a *summary* of the voltages and currents that happen on each cycle. Ohm's law for AC circuits is basically identical to the previous Ohm's law, but the terms are slightly different:

$$V_{\mathrm{RMS}} = I_{RMS} \cdot Z \qquad (22.6)$$

Here, the voltage we are referring to (V_{RMS}) is an *average* voltage through one cycle of AC. This average is known as the **RMS** average. It is a little different than the typical average you might think of. If an AC voltage is swinging back and forth from positive to negative, the actual average voltage is probably around zero. However, RMS voltage is about calculating the average amount of push in any direction—positive or negative. Therefore, the RMS voltage will always yield a positive answer.[1]

Likewise, the current refers to the RMS current (I_{RMS}). Just like the RMS voltage, the RMS current will always be positive, because it is the measure of the average amount of flow in *any* direction.

Finally, the impedance Z is calculated as we have noted in this chapter—by combining resistances and reactances together into an impedance.

---

[1] RMS stands for "root mean square." It is obtained by (a) squaring every data point, (b) averaging the squares, and then (c) taking the square root of the average. This is why it will be positive—it deals in squares.

Thus, Ohm's law for AC circuits can be used to express summary relationships about average voltage, average current, and impedance in an AC signal.

> **Example 22.25** I have an AC circuit whose RMS voltage is 10 V. I have calculated the impedance of this circuit to be 20 Ω. What is the RMS current of this circuit?
>
> To find this out, we just rearrange Ohm's law a little bit:

$$V_{\text{RMS}} = I_{RMS} \cdot Z$$
$$I_{\text{RMS}} = \frac{V_{\text{RMS}}}{Z}$$

Now I just use the values given to fill in the blanks:

$$\begin{aligned} I_{RMS} &= \frac{V_{RMS}}{Z} \\ &= \frac{10}{20} = 0.5 \text{ A} \end{aligned}$$

In this circuit, we would have an average of half an amp (500 milliamps) flowing through the circuit.

> **Example 22.26** I have an AC voltage source with an RMS voltage of 5 V running at 200 Hz. It is connected in series with a 50 kΩ resistor and a 50 nF capacitor. What is the current in this circuit?
>
> To find this out, we have to first find the total impedance of the circuit. That means we have to use Equation 22.1 to find the reactance of the capacitor:

$$
\begin{aligned}
X_C &= -\frac{1}{2\pi \cdot f \cdot C} \\
&= \frac{1}{2 \cdot 3.14 \cdot 200 \cdot 0.000005} \\
&= \frac{1}{0.00000628} \\
&\approx -j159236\Omega
\end{aligned}
$$

Now that we have the resistance (50 kΩ) and the reactance ($-j159236\,\Omega$), we can use them in Equation 22.5:

$$
\begin{aligned}
Z &= \sqrt{R^2 + X^2} \\
&= \sqrt{50000^2 + 159236^2} \\
&= \sqrt{2500000000 + 25356103696} \\
&= \sqrt{27856103696} \\
&\approx 166901\Omega
\end{aligned}
$$

Now we can use Ohm's law for AC circuits (Equation 22.6 to find the current):

$$
\begin{aligned}
I_{\text{RMS}} &= \frac{V_{\text{RMS}}}{Z} \\
&= \frac{5}{166901} \\
&\approx 0.00003\text{A}
\end{aligned}
$$

This means that the average current (I_{RMS}) will be approximately 0.00003 A, or 30 μA.

22.5 Resonant Frequencies of RLC Circuits

As we have seen, the capacitative reactance goes closer to zero when the frequency goes up. Likewise, the inductive reactance increases when the frequency goes up. Additionally, the capacitative reactance and the inductive reactance have opposite signs—negative for capacitative reactance and positive for inductive reactance.

What is interesting is that if you have a combination of inductors and capacitors, there is always some frequency at which their reactances exactly cancel each other out. This point is known as the **resonant frequency** of the circuit.

When a capacitor and an inductor are in series with each other, it is termed an LC series circuit. Because the inductor inhibits high frequencies and the capacitor inhibits low frequencies, LC circuits can be used to let through a very specific frequency range. The center of this range is known as the **resonant frequency** of the circuit.

Now, if you are good with algebra, you can combine Equation 22.1 and Equation 22.2 to figure out the resonant frequency of a circuit (i.e., set them to add up to zero and then solve for the frequency f). However, to spare you the trouble, there is a formula that you can use to find the resonant frequency of a circuit:

$$f = \frac{1}{2\pi\sqrt{L \cdot C}} \tag{22.7}$$

At this frequency, there is no total reactance to the circuit—the only impedance comes from the resistance.

> **Example 22.27** Let's say that you have a 20 μF capacitor in series with a 10 mH inductor. What is the resonant frequency of this circuit?
>
> To find the resonant frequency, we only need to employ Equation 22.7:

$$
\begin{aligned}
f &= \frac{1}{2\pi\sqrt{L\cdot C}}\\
&= \frac{1}{2\pi\sqrt{0.01\cdot 0.00002}}\\
&= \frac{1}{2\pi\sqrt{0.0000002}}\\
&\approx \frac{1}{2\pi\cdot 0.000447}\\
&\approx \frac{1}{0.00279}\\
&\approx 358\text{Hz}
\end{aligned}
$$

> Therefore, this circuit has a resonant frequency of 358 Hz. This means that, at this frequency, this circuit has no reactive impedance.

Resonance frequencies are important in signal processing. They can be used in audio equipment to boost the sound of a specific frequency (since all other frequencies will have resistance). They can be used to select radio stations in radio equipment (since it will be the only frequency allowed through without resistance). You can also remove a specific frequency by taking a resonant frequency circuit to ground, thereby having a specific frequency short-circuited to ground with no resistance.

22.6 Low-Pass Filters

As mentioned, capacitors allow AC and block DC. If you wanted to remove the AC component of a signal, a capacitor can be connected to take the AC portion of your signal to ground. This is known as a low-pass filter, because, since the high-frequency (AC) component of the signal is being sent to ground, the low-frequency (DC) component of the signal is being allowed to pass.
